Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID (gemfibrozil capsules, USP) administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis – LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants – Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy** – Before instituting LOPID therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy** – Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Impairment of Fertility** – Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

4. **Pregnancy Category B** – Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

5. **Nursing Mothers** – Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

6. **Hematologic Changes** – Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

7. **Liver Function** – Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

8. **Use in Children** – Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints, myositis

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope, alopecia

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Caution – Federal law prohibits dispensing without prescription.

we never stop asking

"What if..."

HP's ambulatory ECG system also reads the fine print.

HP's new ambulatory ECG analyzer reads even subtle ECG changes, enhancing your ability to identify abnormalities. With real-time, high-fidelity signal processing, not available in conventional systems, HP's solid-state analyzer reads every beat using techniques verified for accuracy according to AAMI standards. An optional 24-hour Memory Module lets you verify results using our new full-disclosure report. In your office, the analyzer plugs into an HP personal computer and LaserJet printer for review and printing of reports. An efficient, complete system. And very affordable.

Real-time ambulatory ECG. HP's comprehensive, verifiable reader. For more information, contact your local HP representative.

THICK OR THIN SKINNED... THEY RESPOND TO DEPONIT®

System-controlled... not skin-controlled[1-4]

That means variations in thickness of the stratum corneum have no significant effect on skin permeation. Deponit® NTG-FILM is gradient-charged™* to provide controlled release of free drug at the skin surface—for uniform transdermal bioavailability. There is no premature NTG dumping.

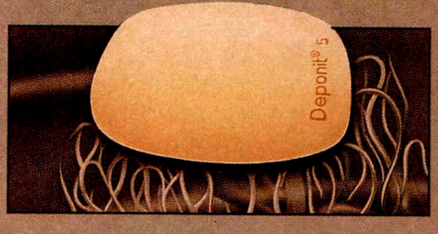
Proven in hundreds of U.S. patients

In studies of over 500 anginal† patients treated with Deponit, the large majority showed a reduced frequency of anginal attacks and improved ability to perform everyday activities such as walking, stair climbing and sex. And Deponit efficacy was sustained during these routine activities.[5]

THE FIRST GRADIENT-CHARGED™ NTG-FILM FOR ANGINA† PROPHYLAXIS

Deponit®

(nitroglycerin transdermal delivery system) 5 mg/24 hours 10 mg/24 hours



THROUGH THICK OR THIN

- System-controlled, not skin-controlled
- Minimal variations in absorption
- No premature release of NTG
- Designed for superior patient acceptance
- Once-a-day dosing, 24-hour delivery
- International record of success

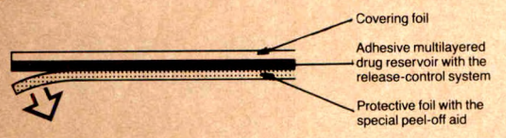
WYETH AYERST™

Wyeth-Ayerst®
Deponit®
(nitroglycerin transdermal delivery system)
5 mg/24 hours, 10 mg/24 hours

Description
Deponit® is a unique nitroglycerin-containing transdermal delivery system. A multilayered self-adhesive film, the system contains nitroglycerin in a matrix composed of lactose, plasticizer, medical adhesive, polyisobutylene, and aluminized plastic for controlled release of the active agent through the skin into the systemic circulation. For the 24 hours during which the system is applied to the intact skin, its technology is intended to deliver an accurate dosage with no premature release of the nitroglycerin or undesired accumulation on the skin. Nitroglycerin (glyceryl trinitrate) is a vasodilator for the relief and prevention of anginal attacks.
Deponit® is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system has a 16 cm^2 releasing surface and contains 16 mg nitroglycerin. The 10 mg/24 hr system has a 32 cm^2 releasing surface and contains 32 mg nitroglycerin.
The Deponit® system is approximately 0.3 mm thick, insoluble in water, and, as illustrated below, consists of two main elements:
1. A flexible, flesh-colored waterproof covering foil.
2. A multilayered adhesive film that constitutes simultaneously the drug reservoir and the release-control system.



The system is protected by an aluminum foil which has a patented S-shaped opening to facilitate its removal prior to use of the system.

Clinical Pharmacology
When the Deponit® system is applied to the skin, nitroglycerin is continuously released for absorption directly into the systemic circulation. Thus, active drug reaches the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth-muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption, secondary to vascular smooth-muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.
In a bioavailability study using healthy volunteers,[1] transdermal absorption of nitroglycerin from the Deponit® system achieved steady-state venous plasma levels and maintained these levels for 24 hours. Detectable plasma levels were attained within 30 minutes after application of the system and were still detectable 30 minutes after removal of the system.
The amount of nitroglycerin released (5 mg/24 hr or 10 mg/24 hr) represents the mean release rate of nitroglycerin from the system as determined from healthy volunteers, and hence, the amount potentially available through the skin. Absorption will vary among individuals. Precise definition of "therapeutic plasma level" is not known at this time.

Indications and Usage
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

Contraindications
Nitroglycerin is contraindicated in patients known to be intolerant of organic nitrate drugs and in patients with marked anemia.

Warnings
In patients with acute myocardial infarction or congestive heart failure, nitroglycerin should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent the sudden withdrawal reactions which are characteristic of vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

Precautions
Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Deponit® is not intended for use in treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitrates may be necessary.
PREGNANCY
Pregnancy Category C. Animal reproduction studies have not been conducted with nitroglycerin. It is not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.
NURSING MOTHERS
It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when the preparation is administered to a nursing woman.

Adverse Reactions
Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Deponit® therapy is continued. When such headaches are unresponsive to treatment, the dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis these symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the Deponit® dose should be reduced or use of the product discontinued.

Dosage and Administration
Deponit® can be applied as a single system or as multiples, depending upon the clinical requirements. Dosage should be titrated to achieve the optimal therapeutic effect by monitoring clinical response, side effects, heart rate, and the effect of therapy upon blood pressure.
Deponit® should be removed from the single-unit package just prior to use. The protective aluminum precut S-shaped foil is removed according to the "Patient Instructions," and the system is applied with a firm pressure on a convenient skin site, preferably on the chest, inner side of the upper arm, or shoulders. Deponit® should not be applied to the distal parts of extremities.
Each system is designed to remain in place for 24 hours; however, the treatment site should be changed daily to minimize skin irritation and should be intact, clean, and dry. If necessary, hair may be removed by clipping.
Therapy should be initiated with application of a single Deponit® system, delivering 5 mg every 24 hours. Response in terms of satisfactory control of anginal symptoms without adverse effects should be evaluated to determine the optimal dose. Some patients may require adjustment of dosage to provide a better clinical response. This can be achieved by removing the system delivering 5 mg/24 hours, and applying a larger system delivering 10 mg/24 hours or a multiple of either system, depending on the dose required to achieve the desired effect.
After 24 hours, the system should be removed and discarded. Because no adhesive residue remains on the skin, there is no need to use a solvent.

Storage Conditions
Store at room temperature not above 25°C (77°F). Do not refrigerate.

Patient Instructions for Application
A leaflet describing use of Deponit® is provided with each package.

How Supplied
Deponit® (nitroglycerin transdermal delivery system), Wyeth-Ayerst®, is packaged in cartons containing unit doses of 30 flesh-colored systems on aluminum backings. See table below.

Nitroglycerin released *in vivo*	Total drug content/ system	System size	Carton size
5 mg/24 hrs	16 mg	16 cm^2	30 Systems **(NDC 0008-4195-01)**
10 mg/24 hrs	32 mg	32 cm^2	30 Systems **(NDC 0008-4196-01)**

Caution: Federal law prohibits dispensing without prescription.

Burdick puts ECG management within the reach of every institution...

at a surprisingly affordable price

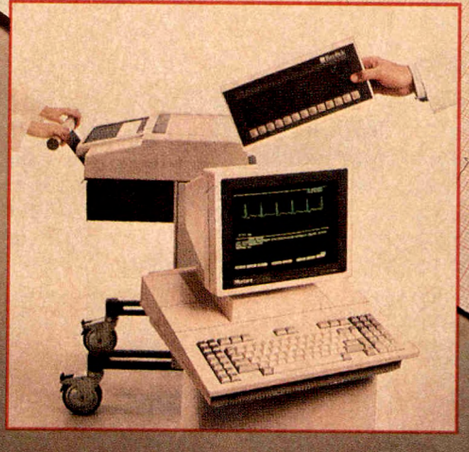
Now there's a total ECG management system designed to meet the patient volume and budgets of any institution, regardless of size.

For a fraction of the cost of much larger systems, Burdick can now tailor a complete system to meet your specific needs.

The Burdick system teams the E-Scribe™ Electronic File Cabinet with the versatile E500 and E600 interpretive electrocardiographs.

The portable E500 and E600 carts serve as mobile data acquisition and interpretive units, transmitting information either directly or over phone lines to the E-Scribe File Cabinet. This information gathering can be easily done in a physician's office, a hospital room, the ER, or wherever the patient is located. The compact E-Scribe, located centrally or linked in a strategic network, receives and files ECG data and makes it available for immediate review, editing or printing.

The Burdick ECG management system provides a highly cost-efficient means of handling the acquisition, transmission, manipulation, storage and retrieval of ECG information—for institutions of all sizes. It streamlines work flow, reduces departmental costs and it's easy to use. No specially trained personnel or expensive room setups are required.



Call your Burdick representative or 1-800-356-0701 today for more detailed information on how to evaluate ECG management systems.

CORGARD provides antianginal protection you can count on...

24 HOURS A DAY

Angina attacks can occur at any time: in the early morning hours, upon awakening; in the evening; or at any time during the day, triggered by exertion.

CORGARD, with just a single daily dose, provides clinically proven, 24-hour protection for your patients.[1-3]

CORGARD® (nadolol tablets)

Because no time is a good time for angina

Please see brief summary on the adjacent page.

CORGARD®
(nadolol tablets)

24-hour protection...because no time is a good time for angina

CORGARD® TABLETS
Nadolol Tablets USP

DESCRIPTION: CORGARD (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2- week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia—Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 year oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy Category C—In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia.

The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE—For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg qd; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg qd (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg qd; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg qd (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information consult package insert.

HOW SUPPLIED: In scored tablets containing 20, 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100. The 40 mg, 80 mg, and 120 mg tablets are available in bottles of 1000 tablets. The 20 mg, 40 mg, and 80 mg tablets are also available in Unimatic® unit-dose packs of 100 tablets.

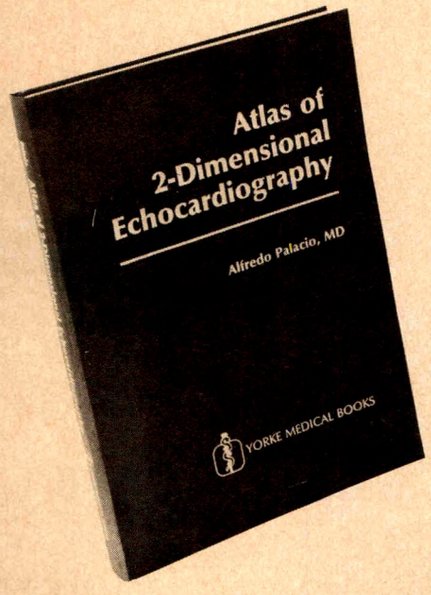
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts
ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

CORONARY ARTERY DISEASE

677 **Determinants and Protective Potential of Coronary Arterial Collaterals as Assessed by an Angioplasty Model**

K. Peter Rentrop, John C. Thornton, Frederick Feit, and Mark Van Buskirk

Two indexes of collateral blood flow, distal coronary occlusion pressure/aortic pressure and angiographic collateral class, were determined during elective angioplasty and correlated with anatomic and clinical variables in 36 patients with normal left ventricular function. A reduction in luminal diameter by >70% predicted collaterals with 100% specificity and 85% sensitivity. Lesion severity correlated with both collaterals indexes, suggesting a quantitative relation between lesion severity and collateral development beyond a threshold value of 70% stenosis. Left ventricular ejection fraction during ischemia caused by balloon occlusion was found to be primarily determined by lesion location; however, collateral flow modified the ejection fraction significantly. A model predicting the hemodynamic and clinical consequences of abrupt coronary closure based on lesion location and severity was developed and subsequently tested in another group of 23 patients who experienced coronary occlusion as a complication of angioplasty. The data suggest an inverse relation between lesion severity and the extent of functional as well as clinical consequences of abrupt coronary closure.

685 **Usefulness of Serial Radionuclide Monitoring During Graded Nitroglycerin Infusion for Unstable Angina Pectoris for Determining Left Ventricular Function and Individualized Therapeutic Dose**

Warren M. Breisblatt, Nestor A. Vita, Marcos Armuchastegui, Lawrence S. Cohen, and Barry L. Zaret

Using serial invasive hemodynamics in concert with noninvasive radionuclide monitoring of left ventricular function, 20 patients with unstable angina were evaluated during incremental infusion of intravenous nitroglycerin. Seventeen of 20 patients demonstrated a favorable hemodynamic response. In general, there was excellent agreement between hemodynamic and noninvasive radionuclide measurements. Cardiac output improved by 29% (mean 4.7 ± 1.2 to 6.0 ± 1.3), left ventricular ejection fraction increased an average of 0.11 (0.39 ± 0.14 to 0.50 ± 0.16) and diastolic function as assessed by peak-filling rate improved from 1.80 ± 0.60 end-diastolic volume/s to 2.7 ± 0.90. The dose of nitroglycerin necessary to produce maximal hemodynamic benefit was variable. In 7 patients, nitroglycerin caused adverse hemodynamics, which corrected with intravenous fluids, allowing continued administration of intravenous nitroglycerin. Peak systolic pressure–end-systolic volume relations were assessed to define possible changes in left ventricular contractility. In 12 patients, this relation was linear, suggesting altered loading as nitroglycerin's mechanism of action. In 3 patients a downward and rightward shift of the systolic relation was seen, suggesting that significant underloading with nitroglycerin was associated with depressed contractility.

ZESTRIL®!
LISINOPRIL
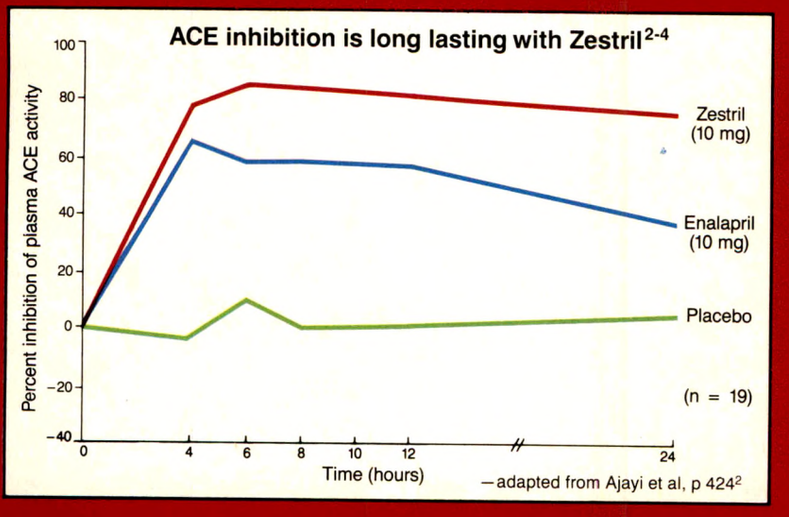
STUART PHARMACEUTICALS
Division of ICI Americas Inc
Wilmington, Delaware 19897

Zestril: The long-acting ACE inhibitor

Zestril achieves 24-hour blood pressure control with a half-life of 12 hours.[1] Angiotensin converting enzyme (ACE) inhibition** is long lasting with Zestril—sustained 24 hours after a single dose.[2-4] The clinical significance of pharmacodynamic differences in hypertensive patients has not been determined.



** In pharmacodynamic studies (utilizing 10 mg of enalapril and lisinopril), ACE inhibition was significantly correlated to plasma renin activity and fall in diastolic blood pressure in normal volunteers.

Zestril: Hypertensive patients start and stay at one tablet a day

A single tablet of Zestril controls blood pressure for a full 24 hours[1]—unlike other ACE inhibitors, which may have to be increased to b.i.d.[5] or t.i.d.[6] dosing in some patients. The predictable once-daily dosage of Zestril enhances patient compliance and cost-effectiveness.

Zestril: 24-hour blood pressure control without liver metabolism

Zestril provides 24-hour control. Zestril is not metabolized by the liver.[7] It does not require bioactivation[7]—as needed with prodrugs such as enalapril.**[5,7] Zestril is absorbed as an active drug.[1] Absorption is unaffected by food.[8]

Zestril: 24-hour blood pressure control that's well tolerated

Zestril achieves 24-hour control with a low incidence of side effects. Rash and/or taste disturbance are rarely seen with Zestril. In Zestril clinical trials, the most frequently reported side effects were as follows:

Side Effects	Zestril (n = 2,003‡)	—	Placebo (n = 207)
Dizziness	6.3%	—	1.9%
Headache	5.3%	—	1.9%
Fatigue	3.3%	—	1.0%
Diarrhea	3.2%	—	2.4%
Upper respiratory symptoms	3.0%	—	0.0%
Cough	2.9%	—	1.0%

‡Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

- Only 6% of patients discontinued therapy in controlled clinical trials.
- Symptomatic hypotension occurs infrequently (0.8%) in patients with normal renal function but is a possible consequence in salt/volume-depleted persons such as those treated vigorously with diuretics.
- Evaluation of the hypertensive patient should always include assessment of renal function. (See Dosage and Administration.)
- Angioedema has been reported with ACE inhibitors, including Zestril. (See Warnings.)

Zestril dosage in hypertension
Starting dose is 10 mg once a day. Usual dosage range for maintenance: 20 to 40 mg per day, administered in a single daily dose.

ZESTRIL®!
LISINOPRIL

**Clinical significance has not been determined in hypertensive patients.

*The antihypertensive effect may diminish at the end of the dosing interval.

Please see last page of this advertisement for brief summary of prescribing information.

INDICATIONS AND USAGE. Zestril is indicated for the treatment of hypertension. It may be used alone as initial therapy or concomitantly with other classes of antihypertensive agents. In using Zestril, consideration should be given to the fact that another angiotensin converting enzyme inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease, and that available data are insufficient to show that Zestril does not have a similar risk. (See WARNINGS.) **CONTRAINDICATIONS.** Zestril is contraindicated in patients who are hypersensitive to this product. **WARNINGS. Angioedema:** Angioedema of the face, extremities, lips, tongue, glottis and/or larynx has been reported in patients treated with angiotensin converting enzyme inhibitors, including Zestril. In such cases, Zestril should be promptly discontinued, and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis or larynx, likely to cause airway obstruction, appropriate therapy, eg, subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL) should be promptly administered. (See ADVERSE REACTIONS.) Hypotension:** Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of use with Zestril in salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. (See PRECAUTIONS, Drug Interactions and ADVERSE REACTIONS.) In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia, and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of Zestril and/or diuretic is increased. Similar considerations apply to patients with ischemic heart or cerebrovascular disease in whom an excessive fall in blood pressure could result in a myocardial infarction or cerebrovascular accident. If hypotension occurs, the patient should be placed in supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses which usually can be given without difficulty once the blood pressure has increased after volume expansion. **Neutropenia/Agranulocytosis:** Another angiotensin converting enzyme inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment especially if they also have a collagen vascular disease. Available data from clinical trials of Zestril are insufficient to show that Zestril does not cause agranulocytosis at similar rates. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered. **PRECAUTIONS. General. Impaired Renal Function:** As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin converting enzyme inhibitors, including Zestril, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. In hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine may occur. Experience with another angiotensin converting enzyme inhibitor suggests that these increases are usually reversible upon discontinuation of Zestril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy. Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when Zestril has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of Zestril and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function. (See DOSAGE AND ADMINISTRATION.) Hyperkalemia:** In clinical trials hyperkalemia (serum potassium greater than 5.7 mEq/L) occurred in approximately 2.2% of hypertensive patients and 4.0% of patients with congestive heart failure. In most cases these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in approximately 0.1% of hypertensive patients. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with Zestril. (See Drug Interactions.) **Surgery/Anesthesia:** In patients undergoing major surgery or during anesthesia with agents that produce hypotension, Zestril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion. **Information for Patients. Angioedema:** Angioedema, including laryngeal edema, may occur especially following the first dose of Zestril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to take no more drug until they have consulted with the prescribing physician. **Symptomatic Hypotension:** Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, the patient should be told to discontinue the drug until they have consulted with the prescribing physician. All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with their physician. **Hyperkalemia:** Patients should be told not to use salt substitutes containing potassium without consulting their physician. **Neutropenia:** Patients should be told to report promptly any indication of infection (eg, sore throat, fever) which may be a sign of neutropenia. **NOTE:** As with many other drugs, certain advice to patients being treated with Zestril is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. **Drug Interactions. Hypotension – Patients on Diuretic Therapy:** Patients on diuretics and especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with Zestril. The possibility of hypotensive effects with Zestril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with Zestril. If it is necessary to continue the diuretic, initiate therapy with Zestril at a dose of 5 mg daily, and provide medical supervision after the initial dose for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS, and DOSAGE AND ADMINISTRATION.) When a diuretic is added to the therapy of a patient receiving Zestril, an additional antihypertensive effect is usually observed. Studies with ACE inhibitors in combination with diuretics indicate that the dose of the ACE inhibitor can be reduced when it is given with a diuretic. (See DOSAGE AND ADMINISTRATION.) **Indomethacin:** In a study in 36 patients with mild to moderate hypertension where the antihypertensive effects of Zestril alone were compared to Zestril given concomitantly with indomethacin, the use of indomethacin was associated with a reduced effect, although the difference between the two regimens was not significant. **Other Agents:** Zestril has been used concomitantly with nitrates and/or digoxin without evidence of clinically significant adverse interactions. No clinically important pharmacokinetic interactions occurred when Zestril was used concomitantly with propranolol or hydrochlorothiazide. The presence of food in the stomach does not alter the bioavailability of Zestril. **Agents Increasing Serum Potassium:** Zestril attenuates potassium loss caused by thiazide-type diuretics. Use of Zestril with potassium-sparing diuretics (eg, spironolactone, triamterene or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated because of demonstrated hypokalemia, they should be used with caution and with frequent monitoring of serum potassium. **Carcinogenesis, Mutagenesis, Impairment of Fertility.** There was no evidence of a tumorigenic effect when lisinopril was administered for 105 weeks to male and female rats at doses up to 90 mg/kg/day (about 56 times* the maximum recommended daily human dose) or when lisinopril was administered for 92 weeks to (male and female) mice at doses up to 135 mg/kg/day (about 84 times* the maximum recommended daily human dose). *Based on patient weight of 50 Kg. Lisinopril was not mutagenic in the Ames microbial mutagen test with or without metabolic activation. It was also negative in a forward mutation assay using Chinese hamster lung cells. Lisinopril did not produce single strand DNA breaks in an in vitro alkaline elution rat hepatocyte assay. In addition, lisinopril did not produce increases in chromosomal aberrations in an in vitro test in Chinese hamster ovary cells or in an in vivo study in mouse bone marrow. There were no adverse effects on reproductive performance in male and female rats treated with up to 300 mg/kg/day of lisinopril. **Pregnancy. Pregnancy Category C:** Lisinopril was not teratogenic in mice treated on days 6-15 of gestation with up to 1,000 mg/kg/day (625 times the maximum recommended human dose). There was an increase in fetal resorptions at doses down to 100 mg/kg; at doses of 1,000 mg/kg this was prevented by saline supplementation. There was no fetotoxicity or teratogenicity in rats treated with up to 300 mg/kg/day (188 times the maximum recommended dose) of lisinopril at days 6-17 of gestation. In rats receiving lisinopril from day 15 of gestation through day 21 postpartum, there was an increased incidence in pup deaths on days 2-7 postpartum and a lower average body weight of pups on day 21 postpartum. The increase in pup deaths and decrease in pup weight did not occur with maternal saline supplementation. Lisinopril, at doses up to 1 mg/kg/day, was not teratogenic when given throughout the organogenic period in saline supplemented rabbits. Saline supplementation (physiologic saline in place of tap water) was used to eliminate maternotoxic effects and enable evaluation of the teratogenic potential at the highest possible dosage level. The rabbit has been shown to be extremely sensitive to angiotensin converting enzyme inhibitors (captopril and enalapril) with maternal and fetotoxic effects apparent at or below the recommended therapeutic dosage levels in man. Fetotoxicity was demonstrated in rabbits by an increased incidence of fetal resorptions at a dose of lisinopril at 1 mg/kg/day and by an increased incidence of incomplete ossification at the lowest dose tested (0.1 mg/kg/day). By whole body autoradiography, radioactivity was found in the placenta following administration of labeled lisinopril to pregnant rats, but none was found in the fetuses. There are no adequate and well-controlled studies in pregnant women. Zestril should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Nursing Mothers:** Milk of lactating rats contains radioactivity following administration of ^{14}C lisinopril. It is not known whether this drug is excreted in human milk.

ZESTRIL® (lisinopril)

Because many drugs are excreted in human milk, caution should be exercised when Zestril is given to a nursing mother. **Pediatric Use:** Safety and effectiveness in children have not been established. **ADVERSE REACTIONS.** Zestril has been found to be generally well tolerated in controlled clinical trials involving 2003 patients and subjects. The most frequent clinical adverse experiences in controlled trials were dizziness (6.3%), headache (5.3%), fatigue (3.3%), diarrhea (3.2%), upper respiratory symptoms (3.0%), and cough (2.9%), all of which were more frequent than in placebo-treated patients. For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6.0% of patients. In clinical trials, the overall frequency of adverse experiences could not be related to total daily dosage within the recommended therapeutic dosage range. For adverse experiences which occurred in more than 1% of patients and subjects treated with Zestril or Zestril plus hydrochlorothiazide in controlled clinical trials, comparative incidence data are listed in the table below.

Percent of Patients in Controlled Studies

	Zestril (n = 2003†) Incidence (discontinuation)	Zestril/Hydrochlorothiazide (n = 644) Incidence (discontinuation)	Placebo (n = 207) Incidence
Dizziness	6.3 (0.6)	9.0 (0.9)	1.9
Headache	5.3 (0.2)	4.3 (0.5)	1.9
Fatigue	3.3 (0.2)	3.9 (0.5)	1.0
Diarrhea	3.2 (0.3)	2.6 (0.3)	2.4
Upper Respiratory Symptoms	3.0 (0.0)	4.5 (0.0)	0.0
Cough	2.9 (0.4)	4.5 (0.8)	1.0
Nausea	2.3 (0.3)	2.5 (0.2)	2.4
Hypotension	1.8 (0.8)	1.6 (0.5)	0.5
Rash	1.5 (0.4)	1.6 (0.2)	0.5
Orthostatic Effects	1.4 (0.0)	3.4 (0.2)	1.0
Asthenia	1.3 (0.4)	2.0 (0.2)	1.0
Chest Pain	1.3 (0.1)	1.2 (0.2)	1.4
Vomiting	1.3 (0.2)	1.4 (0.0)	0.5
Dyspnea	1.1 (0.0)	0.5 (0.2)	1.4
Dyspepsia	1.0 (0.0)	1.9 (0.0)	0.0
Paresthesia	0.8 (0.0)	2.0 (0.2)	0.0
Impotence	0.7 (0.2)	1.6 (0.3)	0.0
Muscle Cramps	0.6 (0.0)	2.8 (0.6)	0.5
Back Pain	0.5 (0.0)	1.1 (0.0)	1.4
Nasal Congestion	0.3 (0.0)	1.2 (0.0)	0.0
Decreased Libido	0.2 (0.1)	1.2 (0.0)	0.0
Vertigo	0.1 (0.0)	1.1 (0.2)	0.0

†Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

Clinical adverse experiences occurring in 0.3% to 1.0% of patients in the controlled trials and rarer, serious, possibly drug related events reported in uncontrolled studies or marketing experience included: BODY AS A WHOLE: Chest discomfort, fever, flushing. CARDIOVASCULAR: Angina pectoris, orthostatic hypotension, rhythm disturbances, tachycardia, peripheral edema, palpitation. DIGESTIVE: Abdominal pain, anorexia, constipation, flatulence. METABOLISM: Gout. MUSCULOSKELETAL: Joint pain, shoulder pain. NERVOUS SYSTEM/PSYCHIATRIC: Depression, somnolence, insomnia, stroke. RESPIRATORY SYSTEM: Bronchitis, sinusitis, pharyngeal pain. UROGENITAL: Oliguria, progressive azotemia, acute renal failure. OTHER: Blurred vision, pruritus, urinary tract infection, vasculitis of the legs. ANGIOEDEMA: Angioedema has been reported in patients receiving Zestril (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis and/or larynx occurs, treatment with Zestril should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.) HYPOTENSION: In hypertensive patients, hypotension occurred in 1.2% and syncope occurred in 0.1% of patients. Hypotension or syncope was a cause of discontinuation of therapy in 0.5% of hypertensive patients. (See WARNINGS.) In patients with congestive heart failure, hypotension occurred in 5.0% and syncope occurred in 1.0% of patients. These adverse experiences were causes for discontinuation of therapy in 1.3% of these patients. **Clinical Laboratory Test Findings. Serum Electrolytes:** Hyperkalemia (See PRECAUTIONS.) **Creatinine, Blood Urea Nitrogen:** Minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 2.0% of patients with essential hypertension treated with Zestril alone. Increases were more common in patients receiving concomitant diuretics and in patients with renal artery stenosis. (See PRECAUTIONS.) Reversible minor increases in blood urea nitrogen and serum creatinine were observed in approximately 9.1% of patients with congestive heart failure on concomitant diuretic therapy. Frequently, these abnormalities resolved when the dosage of the diuretic was decreased. **Hemoglobin and Hematocrit:** Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.4 g% and 1.3 vol%, respectively) occurred frequently in patients treated with Zestril but were rarely of clinical importance in patients without some other cause of anemia. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia. **Other (Causal Relationship Unknown):** Rarely, elevations of liver enzymes and/or serum bilirubin have occurred. Overall, 2.0% of patients discontinued therapy due to laboratory adverse experiences, principally elevations in blood urea nitrogen (0.6%), serum creatinine (0.5%), and serum potassium (0.4%). **OVERDOSAGE.** The oral LD_{50} of lisinopril is greater than 20 g/kg in mice and rats. The most likely manifestation of overdosage would be hypotension, for which the usual treatment would be intravenous infusion of normal saline solution. **DOSAGE AND ADMINISTRATION. Initial Therapy:** In patients with uncomplicated essential hypertension not on diuretic therapy, the recommended initial dose is 10 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 20-40 mg per day administered in a single daily dose. The antihypertensive effect may diminish toward the end of the dosing interval regardless of the administered dose, but most commonly with a dose of 10 mg daily. This can be evaluated by measuring blood pressure just prior to dosing to determine whether satisfactory control is being maintained for 24 hours. If it is not, an increase in dose should be considered. Doses up to 80 mg have been used but do not appear to give greater effect. If blood pressure is not controlled with Zestril alone, a low dose of a diuretic may be added. Hydrochlorothiazide, 12.5 mg has been shown to provide an additive effect. After the addition of a diuretic, it may be possible to reduce the dose of Zestril. **Diuretic Treated Patients:** In hypertensive patients who are currently being treated with a diuretic, symptomatic hypotension may occur occasionally following the initial dose of Zestril. The diuretic should be discontinued, if possible, for two or three days before beginning therapy with Zestril to reduce the likelihood of hypotension. (See WARNINGS.) The dosage of Zestril should be adjusted according to blood pressure response. If the patient's blood pressure is not controlled with Zestril alone, diuretic therapy may be resumed as described above. If the diuretic cannot be discontinued, an initial dose of 5 mg should be used under medical supervision for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS and PRECAUTIONS, Drug Interactions.) Concomitant administration of Zestril with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium. (See PRECAUTIONS.) **Use in Elderly:** In general, blood pressure response and adverse experiences were similar in younger and older patients given similar doses of Zestril. Pharmacokinetic studies, however, indicate that maximum blood levels and area under the plasma concentration time curve (AUC) are doubled in older patients so that dosage adjustments should be made with particular caution. **Dosage Adjustment in Renal Impairment:** The usual dose of Zestril (10 mg) is recommended for patients with creatinine clearance > 30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance > 10 mL/min ≤ 30 mL/min (serum creatinine ≥ 3 mg/dL), the first dose is 5 mg once daily. For patients with creatinine clearance < 10 mL/min (usually on hemodialysis) the recommended initial dose is 2.5 mg. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily.

Renal Status	Creatinine-Clearance mL/min	Initial Dose mg/day
Normal Renal Function to Mild Impairment	>30	10
Moderate to Severe Impairment	≥10 ≤30	5
Dialysis Patients	<10	2.5‡

‡Dosage or dosing interval should be adjusted depending on the blood pressure response. Rev E 12/87

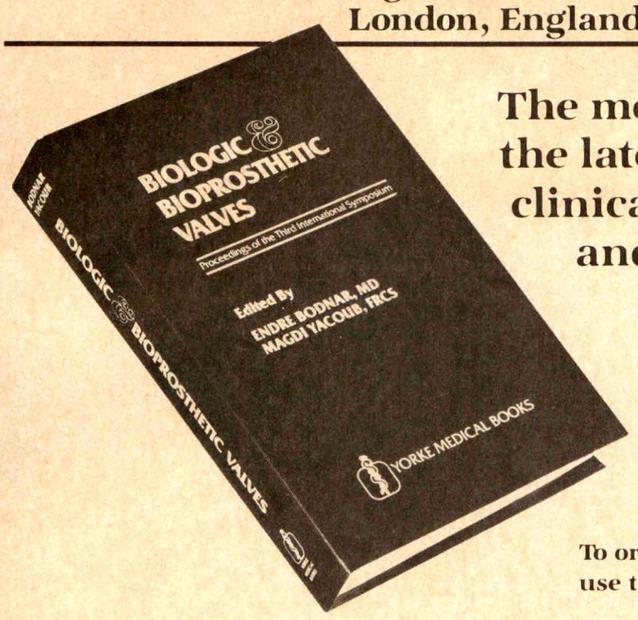
Biologic & Bioprosthetic Valves

Proceedings of the Third International Symposium
London, England, May 21-23, 1985



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

edited by Endre Bodnar, MD, and Magdi Yacoub, FRCS
ISBN 0-914316-49-4, 920 pp., May, 1986, $125.00

To order your copy of this important new book use the order form below.

The Third International Symposium on Cardiac Bioprostheses was held May 21-23, 1985, at the Grosvenor House Hotel, London. Six years have passed since the first meeting of this kind was held in Munich and 3 years since the second conference in Rome. The reassessment of the state of the art with biologic and bioprosthetic valves seems to have become a regular 3-yearly fixture reflecting the fast development of these devices, as well as the desire of surgeons and academics working in this field to share experiences, exchange ideas, and to resolve problems together.

The London meeting brought together surgeons, cardiologists, pathologists, engineers, and basic scientists, and the 3-day program accommodated 96 formal presentations with nearly 7 hours of discussion. It is a credit to the session chairmen and participants that the discussions were frank, outspoken, but fair and always to the point, and they have been added to this volume, and they certainly enhance its value.

This volume incorporates the work of the best specialists in the field, and should not be missing from your own professional library.

The Editors are eminently qualified to do this book, Dr. Bodnar is with the Cardiothoracic Institute, London, England, and Mr. Yacoub is with Harefield Hospital, Middlesex, England.

691 Acute Effects of Felodipine in Exertional Angina Pectoris

Sabino Scardi, Claudio Pandullo, Fulvio Pivotti, Giuliano Ceschia, and Giorgio Pollavini

To investigate antianginal efficacy, duration of action and tolerability, 2 doses of the new calcium antagonist felodipine were studied in 15 patients with stable exertional angina pectoris. Five and 10 mg of felodipine and placebo were randomly given, in double-blind conditions, on 3 different days. Exercise tests were performed 3 and 10 hours after dosing. In comparison with placebo, the 2 felodipine doses significantly increased anginal and ischemic thresholds as well as duration of exercise and total work to peak exercise, at both 3 and 10 hours after administration. At the third hour, the 2 doses of the active drug were equally effective while after 10 hours felodipine 10 mg was superior to the lower dose in total work at the onset of angina as well as in total work and duration of exercise at peak exercise. A single administration of felodipine, 5 and 10 mg, may improve exercise capacity over a 10-hour period in patients with stable exercise angina due to atherosclerotic heart disease.

697 Correlation of Minimum Coronary Lumen Diameter with Left Ventricular Functional Impairment Induced by Atrial Pacing

Jonathan Tobis, David Sato, Orhan Nalcioglu, Warren D. Johnston, John Mallery, Jackie See, Lian Qu, Tim Reese, Jim Paynter, Steve Montelli, and Walter L. Henry

To understand whether quantitative measurement of minimal coronary luminal diameter is a better method than percent diameter narrowing for assessing the functional impairment of myocardial contractility produced by coronary artery stenoses, measurements were made from 37 stenotic segments in 27 patients with coronary artery disease and from corresponding segments in 10 subjects without coronary artery narrowing. An assessment of the reliability of the 2 types of measurements was made by correlating them with the physiologic parameters of both segmental wall motion and global ejection fraction response induced by atrial pacing. A minimal lumen diameter of ≤1.5 mm identified patients who were likely to have a functional impairment during atrial pacing as assessed by either global ejection fraction or segmental wall motion defects. The results demonstrate that the measurement of minimal lumen diameter is more accurate than measurements of percent narrowing in predicting the effects of an atrial pacing stress test on segmental wall motion. We conclude that minimal coronary luminal diameter provides a better method than percent diameter narrowing calculations to measure the anatomic severity of coronary artery narrowing.

704 Recruitment and Baseline Description of Patients in the Cardiac Arrhythmia Pilot Study

The Cardiac Arrhythmia Pilot Study (CAPS) Investigators

The Cardiac Arrhythmia Pilot Study tested the feasibility of performing a large-scale study to evaluate the effect of therapy of ventricular arrhythmias after acute myocardial infarction (AMI). Patients with ≥10 ventricular premature complexes/hour, recorded 6 to 60 days after AMI, and with an ejection fraction >0.20 were randomized to receive encainide, flecainide, imipramine, morcizine or placebo. Successful therapy was defined as ≥70% suppression of ventricular premature complexes and >90%

Excellence in the
Service of Time...
Commemorating a Decade of
Medtronic Hall™ Valve
Performance

Our Valve Deserves Its Signature

We create the Medtronic Hall™ Heart Valve like a fine-crafted work of art. Each valve is individually tested and personally, carefully, thoroughly inspected. Only then is it signed, sealed and delivered. Behind our confident signature is a decade of excellent hemodynamic performance and structural durability.

Though others may attempt to offer imitations, why settle for anything less than a signed original?

For detailed information describing intended use, warnings, precautions, and contraindications, refer to the instructions provided with each device or contact your local Medtronic representative.

suppression of runs of ventricular tachycardia. One-half of patients were randomized within 1 month after their AMI. The mean ejection fraction was 0.45. Approximately one-third of all patients had at least 1 run of unsustained ventricular tachycardia. Over 20 AMI- and age-eligible patients were identified to obtain each randomized patient. The randomization process successfully distributed baseline variables across drug groups.

714 Prevalence and Significance of Atrial Fibrillation in Coronary Artery Disease (CASS Registry)

Airlie Cameron, Miles J. Schwartz, Richard A. Kronmal, and Andrzej S. Kosinski

Atrial fibrillation (AF) was present in 116 (0.6%) of 18,343 patients with angiographically demonstrated coronary artery disease. The presence of AF was positively associated with the following clinical and angiography variables: older age, sex (male), mitral regurgitation and functional impairment due to congestive heart failure. The number of diseased coronary arteries was negatively related to the presence of AF. Atrial fibrillation was an independent predictor of survival and its presence doubled the estimated risk over those patients without AF.

718 Helicopter Transport of Patients During Acute Myocardial Infarction

Raye L. Bellinger, Robert M. Califf, Daniel B. Mark, Rita A. Weber, Patricia Collins, Janice Stone, Harry R. Phillips, III, Lawrence German, and Richard S. Stack

This study examines the initial experience of a regional helicopter system transporting patients with acute myocardial infarction, with particular attention to complications encountered. Over a 15-month period, 250 patients were transported. Most patients received thombolytic therapy before or during transport. The most frequent complication was transient hypotension (21 patients), usually treated with fluid boluses. Third-degree atrioventricular block and nonsustained ventricular tachycardia were the next most common. There were no instances of ventricular fibrillation, asystole or respiratory arrest in-flight. No patient required cardioversion, defibrillation or intubation during transport. Five patients received cardiopulmonary resuscitation in-flight; in 3, cardiopulmonary resuscitation had been started before liftoff. We conclude that complications are infrequent during emergency helicopter transport of patients with acute myocardial infarction. The cost/benefit ratio of such a transport system, however, remains to be determined.

723 Comparison of Two Dose Regimens of Intravenous Tissue Plasminogen Activator for Acute Myocardial Infarction

Eric J. Topol, Barry S. George, Dean J. Kereiakes, Richard J. Candela, Charles W. Abbottsmith, David C. Stump, Jane Boswick, Richard S. Stack, Robert M. Califf, and the TAMI Study Group

We compared 2 dosing schedules of intravenous tissue plasminogen activator (t-PA) for acute myocardial infarction in a multicenter trial. For the first 178 patients (group A), 60 mg was given in the first-hour dose and 90 mg was infused over 7 hours. In the subsequent 208 patients (group B), the first-hour dose was 1.0 mg/kg, with additional 150 mg given over 5 hours.

Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet

Now available
"**UNIT OF USE**"
A full month's supply
(120 tablets) for each
dosage strength

Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR (procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

> The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: Hypersensitivity to procainamide is an absolute contraindication. In this connection, cross-sensitivity to procaine and related drugs must be borne in mind.

Procainamide should not be administered to patients with complete atrioventricular heart block. It is also contraindicated in cases of second degree and third degree A-V nodal block unless an electrical pacemaker is operative.

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis.

WARNINGS: Granulocytopenia may follow the use of procainamide, and deaths from sepsis have occurred. Leukocyte changes are most likely to occur during the first three months of therapy. During this time routine blood counts should be done at least every two weeks and thereafter at longer intervals throughout maintenance procainamide therapy. Complaints of malaise and aches (a flu-type syndrome) are often reported in association with the granulocyte depression.

Patients should be instructed to report such symptoms promptly, as well as any soreness of mouth, throat or gums, unexplained fever, or symptoms of an upper respiratory tract infection. If these should occur and a complete blood count indicates a granulocyte depression, procainamide therapy should be discontinued immediately and appropriate treatment instituted. Recovery of leukocyte count usually occurs within a few weeks.

The incidence of granulocytopenia appears to be higher with procainamide sustained-release tablets than with standard tablets.

PRECAUTIONS: General— During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgment of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Serious hypotension can result from peripheral vasodilation and from decreases in cardiac output. At high plasma levels, procainamide may produce sinus tachycardia due to reflex sympathetic response to its hypotensive effect. Large doses may increase cardiac automaticity and can induce complete atrioventricular block, cardiac standstill, or ventricular extrasystoles that may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram: a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged; and the QRS and T waves show some decrease in voltage.

Antinuclear antibodies (ANA) are often found in patients receiving long-term procainamide therapy. The induction of ANA appears to be independent of dosage. Patients with procainamide-induced increases in ANA titers may develop a syndrome resembling systemic lupus erythematosus (SLE). The mechanism of this syndrome is uncertain. Polyarthralgia, arthritic symptoms, and pleuritic pain are common symptoms; to a lesser extent fever, myalgia, skin lesions, pleural effusion, pericarditis, headache, fatigue, weakness, nausea and abdominal pain may occur. Rare cases of thrombocytopenia, Coombs' positive hemolytic anemia, increased SGOT, SGPT, and serum amylase have been reported which may be related to this SLE-like syndrome.

It is recommended that tests for systemic lupus erythematosus be carried out at regular intervals in patients receiving maintenance or prolonged procainamide therapy. The drug should be discontinued if there is a rising ANA titer or clinical symptoms of SLE appear. The SLE-like syndrome may be reversible upon discontinuation of the drug. If discontinuation does not cause remission of the symptoms, corticosteroid therapy may be effective. If the SLE-like syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, corticosteroid suppressive therapy may be used concomitantly with procainamide.

Information for Patient— Practitioners should give the following information and instructions to patients receiving Procan SR. 1. Do not crush or chew these tablets. Swallow them whole. 2. Take this medicine exactly as directed by your doctor. Do not miss any doses and do not take more medicine than ordered. Do not stop taking this medicine without first checking with your doctor. 3. If you miss a dose and remember within one hour or so, take it as soon as possible. Then go back to your regular dosing schedule. Do not take double doses. If you have any questions about this, check with your doctor. 4. Report to your doctor any flu-type symptoms, such as malaise and aches, as well as any soreness of the mouth, throat or gums, unexplained fever, skin rash, unusual bleeding or bruising, symptoms that resemble arthritis, or symptoms of an upper respiratory tract infection. 5. Do not be concerned if you occasionally notice in your stool something that looks like a tablet. In Procan SR (procainamide hydrochloride tablets), the drug is "held" in a wax core that has been specially designed to slowly release the drug for your body to absorb. When this process is completed the empty, nonabsorbable wax core, which looks nearly unchanged, is eliminated from your body. 6. Keep container tightly closed and store in a cool, dry place.

Procan® SR (procainamide hydrochloride tablets)

Laboratory Tests— Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals.

Routine blood counts are advisable during maintenance procainamide therapy. See WARNINGS for additional information.

Plasma concentrations of procainamide and NAPA should be monitored in patients with renal disease, hepatic disease, cardiac failure, or low cardiac output states.

Drug Interactions: 1. **Antiarrhythmics:** Concurrent use with procainamide may result in additive cardiac effects and/or additive toxic effects. 2. **Anticholinergics:** Procainamide enhances the anticholinergic effects. Extreme caution must be exercised with such a combination. 3. **Anticholinesterases:** Procainamide antagonizes the effect of anticholinesterases in myasthenia gravis, and paralysis returns. 4. **Antihypertensives:** Procainamide may potentiate the hypotensive effects of thiazide diuretics and other antihypertensive agents. Adjustment of dosage may be required. 5. **Histamine H_2-receptor antagonists:** It has been reported that histamine H_2-receptor antagonists such as cimetidine and ranitidine reduce renal clearance of procainamide and NAPA, resulting in higher plasma concentrations for longer durations. Caution should be exercised when administering these drugs concurrently, especially in the elderly, who have a reduced ability to clear all three. Dosage modification may be required. 6. **Neuromuscular Blocking Agents:** Procainamide potentiates the effects of skeletal muscle relaxants such as succinylcholine. It also may enhance or prolong the neuromuscular blocking activity of bacitracin, colistimethate, dihydrostreptomycin, gentamicin, gramicidin, kanamycin, neomycin, polymyxin B, streptomycin, and viomycin, producing respiratory depression.

Pregnancy— Pregnancy Category C. Animal reproduction studies have not been conducted with procainamide. It is also not known whether procainamide can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Procainamide should be given to a pregnant woman only if clearly needed.

Nursing Mothers— Procainamide and its major metabolite, NAPA, have been identified in breast milk. Caution should be exercised when procainamide is administered to a nursing woman.

ADVERSE REACTIONS: Most frequent, especially with large oral doses: 1. Anorexia; 2. Nausea; 3. Vomiting; 4. Diarrhea; 5. Urticaria; 6. Pruritus.

Less frequent: 1. Reactions in patients on long-term procainamide therapy: a. Antinuclear antibodies (ANA); b. Syndrome resembling systemic lupus erythematosus (SLE) (See PRECAUTIONS); 2. Hypersensitivity reactions: a. Angioneurotic edema; b. Maculopapular rash; c. Fever; d. Eosinophilia; e. Hypergammaglobulinemia.

Infrequent: 1. Granulocytopenia, sometimes resulting in death (See WARNINGS); 2. Convulsions; 3. Psychosis with hallucinations; 4. Confusion; 5. Mental depression; 6. Giddiness; 7. Lightheadedness; 8. Weakness; 9. Bitter taste.

Rare: 1. Hypotension; 2. A case was reported with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following a single dose of the drug.

OVERDOSAGE: Signs and Symptoms: Severe hypotension, ventricular fibrillation, widening of QRS complex, junctional tachycardia, intraventricular conduction delay, oliguria, lethargy, confusion, nausea, and vomiting.

Treatment: If ingestion is recent, emesis, activated charcoal, or gastric lavage may reduce absorption. Dopamine, phenylephrine, or levarterenol may be helpful in reversing severe hypotensive responses.

Management of overdosage includes symptomatic treatment with ECG and blood pressure monitoring. Procainamide toxicity can usually be treated, if necessary, by administering vasopressors after adequate fluid volume replacement. Intravenous infusion of 1/6 molar sodium lactate injection reportedly reduces the cardiotoxic effects of procainamide.

If procainamide toxicity causes severe hypotension and renal insufficiency, urinary elimination of procainamide and NAPA is decreased, and hemodialysis may be required. Hemodialysis significantly reduces the serum half-life of procainamide, and effectively removes procainamide and NAPA. Peritoneal dialysis is not effective.

It has been reported that one patient who ingested approximately 7 grams of procainamide hydrochloride recovered after treatment consisting of IV levarterenol, IV furosemide, attempted volume expansion with albumin, and hemodialysis. Also reported is the case of an elderly patient who recovered after ingestion of approximately 19 grams of procainamide hydrochloride. The patient was treated with IV isoproterenol and IV epinephrine. The latter report suggested that insertion of a ventricular pacing electrode is a reasonable precautionary measure in case high grade A-V block develops.

Storage Conditions: Protect from moisture. Store bottles below 30°C (86°F). Store unit-dose packages at controlled room temperature, 15°-30°C (59°-86°F).

Caution— Federal law prohibits dispensing without prescription. 0207G014

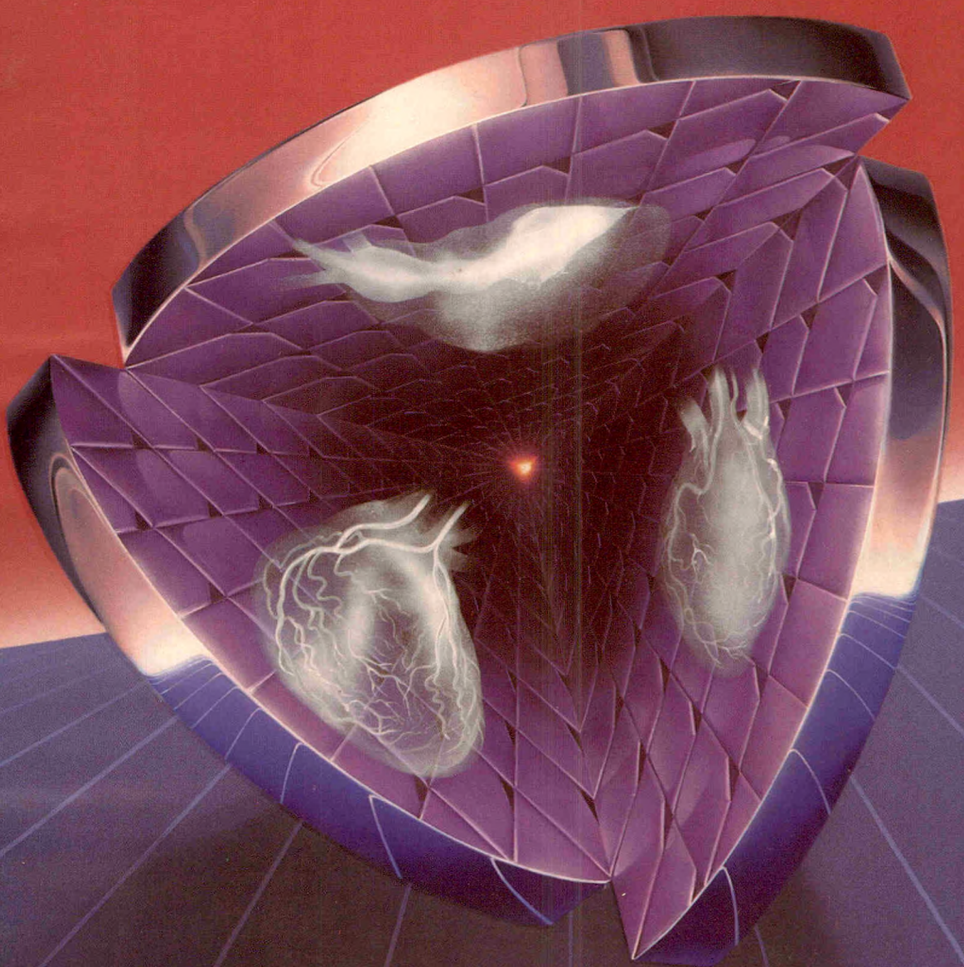
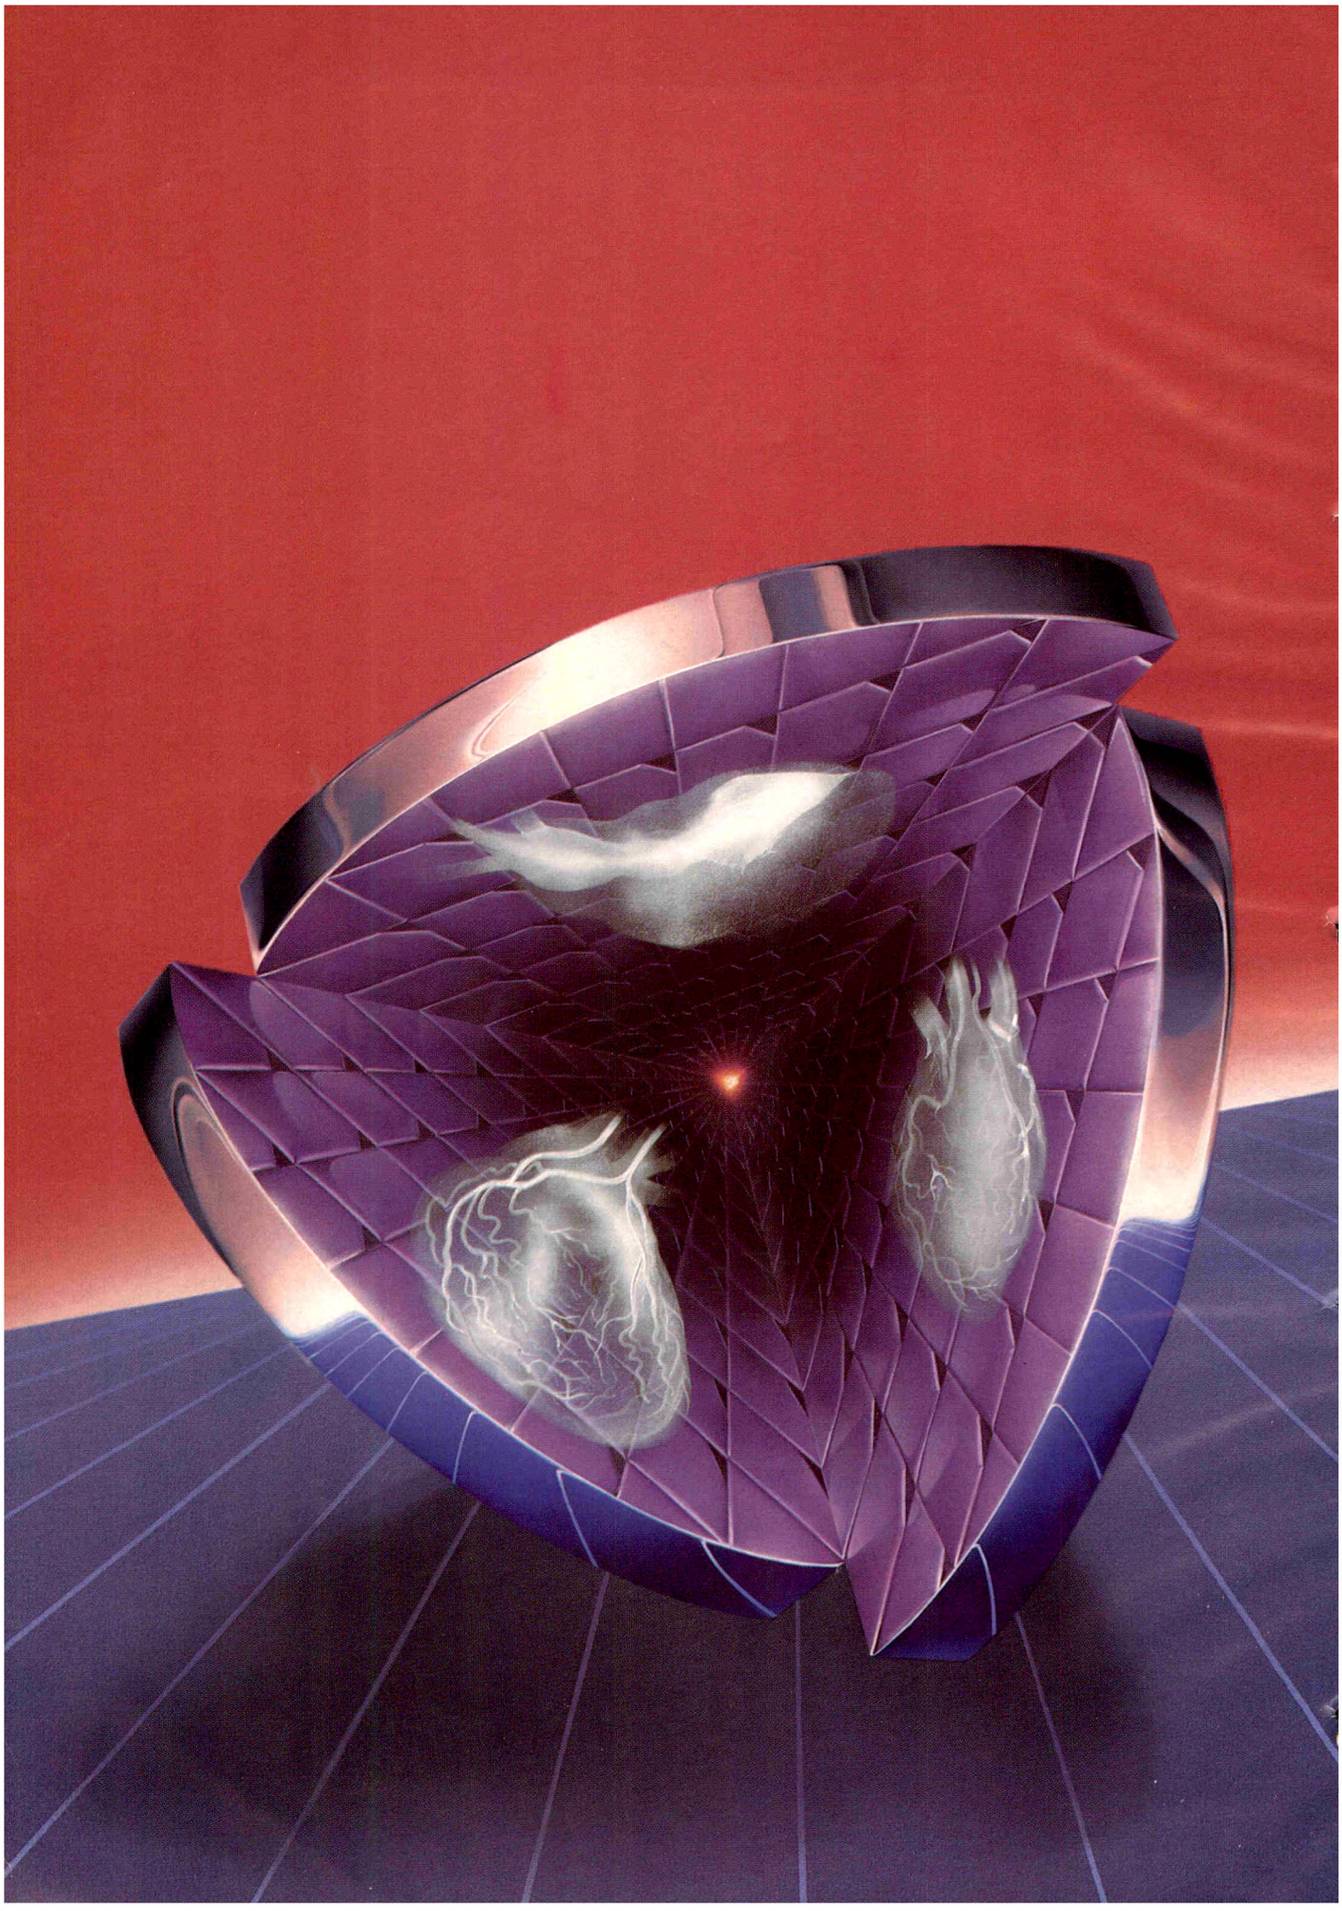
The image of safety.



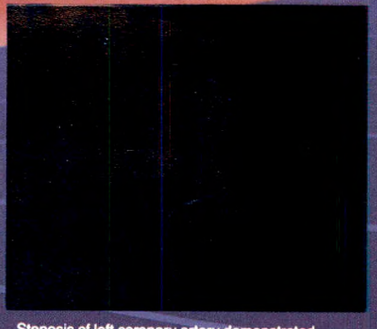


The image of safety in angiocardiography.

In angiocardiography, you ask a lot of the contrast agent you use.

Safety.
Imaging performance.
Patient comfort and tolerance.

Experience with OMNIPAQUE in clinical use and trials continues to demonstrate its unique combination of lowest chemotoxicity and low osmolality, providing the best of all three.



Stenosis of left coronary artery demonstrated with OMNIPAQUE.

NONIONIC

OMNIPAQUE®

(IOHEXOL)

An ongoing record of safety in angiocardiography.

See next page for important product information concerning contraindications, warnings, adverse reactions, patient selection, and prescribing and precautionary recommendations.

OMNIPAQUE® 240 300 350

INJECTION (IOHEXOL) INTRAVASCULAR

PLEASE CONSULT FULL PRODUCT INFORMATION BEFORE USING.
A SUMMARY FOLLOWS:

DESCRIPTION: OMNIPAQUE is a nonionic, water-soluble radiographic contrast medium for intravascular administration in concentrations of 240, 300, and 350 mgI/mL. Each milliliter of iohexol solution contains 1.21 mg tromethamine and 0.1 mg edetate calcium disodium with the pH adjusted between 6.8 and 7.7 with hydrochloric acid or sodium hydroxide, but it contains no preservatives.

CONTRAINDICATIONS: OMNIPAQUE should not be administered to patients with a known hypersensitivity to iohexol.

WARNINGS: OMNIPAQUE should be used with extreme care in patients with severely impaired renal and/or hepatic function; severe thyrotoxicosis, hyperthyroidism, or an autonomously functioning thyroid nodule; diabetes with a serum creatinine level above 3 mg/dL. It is not recommended for use in patients with anuria.

Patients with known or suspected pheochromocytoma should receive a minimum of contrast medium if the benefit of the examination is judged to outweigh its risk; blood pressure should be monitored throughout the procedure, and measures for the treatment of hypertensive crisis should be readily available.

Contrast agents are potentially hazardous in patients with multiple myeloma or other paraproteinemia, particularly those with therapeutically resistant anuria. The combination of contrast agent and dehydration may precipitate myeloma protein in the renal tubules. No form of therapy, including dialysis, has been successful in reversing the effect. Myeloma, which occurs most commonly in persons over age 40, should be considered before instituting intravascular administration of contrast agents.

Ionic contrast media, when injected intravenously or intra-arterially, may promote sickling in individuals who are homozygous for sickle cell disease.

PRECAUTIONS: Diagnostic procedures that involve the use of radiopaque diagnostic agents should be carried out under the direction of personnel with the prerequisite training and with a thorough knowledge of the particular procedure to be performed. Appropriate facilities should be available for coping with any complication of the procedure, as well as for emergency treatment of severe reactions to the contrast agent itself. Competent personnel and emergency facilities should be available, since severe delayed reactions have been reported (see ADVERSE REACTIONS). The possibility of serious, life-threatening, fatal, anaphylactoid, or cardiovascular reactions should always be considered (see ADVERSE REACTIONS). It is of utmost importance that a course of action be carefully planned in advance for immediate treatment of serious reactions. Preparatory dehydration is dangerous and may contribute to acute renal failure in patients with advanced vascular disease, in diabetic patients, and in susceptible nondiabetic patients (often elderly with preexisting renal disease). *Patients should be well hydrated prior to and following iohexol administration.* Careful consideration of the potential risk of acute renal failure should be given before performing excretory urography in diabetic patients with diabetic nephropathy and in susceptible nondiabetic patients (often elderly with preexisting renal disease). Immediately following surgery, excretory urography should be used with caution in renal transplant recipients. The possibility of an idiosyncratic reaction in susceptible patients should always be considered (see ADVERSE REACTIONS). The susceptible population includes, but is not limited to, patients with a history of a previous reaction to contrast media, patients with a known sensitivity to iodine per se, and patients with a known clinical hypersensitivity: bronchial asthma, hay fever, and food allergies. A thorough medical history with emphasis on allergy and hypersensitivity, prior to the injection of any contrast media, may be more accurate than pretesting in predicting potential adverse reactions.

A positive history of allergies or hypersensitivity does not arbitrarily contraindicate the use of a contrast agent where a diagnostic procedure is thought essential, but caution should be exercised (see ADVERSE REACTIONS). Premedication with antihistamines or corticosteroids to avoid or minimize possible allergic reactions in such patients should be considered and administered using separate syringes. Recent reports indicate that such pretreatment does not prevent serious, life-threatening reactions but may reduce both their incidence and severity.

Even though the osmolality of OMNIPAQUE is low compared to diatrizoate- or iothalamate-based ionic agents of comparable iodine concentration, the potential transitory increase in circulatory osmotic load in patients with congestive heart failure requires caution during injection. These patients should be observed for several hours following the procedure to detect delayed hemodynamic disturbances.

General anesthesia may be indicated in the performance of some procedures in selected adult patients; however, a higher incidence of adverse reactions has been reported in these patients and may be attributable to the inability of the patient to identify untoward symptoms or to the hypotensive effect of the anesthesia which can reduce cardiac output and increase the duration of exposure to the contrast agent.

Angiography should be avoided whenever possible in patients with homocystinuria, because of the risk of inducing thrombosis and embolism.

In angiographic procedures, the possibility of dislodging plaques or damaging or perforating the vessel wall should be borne in mind during the catheter manipulations and contrast medium injection. Test injections to ensure proper catheter placement are recommended.

Selective coronary arteriography should be performed only in those patients in whom the expected benefits outweigh the potential risk. The inherent risks of angiocardiography in patients with chronic pulmonary emphysema must be weighed against the necessity for performing this procedure.

When OMNIPAQUE is to be injected using plastic disposable syringes, the contrast medium should be drawn into the syringe and used immediately.

The inhibitory effects of nonionic contrast media on mechanisms of hemostasis have been shown, in vitro, to be less than those of ionic contrast media at comparable concentrations. For this reason, standard angiographic procedures should always be followed: angiographic catheters should be flushed frequently, and prolonged contact of blood with contrast media in syringes and catheters should be avoided.

If nondisposable equipment is used, scrupulous care should be taken to prevent residual contamination with traces of cleansing agents.

Parenteral products should be inspected and discarded if particulate matter or discoloration is present.

Drug/Laboratory Test Interaction: If iodine-containing isotopes are to be administered for the diagnosis of thyroid disease, the iodine-binding capacity of thyroid tissue may be reduced for up to 2 weeks after contrast medium administration. Thyroid function tests which do not depend on iodine estimation, eg, T_3 resin uptake or direct thyroxine assays, are not affected. Many radiopaque contrast agents are incompatible in vitro with some antihistamines and many other drugs; therefore, no other pharmaceuticals should be admixed with contrast agents.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term animal studies have been performed to evaluate carcinogenic potential, mutagenesis, or whether OMNIPAQUE can affect fertility in men or women.

Pregnancy Category B: Reproduction studies have been performed in rats and rabbits with up to 100 times the recommended human dose. No evidence of impaired fertility or harm to the fetus has been demonstrated due to OMNIPAQUE. There are, however, no studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known to what extent iohexol is excreted in human milk. However, many injectable contrast agents are excreted unchanged in human milk. Although it has not been established that serious adverse reactions occur in nursing infants, caution should be exercised when intravascular contrast media are administered to nursing women. Bottle feedings may be substituted for breast feedings for 24 hours following administration of OMNIPAQUE.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Usually mild to moderate in severity. However, serious, life-threatening, and fatal reactions, mostly of cardiovascular origin, have been associated with the administration of iodine-containing contrast media, including OMNIPAQUE. The injection of contrast media is frequently associated with the sensation of warmth and pain, especially in peripheral angiography; pain and warmth are less frequent and less severe with OMNIPAQUE than with many contrast media.

Cardiovascular System: Arrhythmias including PVCs and PACs (2%), angina/chest pain (1%), and hypotension (0.8%). Others including cardiac failure, asystole, bradycardia, tachycardia, and vasovagal reaction were reported with an individual incidence of less than 0.4%. In controlled clinical trials involving 1,213 patients, one fatality occurred. A cause-and-effect relationship between this death and iohexol has not been established.

Nervous System: Vertigo [including dizziness and lightheadedness] (0.7%), pain (3%), photomas (2%), headache (2%), and taste perversion (1%). Others including anxiety, blurred vision, fever, motor and speech dysfunction, convulsion, paresthesia, somnolence, stiff neck, hemiparesis, and nystagmus were reported, with an individual incidence of less than 0.3%.

Respiratory System: Dyspnea and laryngitis, with an individual incidence of 0.1%.

Gastrointestinal System: Nausea (2%) and vomiting (0.6%). Others including diarrhea, dyspepsia, and dry mouth were reported, with an individual incidence of less than 0.2%.

Skin and Appendages: Urticaria (0.3%) and purpura (0.1%).

General Adverse Reactions to Contrast Media: The following reactions have been reported after administration of other intravascular iodinated contrast media, and rarely with iohexol. *Reactions due to technique:* hematomas and ecchymoses. *Hemodynamic reactions:* vein cramp and thrombophlebitis following intravenous injection. *Cardiovascular reactions:* rare cases of cardiac arrhythmias, reflex tachycardia, chest pain, cyanosis, hypertension, hypotension, peripheral vasodilatation, shock, and cardiac arrest. *Renal reactions:* occasionally, transient proteinuria; rarely, oliguria or anuria. *Allergic reactions:* asthmatic attacks, nasal and conjunctival symptoms, dermal reactions such as urticaria with or without pruritus, as well as pleomorphic rashes, sneezing, and lacrimation; rarely, anaphylactic reactions. Rare fatalities have occurred due to these or unknown causes. *Signs and symptoms related to the respiratory system:* pulmonary or laryngeal edema, bronchospasm, dyspnea; or *to the nervous system:* restlessness, tremors, convulsions. *Other reactions:* flushing, pain, warmth, metallic taste, nausea, vomiting, anxiety, headache, confusion, pallor, weakness, sweating, localized areas of edema (especially facial cramps), neutropenia, and dizziness. Rarely, immediate or delayed rigors can occur, sometimes accompanied by hyperpyrexia. Infrequently, "iodism" (salivary gland swelling) from organic iodinated compounds appears 2 days after exposure and subsides by the sixth day.

In general, the reactions that are known to occur upon parenteral administration of iodinated contrast agents are possible with any nonionic agent. Approximately 95% of adverse reactions accompanying the use of water-soluble intravascularly administered contrast agents are mild to moderate in degree. However, severe, life-threatening anaphylactoid reactions, mostly of cardiovascular origin, have occurred. Reported incidences of death range from 6.6 per 1 million (0.00066%) to 1 in 10,000 (0.01%). Most deaths occur during injection or 5 to 10 minutes later, the main feature being cardiac arrest, with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. The incidence of shock is estimated to be 1 out of 20,000 (0.005%) patients.

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions.

Chemotoxic reactions result from the physicochemical properties of the contrast media, the dose, and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the amount of dose injected, the speed of injection, and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate, and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

The reported incidence of adverse reactions to contrast media in patients with a history of allergy is twice that in the general population. Patients with a history of previous reactions to a contrast medium are three times more susceptible than other patients. However, sensitivity to contrast media does not appear to increase with repeated examinations.

Most adverse reactions to injectable contrast media appear within 1 to 3 minutes after the start of injection, but delayed reactions may occur.

Regardless of the contrast agent employed, the overall estimated incidence of serious adverse reactions is higher with angiocardiography than with other procedures. Cardiac decompensation, serious arrhythmias, angina pectoris, or myocardial ischemia or infarction may occur during angiocardiography and left ventriculography. Electrocardiographic and hemodynamic abnormalities occur less frequently with OMNIPAQUE than with diatrizoate meglumine and diatrizoate sodium injection.

OVERDOSAGE: Overdosage may occur. The adverse effects of overdosage are life-threatening and affect mainly the pulmonary and cardiovascular systems. The symptoms include cyanosis, bradycardia, acidosis, pulmonary hemorrhage, convulsions, coma, and cardiac arrest. Treatment of an overdosage is directed toward the support of all vital functions and prompt institution of symptomatic therapy.

The intravenous LD_{50} values of OMNIPAQUE (in grams of iodine per kilogram body weight) are 24.2 in mice and 15.0 in rats.

Hear a master piece in one movement.

The new Littmann® Master Cardiology stethoscope is truly a masterpiece. In acoustical performance. And in design.

No other stethoscope is designed to let you hear both high and low frequency sounds from a single-sided chestpiece. Subtle fingertip pressure is all it takes to switch from the traditional bell mode to diaphragm mode. Because there's no need to move the chestpiece, you get uninterrupted diagnostic response. So you don't miss a beat.

The Littmann Master Cardiology stethoscope provides unsurpassed acoustical performance. And unsurpassed quality and durability. The handcrafted solid stainless steel chestpiece, polished stainless steel eartubes and long-life tubing make it a sound investment. And the entire scope is backed by a seven year warranty—the most substantial warranty available on a stethoscope today.

For more information call 1-800-328-5727 ext. 8938 (in MN call 1-800-742-5685, ext. 8938). Try a Littmann Master Cardiology stethoscope and hear a command performance from the ultimate acoustical stethoscope. Bravisimo. 3M Health Care Products.

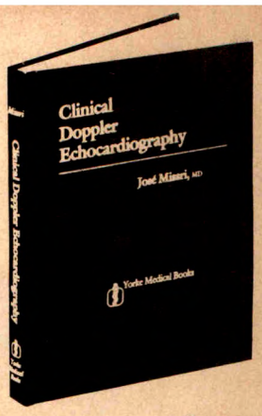
...a comprehensive text emphasizing the clinical aspects of Doppler echocardiography



Clinical Doppler Echocardiography

by José Missri, MD
0-914316-51-6 256 pp., April 1986, 175 illustrations, $55.00

The development and refinement of Doppler echocardiography represent a major advance in the diagnostic applications of ultrasound in heart disease.

Dr. Missri has written *Clinical Doppler Echocardiography* to provide clinical cardiologists, postdoctoral fellows and "echo" technologists with practical information on cardiac Doppler applied to acquired and congenital disease.

Clearly written, logically presented, generously illustrated—including 4-color examples of Doppler color-flow mapping—and thoroughly indexed, *Clinical Doppler Echocardiography* is a must addition for personal and medical center libraries.

Table of Contents (in brief)

INTRODUCTION TO DOPPLER ECHOCARDIOGRAPHY
PRINCIPLES OF DOPPLER ECHOCARDIOGRAPHY AND INSTRUMENTATION
DOPPLER EXAMINATION OF THE HEART AND GREAT VESSELS
DOPPLER EVALUATION OF MITRAL VALVE DISEASE
DOPPLER EVALUATION OF AORTIC VALVE DISEASE
DOPPLER EVALUATION OF RIGHT SIDED LESIONS AND PULMONARY HYPERTENSION
DOPPLER ASSESSMENT OF PROSTHETIC VALVES
DOPPLER ECHOCARDIOGRAPHY IN THE EVALUATION OF CONGENITAL HEART DISEASE
EVALUATION OF CARDIAC FUNCTION AND ASSESSMENT OF CARDIOMYOPATHY BY DOPPLER ECHOCARDIOGRAPHY

TRANDATE® Tablets
(labetalol hydrochloride)

BRIEF SUMMARY OF PRODUCT INFORMATION

The following is a brief summary only. Before prescribing, see complete prescribing information in TRANDATE® Tablets product labeling.

INDICATIONS AND USAGE: TRANDATE® Tablets are indicated in the management of hypertension. TRANDATE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS: TRANDATE® Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater-than-first-degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS: Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta-blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary labetalol HCl can be used with caution in patients with a history of heart failure who are well compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response should be observed closely. If cardiac failure continues despite adequate digitalization and diuretic, TRANDATE® therapy should be withdrawn (gradually, if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered TRANDATE, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, TRANDATE administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue TRANDATE therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (eg, Chronic Bronchitis and Emphysema): Patients with bronchospastic disease should, in general, not receive beta-blockers. TRANDATE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if TRANDATE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma: Labetalol HCl has been shown to be effective in lowering blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (eg, tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heartbeat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions** under **PRECAUTIONS**).

PRECAUTIONS: General: ***Impaired Hepatic Function:*** TRANDATE® Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction: On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients: As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incidence of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with TRANDATE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with TRANDATE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with TRANDATE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests: As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions: In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown, but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal antiasthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions: The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term oral dosing studies with labetalol HCl for 18 months in mice and for two years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl using dominant lethal assays in rats and mice and exposing microorganisms according to modified Ames tests showed no evidence of mutagenesis.

Pregnancy: ***Teratogenic Effects: Pregnancy Category C:*** Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately six and four times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Infants of mothers who were treated with labetalol HCl during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of two to four times the MRHD caused a decrease in neonatal survival.

Labor and Delivery: Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers: Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when TRANDATE Tablets are administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects are mild, transient, and occur early in the course of treatment. In controlled clinical trials of three to four months' duration, discontinuation of TRANDATE® Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8% to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The following adverse reactions were derived from multi-center, controlled clinical trials over treatment periods of three and four months. The rates, which ranged from less than 1% to 5% except as otherwise noted, are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (eg, dizziness, 20%; nausea, 14%; fatigue, 11%).

Body as a Whole: Fatigue, asthenia, and headache.

Gastrointestinal: Nausea (6%), vomiting, dyspepsia, diarrhea, and taste distortion.

Central and Peripheral Nervous Systems: Dizziness (11%), paresthesia, and drowsiness.

Autonomic Nervous System: Nasal stuffiness, ejaculation failure, impotence, and increased sweating.

Cardiovascular: Edema and postural hypotension.

Respiratory: Dyspnea.

Skin: Rash.

Special Senses: Vision abnormality and vertigo.

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, ie, a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2,400 mg in more severely hypertensive patients. The US therapeutic trials data base for adverse reactions that are clearly or possibly dose-related shows that the following side effects increased with increasing dose: dizziness, fatigue, nausea, vomiting, dyspepsia, paresthesia, nasal stuffiness, ejaculation failure, impotence, and edema.

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular: Postural hypotension, including rarely, syncope.

Central and Peripheral Nervous Systems: Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient, and usually occurred at the beginning of treatment.

Collagen Disorders: Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes: Dry eyes.

Immunological System: Antimitochondrial antibodies.

Liver and Biliary System: Cholestasis with or without jaundice.

Musculoskeletal System: Muscle cramps; toxic myopathy.

Respiratory System: Bronchospasm.

Skin and Appendages: Rashes of various types, such as generalized maculopapular, lichenoid, urticarial, bullous lichen planus, psoriaform, and facial erythema; Peyronie's disease; reversible alopecia.

Urinary System: Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects: In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System: Reversible mental depression progressing to catatonia, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance or neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Allergic: Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal: Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical Laboratory Tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.

DOSAGE AND ADMINISTRATION: DOSAGE MUST BE INDIVIDUALIZED. The recommended *initial* dosage is 100 mg *twice* daily whether used alone or added to a diuretic regimen. After two or three days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every two or three days. The usual *maintenance* dosage of labetalol HCl is between 200 and 400 mg *twice* daily. Before use, see complete prescribing information for dosage details.

HOW SUPPLIED: TRANDATE® Tablets, 100 mg, light orange, round, scored, film-coated tablets engraved on one side with "TRANDATE 100 GLAXO," bottles of 100 (NDC 0173-0346-43) and 500 (NDC 0173-0346-44) and unit dose packs of 100 tablets (NDC 0173-0346-47).

TRANDATE Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with "TRANDATE 200 GLAXO," bottles of 100 (NDC 0173-0347-43) and 500 (NDC 0173-0347-44) and unit dose packs of 100 tablets (NDC 0173-0347-47).

TRANDATE Tablets, 300 mg, peach, round, scored, film-coated tablets engraved on one side with "TRANDATE 300 GLAXO," bottles of 100 (NDC 0173-0348-43) and 500 (NDC 0173-0348-44) and unit dose packs of 100 tablets (NDC 0173-0348-47).

TRANDATE Tablets should be stored between 2° and 30°C (36° and 86°F). TRANDATE Tablets in the unit dose boxes should be protected from excessive moisture.

©1987, Glaxo Inc. TRN263 April 1987

At initial angiography, 94 ± 30 minutes into therapy, the infarct vessel patency was 64% in group A versus 75% in group B ($p = 0.02$). However, bleeding was reduced in group B patients as evidenced by a decrease in requirement for ≥2 units of packed red blood cell transfusion (group A 36%, group B 27%, $p = 0.05$) and lower incidence of gastrointestinal bleeding (group A 12%, group B 4%, $p = 0.002$). To further study the importance of weight adjustment, patients were divided into 2 groups according to weight (≤90 kg vs >90 kg). According to the results, lighter weight patients had greater transfusion requirements (35% vs 20%, $p = 0.006$) and more frequent major bleeding episodes (16% vs 7%, $p = 0.025$). Thus, a higher, weight-adjusted first-hour dose of intravenous t-PA, with a shorter duration of maintenance infusion, is associated with: (1) improved infarct vessel patency; (2) more rapid recanalization; and (3) less bleeding complications without more fibrinogenolysis.

729 Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size. VI: Identification of Screening Criteria for Non-Acute Myocardial Infarcts

William D. Anderson, Nancy B, Wagner, Kerry L. Lee, Richard D. White, James Yuschak, Victor S. Behar, Ronald H. Selvester, Raymond E. Ideker, and Galen S. Wagner

Fifty-four criteria in a 32-point QRS scoring system for estimating myocardial infarct (MI) size from the standard 12-lead electrocardiogram were analyzed to identify those with high specificity and maximal sensitivity in detecting the presence of non-acute MI. Sensitivity was tested in a population consisting of 122 patients with single anterior or inferior MIs, while specificity was determined in a population of 500 normal subjects. Three MI screening criteria were selected using a stepwise logistic regression analysis: (1) aVF: Q wave ≥30 ms, (2) V_2: R ≤10 ms and ≤0.1 mV and (3) V_1: R ≥40 ms. The cumulative sensitivity was 80% while maintaining specificity at ≥95%.

734 Development and Validation of an Automated Method of the Selvester QRS Scoring System for Myocardial Infarct Size

James E. Pope, Nancy B. Wagner, David Dubow, John H. Edmonds, Galen S. Wagner, and W. Kenneth Haisty, Jr.

The Selvester QRS score for estimation of myocardial infarct size from the standard 12-lead electrocardiogram has not yet experienced general clinical acceptance primarily because it is limited by manual application of the 54 criteria. This study examined the electrocardiograms of 438 patients to develop software for an automated method of the Selvester system. After a comprehensive validation process involving extensive interactions between the manual scorer and the developer of the software, an automated method of Selvester scoring was generated that had a high correlation with manual application of the system ($r = 0.94$) and was superior regarding time, training, reproducibility of criteria selection and precision of waveform measurements.

739 Significance of Q-Wave Regression After Transmural Acute Myocardial Infarction

Santiago Coll, Amadeo Betriu, Tomás de Flores, Eulalia Roig, Ginés Sanz, Luis Mont, Jorge Magriñá, Antonio Serra, and Francisco Navarro-López

The prevalence and clinical implications of Q-wave loss after transmural acute myocardial infarction were assessed in a series of 313 consecutive patients. After a mean follow-up of 65 (1 to 100) months, 34 patients lost their Q waves. The time interval from the acute myocardial infarction to the first electrocardiogram showing Q-wave disappearance was 14 (1 to 32) months. The peak creatine kinase value was higher in patients who retained their Q waves than in those who lost them. The severity of coronary artery disease was similar in both groups, but patients with a normalized electrocardiogram had lower left ventricular end-diastolic pressure, higher ejection fraction and fewer abnormally contracting segments than their counterparts; in addition, no patient with Q-wave regression presented with left ventricular aneurysm. Although differences in mortality, nonfatal reinfarction and new onset of angina between the 2 groups were not significant, congestive heart failure was prevalent among patients with permanent Q waves. These findings suggest a smaller infarct size in patients showing Q-wave regression.

743 Limitations in the Interpretation of Rest-Exercise Ejection Fraction Changes After Early Thrombolytic Therapy During Acute Myocardial Infarction

Florence H. Sheehan, Detlef G. Mathey, Joachim Schofer, Suzanne Mitten, and Edward L. Bolson

The effect of exercise on left ventricular function was studied in 24 patients who underwent contrast ventriculography and supine bicycle exercise >2 weeks after acute myocardial infarction treated with intracoronary streptokinase. The ejection fraction response correlated poorly with the exercise response of motion in the infarct region ($r = 0.38$). In only half of patients whose infarct and noninfarct regions responded to exercise in opposing directions did the ejection fraction response reflect the response in the infarct region. The regional response to exercise better distinguished reperfused from nonreperfused patients than did the global response. Thus, the efficacy of thrombolytic therapy in salvaging myocardium is more accurately evaluated from the rest-exercise change in regional wall motion.

749 Use of Initial ST-Segment Deviation for Prediction of Final Electrocardiographic Size of Acute Myocardial Infarcts

Harry R. Aldrich, Nancy B. Wagner, Jane Boswick, Anne T. Corsa, Michael G. Jones, Peer Grande, Kerry L. Lee, and Galen S. Wagner

Because the decision to administer thrombolytic therapy for limitation of acute myocardial infarction (AMI) size must occur when only the history, physical examination and 12-lead electrocardiogram of a patient are

The benefit of antianginal protection plus safety...

CARDIZEM®: A FULLER LIFE

diltiazem HCl/Marion

60 mg 90/120 mg GREATER DOSAGE FLEXIBILITY

- ***A remarkable safety profile***[1-6]
  The low incidence of side effects with Cardizem allows patients to feel better.
- ***Protection against angina attacks***[1,5,7-9]
  The predictable efficacy of Cardizem in stable exertional and vasospastic angina allows patients to do more.*
- ***A decrease in myocardial oxygen demand***
  Resulting from a lowered heart rate-blood pressure product.[5]
- ***Compatible with other antianginals***[6]†
- ***Safe in angina with coexisting hypertension, COPD, asthma, or PVD***[1,3,5,6]

**CARDIZEM® (diltiazem HCl) is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.*

†See Warnings and Precautions.

Please see brief summary of prescribing information on the next page.

0778A8

CARDIZEM® ANTIANGINAL PROTECTION PLUS SAFETY

diltiazem HCl/Marion

Usual maintenance dosage range: 180-360 mg/day

BRIEF SUMMARY
Professional Use Information

CARDIZEM®
(diltiazem HCl)
30 mg, 60 mg, 90 mg, and 120 mg Tablets

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), and (4) patients who have demonstrated hypersensitivity to the drug.

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1,243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in most cases, but probable in some. (See PRECAUTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.)

Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities.

Administration of CARDIZEM (diltiazem hydrochloride) concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the-curve (53%) after a one-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.

Digitalis: Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/ postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences as well as their frequency of presentation are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%). In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	Angina, arrhythmia, AV block (first degree), AV block (second or third degree—see conduction warning), bradycardia, congestive heart failure, flushing, hypotension, palpitations, syncope.
Nervous System:	Amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tinnitus, tremor.
Gastrointestinal:	Anorexia, constipation, diarrhea, dysgeusia, dyspepsia, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH (see hepatic warnings), vomiting, weight increase.
Dermatologic:	Petechiae, pruritus, photosensitivity, urticaria.
Other:	Amblyopia, CPK elevation, dyspnea, epistaxis, eye irritation, hyperglycemia, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, gingival hyperplasia, erythema multiforme, and leukopenia. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established. Issued 6/87

See complete Professional Use Information before prescribing.

available, a method that could quickly assess the amount of jeopardized myocardium would be of great clinical value. This retrospective study compared the epicardial injury (STΔ) on the admission electrocardiogram to the final AMI size estimated by the Selvester QRS score on the predischarge electrocardiogram to generate formulas able to predict the ultimate extent of AMI from the admission STΔ in 148 patients receiving no interventions aimed at reperfusion:

$$\text{Anterior AMI} = 3[1.5(\text{number leads } ST\uparrow) - 0.4];$$

$$\text{Inferior} = 3[0.6(AT\uparrow \text{ II, III, aVF}) + 2.0].$$

These formulas based on the extent of initial STΔ are predictive of the final AMI size and may be useful in determining the efficacy of acute reperfusion therapy.

754 Usefulness of Lactate Dehydrogenase and Lactate Dehydrogenase Isoenzymes for Diagnosis of Acute Myocardial Infarction

Gregg J. Reis, Harvey W. Kaufman, Gary L. Horowitz, and Richard C. Pasternak

The marginal benefit of lactate dehydrogenase (LD) and LD isoenzymes was reviewed in a retrospective analysis of 247 patients with cardiac enzymes ordered over a 1-month period. Of these, only 2 (0.8%) had acute myocardial infarction (AMI) with *normal* creatine kinase and creatine kinase MB but *abnormal* LD isoenzymes. Seven patients had false-positive LD isoenzymes. Thus, the routine use of LD and LD isoenzymes was of no use in the vast majority (96%) of patients and led to an incorrect diagnosis of AMI more often than it helped with the correct diagnosis. Total 1-month charges for LD and LD isoenzymes were $42,450. Therefore, it appears that LD and LD isoenzymes are not routinely useful in the diagnosis of AMI and it is suggested that they be ordered only under suspicion of late presentation (>48 hours) of AMI.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

759 Direct and Autonomically Mediated Effects of Oral Flecainide

Paolo Alboni, Nelly Paparella, Riccardo Cappato, and Gian Carlo Candini

The electrophysiologic modes of action of oral flecainide were assessed in 15 patients with normal sinus node and atrioventricular node. Two electrophysiologic studies were performed in each patient. In the first, the variables of the 2 nodes were evaluated both in the basal state and after autonomic blockade (propranolol 0.2 mg/kg and atropine 0.04 mg/kg). Oral flecainide was administered for 4 to 5 days (200 to 250 mg daily) and the study was then repeated with the same methods. In the basal state, flecainide did not change significantly the sinus node measures (overall effect); in contrast, after autonomic blockade, these measures were increased ($p < 0.01$) by the drug (direct depressant effect). Flecainide increased significantly the atrioventricular node measures both in the basal state and after autonomic blockade ($p < 0.01$), but the degree of increase was more marked after autonomic blockade ($p < 0.05$). These data provide evidence of dual effects of oral flecainide: a direct depressant action and an autonomically mediated opposing action, likely of a vagolytic type.

CARDIOSELECTIVE*
HYDROPHILIC

ONE TABLET A DAY

TENORMIN®
(atenolol)

SIMPLE TO START WITH.
BETTER TO STAY WITH.

A $beta_1$-selective (cardioselective) blocking agent.

DESCRIPTION: TENORMIN (atenolol), a synthetic, $beta_1$-selective (cardioselective) adrenoreceptor blocking agent, may be chemically described as benzeneacetamide, 4-[2′-hydroxy-3′-[(1 methylethyl) amino] propoxy]-. Atenolol (free base) has a molecular weight of 266. It is a relatively polar hydrophilic compound with a water solubility of 26.5 mg/mL at 37°C and a log partition coefficient (octanol/water) of 0.23. It is freely soluble in 1N HCl (300 mg/mL at 25°C) and less soluble in chloroform (3 mg/mL at 25°C).

TENORMIN is available as 50 mg and 100 mg tablets for oral administration.

Inactive Ingredients: magnesium stearate, microcrystalline cellulose, povidone, sodium starch glycolate.

INDICATIONS AND USAGE: Hypertension: TENORMIN is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

Angina Pectoris Due to Coronary Atherosclerosis: TENORMIN is indicated for the long-term management of patients with angina pectoris.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure. (See WARNINGS.)

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues despite adequate digitalization and diuresis, TENORMIN should be withdrawn. (See Dosage and Administration.)

Cessation of Therapy With TENORMIN: Patients with coronary artery disease, who are being treated with TENORMIN, should be advised against abrupt discontinuation of therapy. Severe exacerbation of angina and the occurrence of myocardial infarction and ventricular arrhythmias have been reported in angina patients following the abrupt discontinuation of therapy with other beta blockers. The last two complications may occur with or without preceding exacerbation of the angina pectoris. To date, there has been no report of myocardial infarction or severe angina upon withdrawal of TENORMIN, probably due to its long plasma half-life. Because of the problems encountered with other beta blockers, when discontinuation of TENORMIN is planned, the patients should be carefully observed and advised to limit physical activity to a minimum. If the angina worsens or acute coronary insufficiency develops, it is recommended that TENORMIN be promptly reinstituted, at least temporarily. (See Dosage and Administration.)

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative $beta_1$ selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since $beta_1$ selectivity is not absolute, the lowest possible dose of TENORMIN should be used with therapy initiated at 50 mg, and a $beta_2$-stimulating agent (bronchodilator) should be made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see section on Overdosage). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg IV).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely. (See Dosage and Administration.)

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function. (See Dosage and Administration.)

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose), and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg/day or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg/day or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Atenolol is excreted in human breast milk at a ratio of 1.5 to 6.8 when compared to the concentration in plasma. Caution should be exercised when TENORMIN is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (US studies) or elicited, eg, by checklist (foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN (atenolol) and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the US studies (volunteered side effects) and then from both US and foreign studies (volunteered and elicited side effects):

US STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), lightheadedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS US AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), lightheadedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN.

HEMATOLOGIC: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

ALLERGIC: Fever, combined with aching and sore throat, laryngospasm, and respiratory distress.

CENTRAL NERVOUS SYSTEM: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

GASTROINTESTINAL: Mesenteric arterial thrombosis, ischemic colitis.

OTHER: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

MISCELLANEOUS: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

BRADYCARDIA: Atropine or another anticholinergic drug.

HEART BLOCK (SECOND OR THIRD DEGREE): Isoproterenol or transvenous cardiac pacemaker.

CONGESTIVE HEART FAILURE: Conventional therapy.

HYPOTENSION (DEPENDING ON ASSOCIATED FACTORS): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

BRONCHOSPASM: Aminophylline, isoproterenol, or atropine.

HYPOGLYCEMIA: Intravenous glucose.

DOSAGE AND ADMINISTRATION: Hypertension: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within 1 to 2 weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Angina Pectoris: The initial dose of TENORMIN is 50 mg given as one tablet a day. If an optimal response is not achieved within 1 week, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Some patients may require a dosage of 200 mg once a day for optimal effect.

Twenty-four hour control with once-daily dosing is achieved by giving doses larger than necessary to achieve an immediate maximum effect. The maximum early effect on exercise tolerance occurs with doses of 50 to 100 mg, but at these doses the effect at 24 hours is attenuated, averaging about 50% to 75% of that observed with once-a-day oral doses of 200 mg.

Patients with Renal Impairment: Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 mL/min/1.73 m^2 (normal range is 100-150 mL/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (mL/min/1.73 m^2)	Atenolol Elimination Half-life (h)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

Cessation of Therapy: If withdrawal of TENORMIN therapy is planned, it should be achieved gradually over a period of about 2 weeks. Patients should be carefully observed and advised to limit physical activity to a minimum.

HOW SUPPLIED: Tablets of 50 mg atenolol, NDC 0310-0105 (round, flat, uncoated white tablets identified with ICI debossed on one side and 105 debossed on the other side, bisected) are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Tablets of 100 mg atenolol, NDC 0310-0101 (round, flat, uncoated white tablets identified with ICI debossed on one side and 101 debossed on the other side) are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture.

A/11/86

*Cardioselectivity denotes a relative preference for β_1-receptors, located chiefly in cardiac tissue. This preference is not absolute.

For comprehensive stress testing, Make the Obvious Choice

The New Quinton Q4000 Stress Test System

Quinton introduces the best reason to stress test in your institution or office: the new Q4000 Stress Test System.

Choose the Q4000 because it provides additional services for your patients, is easy to operate, and offers many advanced features. All at a surprisingly low cost.

When you choose the Q4000, you can:

- Use one of four resident protocols (Bruce, Modified Bruce, Modified Balke, and Naughton) ***and***
- Customize eight more protocols
- Run a stress test with only six keystrokes
- Greatly reduce artifact with advanced signal averaging (ASVV) and 12-lead average reports
- Freeze half the screen and display live data on the other half
- Customize report headers with any information
- Save time with the Q4000's eleven reports (seven in-test and four final reports), including ST Level and ST Slope Trend Graphs for all 12 leads, ***simultaneous*** or ***sequential*** 12-lead reports, and 3- or 12-lead average reports
- Communicate with other equipment (RS-232 interface), allowing you to edit reports on a personal computer (program option) and store them on a floppy diskette
- Broaden your services by interfacing the Q4000 with Quinton's Q-Plex™ ***Pulmonary*** Exercise System
- Select one of Quinton's Q-Series Premium Treadmills, unsurpassed in reliability, quiet, and endurance
- Test the Q4000 and other equipment with the built-in ECG simulator and self-diagnostics

Choose the Q4000 for its expanded diagnostic capabilities. For its value. And for Quinton's worldwide service network that can meet your installation, training, and support needs. Call and ask how. . .

764 Noninvasive Evaluation of Indecainide for Serious Ventricular Tachyarrhythmia

Philip J. Podrid, Stephan Hohnloser, and Bernard Lown

Indecainide was administered to 16 patients with a history of a sustained ventricular tachyarrhythmia. Therapy involved acute loading dose followed by a brief maintenance period with efficacy evaluated noninvasively using monitoring and exercise testing. With the acute drug test, 9 of 16 patients responded. Of the 12 patients who received maintenance therapy, 4 responded to the drug. There was no correlation between dose, blood level and response to drug. Neurologic side effects occurred in 5 patients and 5 patients had arrhythmia aggravation. Left ventricular function was reduced by the drug in each patient. Indecainide is an effective drug in some highly selected patients.

770 Coupling Intervals of Ventricular Extrastimuli Causing Resetting of Sustained Ventricular Tachycardia Secondary to Coronary Artery Disease: Relation to Susbsequent Termination

Mark E. Rosenthal, Nicholas J. Stamato, Jesus M. Almendral, Charles D. Gottlieb, and Mark E. Josephson

Single and double ventricular extrastimuli (VE) were delivered during 80 and 42 sustained, uniform ventricular tachycardias (VT), respectively. Single VE reset 41 VT and terminated 8, while double VE reset 33 VT and terminated 13. Seven of 8 VT terminated with single VE and 12 of 13 VT terminated with double VE were initially reset with longer coupling intervals than those causing termination. Coupling intervals of VE were corrected for tachycardia cycle length. The mean corrected coupling interval of single and double VE initially resulting in VT resetting was significantly longer than those causing termination. If the longest corrected coupling interval at which resetting was noted with single VE was ≥ 0.75, then 7 of 34 (21%) VT terminated compared with only 1 of 46 (2%) if resetting was not seen by this corrected coupling interval ($p < 0.01$). Similarly, for double VE, if the longest coupling interval at which resetting was observed was ≥ 0.75, 13 of 31 (42%) VT terminated versus 0 of 10 if VT resetting was not observed by this coupling interval ($p < 0.02$). These findings demonstrate that critical coupling intervals may exist during the introduction of increasingly premature single and double VE where if resetting has not been observed, termination is unlikely.

775 Validation of Double-Spike Electrograms as Markers of Conduction Delay or Block in Atrial Flutter

Francisco G. Cosio, Fernando Arribas, José María Barbero, Carlos Kallmeyer, and Antonio Goicolea

Fragmented electrograms have been found by endocardial mapping of atrial flutter, often inscribing a double spike. It has been suggested that these electrograms may represent local conduction delays, probably supporting the reentrant circuit. Attempting to understand the meaning of these electrograms, we studied the changes induced by flutter entrainment from the coronary sinus or the anterior right atrium. Entrainment from the coronary sinus increased spike separation, suggesting rate-dependent conduction slowing during orthodromic penetration of the area. Entrainment from the anterior right atrium decreased spike separation,

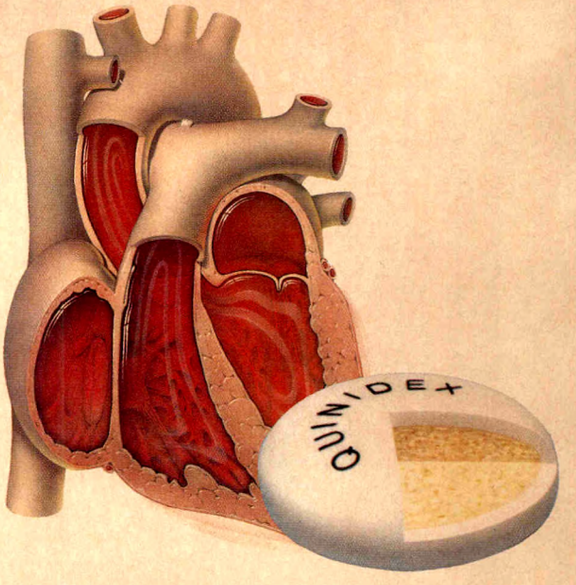
Dependable Delivery Systems Around The Clock!



B.I.D.

Twice-a-day dosing* to make life easier for your arrhythmia patients. That's the Quinidex® advantage. Because, like the heart, Quinidex Extentabs® have been uniquely constructed for dependable around-the-clock performance.

Some patients may require t.i.d. dosing.

QUINIDEX EXTENTABS®

(Quinidine Sulfate, USP) 300mg

A·H·ROBINS

Pharmaceutical Division, Richmond, Virginia 23261-6609

©A. H. Robins Company 1987

Please see adjacent page for brief summary.

QUINIDEX
EXTENTABS®
(Quinidine Sulfate, USP)

The following is a brief summary only. Before prescribing, see complete prescribing information in Quinidex product labeling.

Contraindications: Intraventricular conduction defects. Complete A-V block. A-V conduction disorders caused by digitalis intoxication. Aberrant impulses and abnormal rhythms due to escape mechanisms. Idiosyncrasy or hypersensitivity to quinidine or related cinchona derivatives. Myasthenia gravis.

Warnings: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio, resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

Reports in the literature indicate that serum concentrations of digoxin may increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored for digitalis toxicity. Reduction of digoxin dosage may have to be considered.

Manifestations of quinidine cardiotoxicity such as excessive prolongation of the QT interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function manifested by hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

Quinidine should be used with extreme caution in patients with incomplete AV block since complete AV block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in serum, leading to toxicity.

Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or serum levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

Cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4–8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

Precautions: *General*—All the precautions applying to regular quinidine therapy apply to this product. Hypersensitivity or anaphylactoid reactions to quinidine, although rare, should be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and determination of serum quinidine levels are indicated when large doses of quinidine are used or with patients who present an increased risk.

Information for Patients—As with all solid dosage medications, Quinidex Extentabs should be taken with an adequate amount of fluid, preferably with the patient in an upright position to facilitate swallowing. They should be swallowed whole in order to preserve the controlled-release mechanism.

Laboratory Tests—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy; the drug should be discontinued if blood dyscrasias or evidence of hepatic or renal dysfunction occurs.

Drug Interactions

Drug	Effect
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased serum concentration of digoxin (See Warnings)
Quinidine with amiodarone	Increased serum concentration of quinidine
Quinidine with cimetidine	Prolonged quinidine half-life and an increase in serum quinidine level
Quinidine with ranitidine	Premature ventricular contractions and/or bigeminy
Quinidine with verapamil	Increased quinidine half-life and an increase in serum quinidine level; potential hypotensive reactions
Quinidine with nifedipine	Decreased serum concentrations of quinidine

Carcinogenesis: Studies in animals have not been performed to evaluate the carcinogenic potential of quinidine.

Pregnancy, Teratogenic Effects: Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinidex Extentabs should be administered to a pregnant woman only if clearly indicated.

Nonteratogenic Effects: Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Labor and Delivery—There is no known use for Quinidex Extentabs in labor and delivery. However, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers—Because of passage of the drug into breast milk, caution should be exercised when Quinidex Extentabs are administered to a nursing woman.

Pediatric Use—There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinidex Extentabs in children.

Adverse Reactions: Symptoms of cinchonism, such as ringing in the ears, loss of hearing, dizziness, lightheadedness, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal.

Gastrointestinal—Nausea, vomiting, abdominal pain, diarrhea, anorexia, granulomatous hepatitis (which may be preceded by fever), esophagitis.

Cardiovascular—Ventricular extrasystoles occurring at a rate of one or more every 6 normal beats; widening of the QRS complex and prolonged QT interval; complete A-V block; ventricular tachycardia and fibrillation; ventricular flutter; torsade de pointes; arterial embolism; hypotension; syncope.

Central Nervous System—Headache, vertigo, apprehension, excitement, confusion, delirium, dementia, ataxia, depression.

Ophthalmologic and Otologic—Disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata), optic neuritis, reduced visual field.

Dermatologic—Cutaneous flushing with intense pruritus, photosensitivity, urticaria, rash, eczema, exfoliative eruptions, psoriasis, abnormalities of pigmentation.

Hypersensitivity—Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatotoxicity, granulomatous hepatitis (See Warnings), purpura, vasculitis.

Hematologic—Thrombocytopenia, thrombocytopenic purpura, agranulocytosis, acute hemolytic anemia, hypoprothrombinemia, leukocytosis, shift to left in WBC differential, neutropenia.

Immunologic—Systemic lupus erythematosus, lupus nephritis.

Miscellaneous—Fever, increase in serum skeletal muscle creatine phosphokinase, arthralgia, myalgia.

When the Goal Is to Reduce Elevated Blood Cholesterol...

LORELCO®
PROBUCOL 250 mg tablets

Prescribing Information appears on the last page.

Choose

LORELCO® PROBUCOL

250 mg tablets

as an adjunct to diet

Effectively Lowers Serum Cholesterol with a Unique Combination of Benefits

1 Efficacy

Lorelco works! You can prescribe it with confidence. Lorelco can virtually double the cholesterol-lowering efficacy of diet alone.[1] Total cholesterol-lowering efficacy *beyond diet* ranges from 10.7% to 27% in reported studies.[1-4]

2 Indications

Lorelco is specifically indicated for the reduction of elevated serum cholesterol in patients with primary hypercholesterolemia who have not responded adequately to diet.

Consider the Whole Picture.

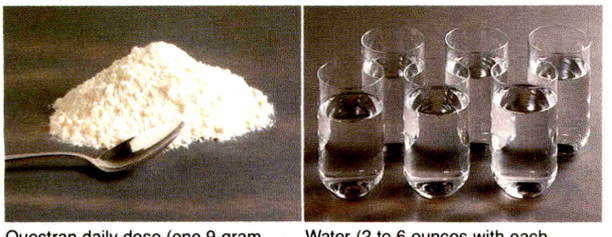
Merrell Dow

#1 selling lipid-lowering agent in the world

3 Compliance

The reasons for excellent compliance with Lorelco become clear with the taste and texture test.

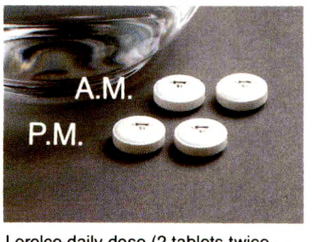
This



Questran daily dose (one 9-gram packet one to six times daily)

Water (2 to 6 ounces with each packet)

or This



Lorelco daily dose (2 tablets twice daily with meals)

Tablet counts in a 7 year study of Lorelco indicated that patients took over 90% of their scheduled dosage.[5]

4 Side Effects

Lorelco side effects are generally tolerable and of short duration.

Most frequent patient complaint is loose stools, which occur in about one in 10 patients and generally subside during therapy (see Prescribing Information for full discussion of side effects).

Lorelco is not an innocuous drug and strict attention should be paid to the Indications, Warnings, and Precautions.

5 Cost

The cost of Lorelco is significantly lower than that of the resins, lovastatin, and niacin tablets USV.

Cost can be a significant factor when therapy may have to be continued long-term, perhaps for years.

10 years of outstanding Lorelco performance[6]

Now prescribed in 27 countries

The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

Prescribing Information appears on the last page.

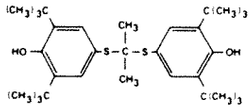
Lorelco® Tablets
(probucol tablets)

CAUTION: Federal law prohibits dispensing without prescription.

DESCRIPTION: Lorelco (probucol) film-coated tablets for oral administration contain 250 mg of probucol per tablet. Each tablet also contains as inactive ingredients: corn starch, ethylcellulose, glycerin, hydroxypropyl cellulose, hydroxypropyl methylcellulose 2910, iron oxide, lactose, magnesium stearate, microcrystalline cellulose, polysorbate 80, talc, and titanium dioxide. Lorelco is an agent for the reduction of elevated serum cholesterol. The chemical name is 4,4'-(isopropylidenedithio) bis (2,6-di-t-butylphenol). Its chemical structure does not resemble that of any other available cholesterol-lowering agent. It is lipophilic.



CLINICAL PHARMACOLOGY: Lorelco (probucol) lowers serum cholesterol and has relatively little effect on serum triglycerides. Patients responding to probucol exhibit a decrease in low density lipoprotein cholesterol. Cholesterol is reduced not only in the low density lipoprotein fraction, but also in some high density lipoprotein fractions with proportionately greater effect on the high density portion in some patients. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. The risk of lowering HDL-cholesterol while lowering LDL-cholesterol remains unknown. There is little or no effect reported on very low density lipoprotein.

Studies on the mode of action of Lorelco indicate that it increases the fractional rate of catabolism of low density lipoproteins. This effect may be linked to the observed increased excretion of fecal bile acids, a final metabolic pathway for the elimination of cholesterol from the body. Lorelco also exhibits inhibition of early stages of cholesterol synthesis and slight inhibition of absorption of dietary cholesterol. There is no increase in the cyclic precursors of cholesterol, namely desmosterol and 7-dehydrocholesterol. On this basis, it is concluded that Lorelco does not affect the later stages of cholesterol biosynthesis.

Absorption of Lorelco from the gastrointestinal tract is limited and variable. When it is administered with food, peak blood levels are higher and less variable. With continuous administration in a dosage of 500 mg b.i.d., the blood levels of an individual gradually increase over the first three to four months and thereafter remain fairly constant. In 116 patients treated with Lorelco for periods of three months to one year, the mean blood level was 23.6 ± 17.2 mcg/ml (± S.D.) ranging to 78.3 mcg/ml. Levels observed after seven years of treatment in 40 patients yielded an average value of 21.5 ± 16.5 mcg/ml (± S.D.) ranging to 62.0 mcg/ml.

At the end of 12 months of treatment in eight patients, blood levels averaged 19.0 mcg/ml. Six weeks after cessation of therapy, the average had fallen by 60 percent. After six months the average had fallen by 80 percent.

In December 1984 a National Institutes of Health Consensus Development Conference Panel1 concluded that lowering definitely elevated blood cholesterol levels (specifically blood levels of low-density lipoprotein cholesterol) will reduce the risk of heart attacks due to coronary heart disease. The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

INDICATIONS AND USAGE: Serious animal toxicity has been encountered with probucol. See WARNINGS and ANIMAL PHARMACOLOGY AND TOXICOLOGY sections. Probucol is not an innocuous drug and strict attention should be paid to the INDICATIONS and WARNINGS.

Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight may be an important factor and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory disease such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with non-drug methods. If the decision ultimately is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

The selection of patients for cholesterol-lowering drug therapy should take into account other important coronary risk factors such as smoking, hypertension and diabetes mellitus. Consideration should be given to the efficacy, safety and compliance factors for each of the cholesterol-lowering drugs prior to selecting the one most appropriate for an individual patient.

Lorelco may be indicated for the reduction of elevated serum cholesterol in patients with primary hypercholesterolemia (elevated low density lipoproteins) who have not responded adequately to diet, weight reduction and control of diabetes mellitus. Lorelco may be useful to lower elevated cholesterol that occurs in patients with combined hypercholesterolemia and hypertriglyceridemia, but it is not indicated where hypertriglyceridemia is the abnormality of most concern.

It is not always possible to predict from the lipoprotein type or other factors which patients will exhibit favorable results. Lipid levels should be periodically assessed. Small or transient changes in high density lipoprotein cholesterol may be due to inaccuracies in the method of determination. Substantial changes are sometimes seen with diet.

The effect of probucol-induced reduction of serum cholesterol or triglyceride levels or alteration of HDL-cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS: (See also PRECAUTIONS.) Lorelco is contraindicated in patients who are known to have a hypersensitivity to it.

WARNINGS: SERIOUS ANIMAL TOXICITY HAS BEEN ENCOUNTERED WITH PROBUCOL IN RHESUS MONKEYS FED AN ATHEROGENIC DIET AND IN BEAGLE DOGS. (SEE ANIMAL PHARMACOLOGY AND TOXICOLOGY SECTION.)

Although Q-T prolongation can occur in patients on probucol, the arrhythmias observed in monkeys fed large doses of probucol added to an atherogenic diet have not been reported in man; nevertheless, the following precautions are deemed prudent:

1. At the start of treatment with Lorelco and throughout the treatment period, patients should be advised to adhere to a low cholesterol, low fat diet.
2. As part of an overall evaluation, a baseline, six month, and one year repeat ECG tracing should be considered. If marked prolongation of the Q-T interval (after correction for rate) occurs, the possible benefits and risks should be carefully considered before making the decision to continue the probucol administration.

Lorelco should not be used in patients with evidence of recent or progressive myocardial damage or findings suggestive of ventricular arrhythmias.

No instances of increase in ectopy attributed to Lorelco have been reported. However, patients with unexplained syncope while on Lorelco should have ECG surveillance.

PRECAUTIONS

General: Because Lorelco is intended for long-term administration, adequate baseline studies should be performed to determine that the patient has elevated serum cholesterol levels. Serum lipid levels should be determined before treatment and repeated during the first few months of treatment and periodically thereafter. A favorable trend in cholesterol reduction should be evident during the first three to four months of administration of Lorelco. Probucol lowers serum total and LDL cholesterol, and also lowers HDL-cholesterol in many patients with elevated LDL-cholesterol. Epidemiologic studies within hypercholesterolemic populations have shown that serum HDL-cholesterol is an independent, inversely correlated, risk factor for coronary heart disease (see CLINICAL PHARMACOLOGY). Animal or human studies which could confirm or deny the hypothesis that drug induced alteration in HDL-cholesterol affects cardiovascular risk have not been carried out. It is not known whether probucol-induced reduction of serum HDL-cholesterol will affect cardiovascular risk since no long-term, controlled clinical trials of probucol for the prevention of coronary heart disease, similar to the LRC-CPPT (See CLINICAL STUDIES), have been performed. The probable benefits obtained from LDL-cholesterol reduction must be weighed against the possible risk of a reduction in HDL-cholesterol when assessing the response of each patient receiving Lorelco treatment. If satisfactory lipid alteration is not achieved, the drug should be discontinued.

Information for Patients: The patient should be instructed to adhere to a prudent diet. Females should be cautioned against becoming pregnant for at least six months after discontinuing Lorelco and should not breast feed their infants during therapy with Lorelco.

Laboratory Tests: The physician should schedule periodic blood lipid determinations and should consider periodic electrocardiograms. (See WARNINGS.)

Elevations of the serum transaminases (glutamic-oxalacetic and glutamic-pyruvic), bilirubin, alkaline phosphatase, creatine phosphokinase, uric acid, blood urea nitrogen and blood glucose above the normal range were observed on one or more occasions in various patients treated with Lorelco. Most often these were transient and/or could have been related to the patient's clinical state or other modes of therapy. Although the basis for the relationship between probucol and these abnormalities is not firm, the possibility that some of these are drug-related cannot be excluded. In the controlled trials, the incidence of abnormal laboratory values was no higher in the patients treated with probucol than in the patients who received placebo. If abnormal laboratory tests persist or worsen, if clinical signs consistent with the abnormal laboratory tests develop, or if systemic manifestations occur, probucol should be discontinued.

Drug Interactions: The addition of clofibrate to probucol is not recommended since the lowering effect on mean serum levels of either LDL or total cholesterol is generally not significantly additive and, in some patients, there may be a pronounced lowering of HDL-cholesterol. Neither oral hypoglycemic agents nor oral anticoagulants alter the effect of Lorelco on serum cholesterol. The dosage of these agents is not usually modified when given with Lorelco. Monkeys fed a high fat, high cholesterol diet admixed with probucol exhibited serious toxicity. The toxicity observed in monkeys has not been reported in man. (See WARNINGS and ANIMAL PHARMACOLOGY AND TOXICOLOGY sections.)

Carcinogenesis, Mutagenesis, Impairment of Fertility
In chronic studies of two years duration in rats, no toxicity or carcinogenicity was observed. These results are consistent with the lack of any adverse effect on fertility and the negative findings in tests for mutagenic activity in rats.

Pregnancy
Teratogenic Effects
Pregnancy—Category B: Reproduction studies have been performed in rats and rabbits at doses up to 50 times the human dose, and have revealed no evidence of impaired fertility or harm to the fetus due to probucol. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. Furthermore, if a patient wishes to become pregnant, it is recommended that the drug be withdrawn and birth control procedures be used for at least six months because of persistence of the drug in the body for prolonged periods. (See CLINICAL PHARMACOLOGY.)

Labor and Delivery: The effect of Lorelco on human labor and delivery is unknown.

Nursing Mothers: It is not known whether this drug is secreted in human milk, but it is likely to be since such excretion has been shown in animals. It is recommended that nursing not be undertaken while a patient is on Lorelco.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Gastrointestinal
diarrhea or loose stools, flatulence, abdominal pain, nausea, vomiting, indigestion, gastrointestinal bleeding

Cardiovascular
prolongation of the Q-T interval on ECG

Neurologic
headache, dizziness, paresthesias, insomnia, tinnitus, peripheral neuritis

Hematologic
eosinophilia, low hemoglobin and/or hematocrit, thrombocytopenia

Dermatologic
rash, pruritus, ecchymosis, petechiae, hyperhidrosis, fetid sweat

Genitourinary
impotency, nocturia

Ophthalmic
conjunctivitis, tearing, blurred vision

Endocrine
enlargement of multinodular goiter

Idiosyncrasies
An idiosyncratic reaction observed with initiation of therapy and characterized by dizziness, palpitations, syncope, nausea, vomiting and chest pain has been observed.

Other
diminished sense of taste and smell, anorexia, angioneurotic edema

DRUG ABUSE AND DEPENDENCE: No evidence of abuse potential has been associated with Lorelco, nor is there evidence of psychological or physical dependence in humans.

OVERDOSAGE: There is a single report of a 15 kg, three-year-old male child who ingested 5 gm of probucol. Emesis was induced by ipecac. The child remained well, apart from a brief episode of loose stools and flatulence. No specific information is available on the treatment of overdosage with Lorelco and no specific antidote is available. Probucol is not dialyzable. Treatment is symptomatic and supportive. Probucol has shown no identifiable acute toxicity in mice and rats. In these animals the LD_{50} (oral) is in excess of 5 gm/kg of body weight.

DOSAGE AND ADMINISTRATION: For adult use only. The recommended and maximal dose is 500 mg (two tablets of 250 mg each) twice daily with the morning and evening meals.

HOW SUPPLIED: Each white film-coated tablet contains 250 mg probucol and is imprinted with the DOW diamond trademark over the code number 51, or LORELCO 250.
Bottles of 120 tablets, a 30-day supply for one patient (NDC 0068-0051-52)

Keep well closed. Store in a dry place. Avoid excessive heat. Dispense in well closed light-resistant container with child-resistant closure.

ANIMAL PHARMACOLOGY AND TOXICOLOGY: In rhesus monkeys administration of probucol in diets containing unusually high amounts of cholesterol and saturated fat resulted in the death of four of eight animals after several weeks. Premonitory syncope was frequently observed and was associated with a pronounced prolongation of the Q-T intervals (30 to 50 percent longer than that observed in untreated monkeys). Serum levels of probucol greater than 20 mcg/ml were generally associated with some prolongation in the Q-T interval in the cholesterol-fed monkey. A 75 msec or greater increase in Q-T interval from control values was usually seen at 40 mcg/ml and above. Blood levels in humans receiving probucol average approximately 20 mcg/ml and not uncommonly reach levels of 40 mcg/ml and higher. Rhesus monkeys fed normal (low fat) chow and receiving probucol three to thirty times the human dose equivalent achieved blood levels only one-third those of many human subjects. No adverse effects were detected in these monkeys over an eight-year period of continuous drug administration. In another study in rhesus monkeys, an atherogenic diet was fed for two years and daily treatment with probucol, separated in time from the atherogenic meal, was carried out during the second year. Serum probucol levels ranged 20 to 50 mcg/ml in five of ten monkeys, and less in the remaining animals. Marked prolongation of the $Q\text{-}T_c$ interval in the electrocardiogram or syncopal behavior was never observed over the entire one-year treatment period. Regression of gross aortic lesions comparable to that observed in a parallel group of monkeys receiving cholestyramine was seen in animals receiving probucol. It should be emphasized that both HDL-cholesterol and LDL-cholesterol were markedly reduced in this regression study. During the performance of a two-year chronic study involving 32 probucol-treated dogs (beagles) there were 12 fatalities. Subsequent experiments have indicated that probucol sensitizes the canine myocardium to epinephrine, resulting in ventricular fibrillation in many dogs. Among the animal species in which probucol has been studied, the dog is peculiar with respect to the phenomenon of sudden death due to the sensitization of the myocardium to epinephrine. In contrast to findings in the dog, injections of epinephrine to probucol-treated monkeys did not induce ventricular fibrillation.

In other studies, monkeys were given probucol either before and after, or only after myocardial infarction induced by coronary artery ligation. In these studies there was no difference between probucol- and placebo-treated groups with respect to either survival or detailed blind quantitation of myocardial changes (gross and histopathologic).

Probucol has shown no identifiable toxicity in mice and rats. In these animals the LD_{50} (oral) is in excess of five gm/kg of body weight. In chronic studies of two-year duration in rats, no toxicity or carcinogenicity was observed.

From studies in rats, dogs and monkeys, it is known that probucol accumulates slowly in adipose tissue. Approximately 90 percent of probucol administered orally is unabsorbed. For that which is absorbed, the biliary tract is the major pathway for clearance from the body and very little is excreted by way of the kidneys.

Myocardial injury was produced in various groups of rats by one of the following procedures: aortic coarctation, coronary ligation, or cobalt or isoproterenol injection. After probucol administration, no deleterious effects related to treatment occurred as measured by survival and microscopic examination of myocardial damage.

Probucol was administered to minipigs beginning ten days before ligation of coronary artery and continued for 60 days post surgery. Challenge with epinephrine at the end of 60 days failed to induce ventricular fibrillation in any of the coronary-ligated, probucol-treated minipigs.

CLINICAL STUDIES: In a multicenter, randomized, double-blind study, the LRC-CPPT2, hypercholesterolemic patients treated with an oral bile acid sequestrant (cholestyramine) and a cholesterol lowering diet experienced average total and low-density lipoprotein cholesterol reductions greater than those obtained in the placebo group treated with diet alone. The cumulative seven-year incidence of the primary end point—combined incidence of definite CHD death and/or definite nonfatal myocardial infarction—was 7% in the cholestyramine group and 8.6% in the placebo group. This was a 19% reduction in risk (P less than 0.05, single-tail test) of the primary end point reflecting a 24% reduction in definite CHD death and a 19% reduction in nonfatal myocardial infarction.

The subjects included in the study were middle-aged men (35-59 years old) with serum cholesterol levels at least 265 mg/dl and no previous history of heart disease. It is not clear to what extent these findings can be extrapolated to other segments of the hypercholesterolemic population not studied.

The bile acid sequestrant, cholestyramine was used in the above trial. Caution should be exercised in extrapolating these results to probucol since it differs from cholestyramine with regard to its mode of action, spectrum of cholesterol-lowering potency, effect on HDL-cholesterol and possible toxicity. The effect of probucol-induced reduction of serum cholesterol levels on morbidity or mortality due to coronary heart disease has not yet been established. Several years may be required before ongoing long-term investigations will resolve this question.

suggesting fusion by antidromic penetration in the area. The findings are compatible with double spikes being a marker of local conduction delays included in the flutter circuit.

781 Characteristics of Entrainment During Autodecremental Atrial and Ventricular Stimulation

Agustin Castellanos, Liaqat Zaman, Pedro Fernandez, Bolivar Portillo, Barouh V. Berkovits, and Robert J. Myerburg

The entrainment of circus movement tachycardias during autodecremental pacing was analyzed in 9 patients with manifest Wolff-Parkinson-White syndrome. During autodecremental atrial stimulation, the phenomenon was observed in 34 of 38 episodes. Because this always occurred during Wenckebach sequences, the His bundle and ventricular cycle lengths were longer than the pacing cycle lengths. Thus, the definition of "classic" entrainment was not fulfilled. On the other hand, during autodecremental ventricular stimulation the phenomenon was seen in 79 of 80 episodes, invariably with the characteristics of the so-called "concealed" entrainment. In addition, because 115 of 118 (98%) of episodes were terminated, autodecremental pacing proved to be very effective in the treatment of circus movement tachycardia.

787 Sensitivity for Ventricular Tachyarrhythmias of an Automatic External Defibrillator in Patients Undergoing Electrophysiologic Studies

Mark D. Carlson, Charles S. Freeman, Hasan Garan, and Jeremy N. Ruskin

An automatic advisory external defibrillator (AED) was activated during all arrhythmias occurring at the time of 77 electrophysiologic studies in 45 patients. The device recommended "shock" during 36 of 55 (65%) episodes of sustained ventricular tachycardia (VT) and all 5 episodes of ventricular fibrillation. Of 10 episodes of nonsustained VT, 6 terminated after analysis was complete. The AED correctly advised "shock" for all 6 episodes. Thus, the sensitivity of the device for all ventricular arrhythmias was 47 of 66 (71%). The AED recommended "shock" for all 31 episodes of rapid VT and 1 of 2 episodes of atrial fibrillation associated with hypotension (32 of 33, 97%). The 19 episodes of VT for which "no shock" was advised were comparatively slow and hemodynamically well tolerated. The device recommended "no shock" during all 21 episodes of normal sinus rhythm and all 20 episodes of rapid atrial pacing analyzed. Thus, the specificity of the AED for wide complex tachyarrhythmias was 100%.

791 Determinants of Survival in Patients with Malignant Ventricular Arrhythmia Associated with Coronary Artery Disease

Steven Lampert, Bernard Lown, Thomas B. Graboys, Philip J. Podrid, and Charles M. Blatt

Patients with coronary artery disease and a history of malignant ventricular arrhythmia (defined as noninfarction ventricular fibrillation or hemodynamically compromising ventricular tachycardia) were followed for up to 9 years and the survival data were analyzed. In this group of 161 patients there were 57 deaths of which 35 (63%) were sudden. Life-table analysis demonstrated a 10% sudden death rate for all patients in the first year and a 7% annual rate in the subsequent 4 years. The likelihood of dying suddenly was related to the state of left ventricular function and the

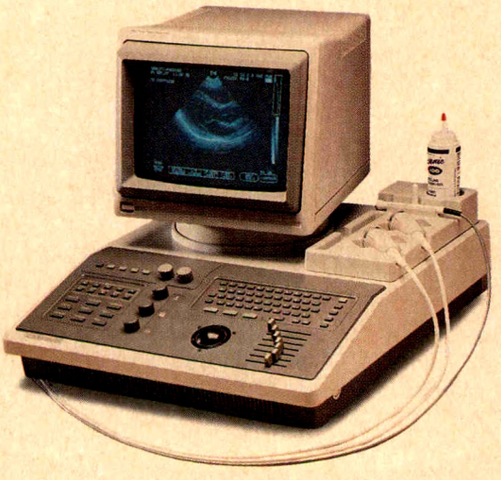
If you thought you couldn't afford HP ultrasound, we have two surprises for you.



MG03801

Introducing the new HP SONOS 100 Imaging System. Designed to fit your office. And your budget.

It's a smaller unit. With a lower price. But the quality is pure HP. Performance. Reliability. Upgradeability.

Through advanced technology, we've been able to integrate the attributes that have made our phased array system the leader in cardiac imaging into the new HP SONOS 100.

Superior image quality. 2-D, M-Mode, PW and CW Doppler capabilities. Excellent resolution over a wide range of cardiac imaging applications in patients ranging from neonates to adults. Plus added features that make the HP SONOS 100 ideal for the office. A large 12″ monitor for easy viewing. A compact, ergonomic design that puts simple, easy-to-use controls at your fingertips.

Portability. Flexibility. We considered these, too. That's why the HP SONOS 100 has been designed to be used on tabletop or cart.

Advanced technology is just the beginning.

Add HP training, service and our nationwide support network, and the picture is clear. The HP SONOS 100 just may be the best surprise you've seen all year.

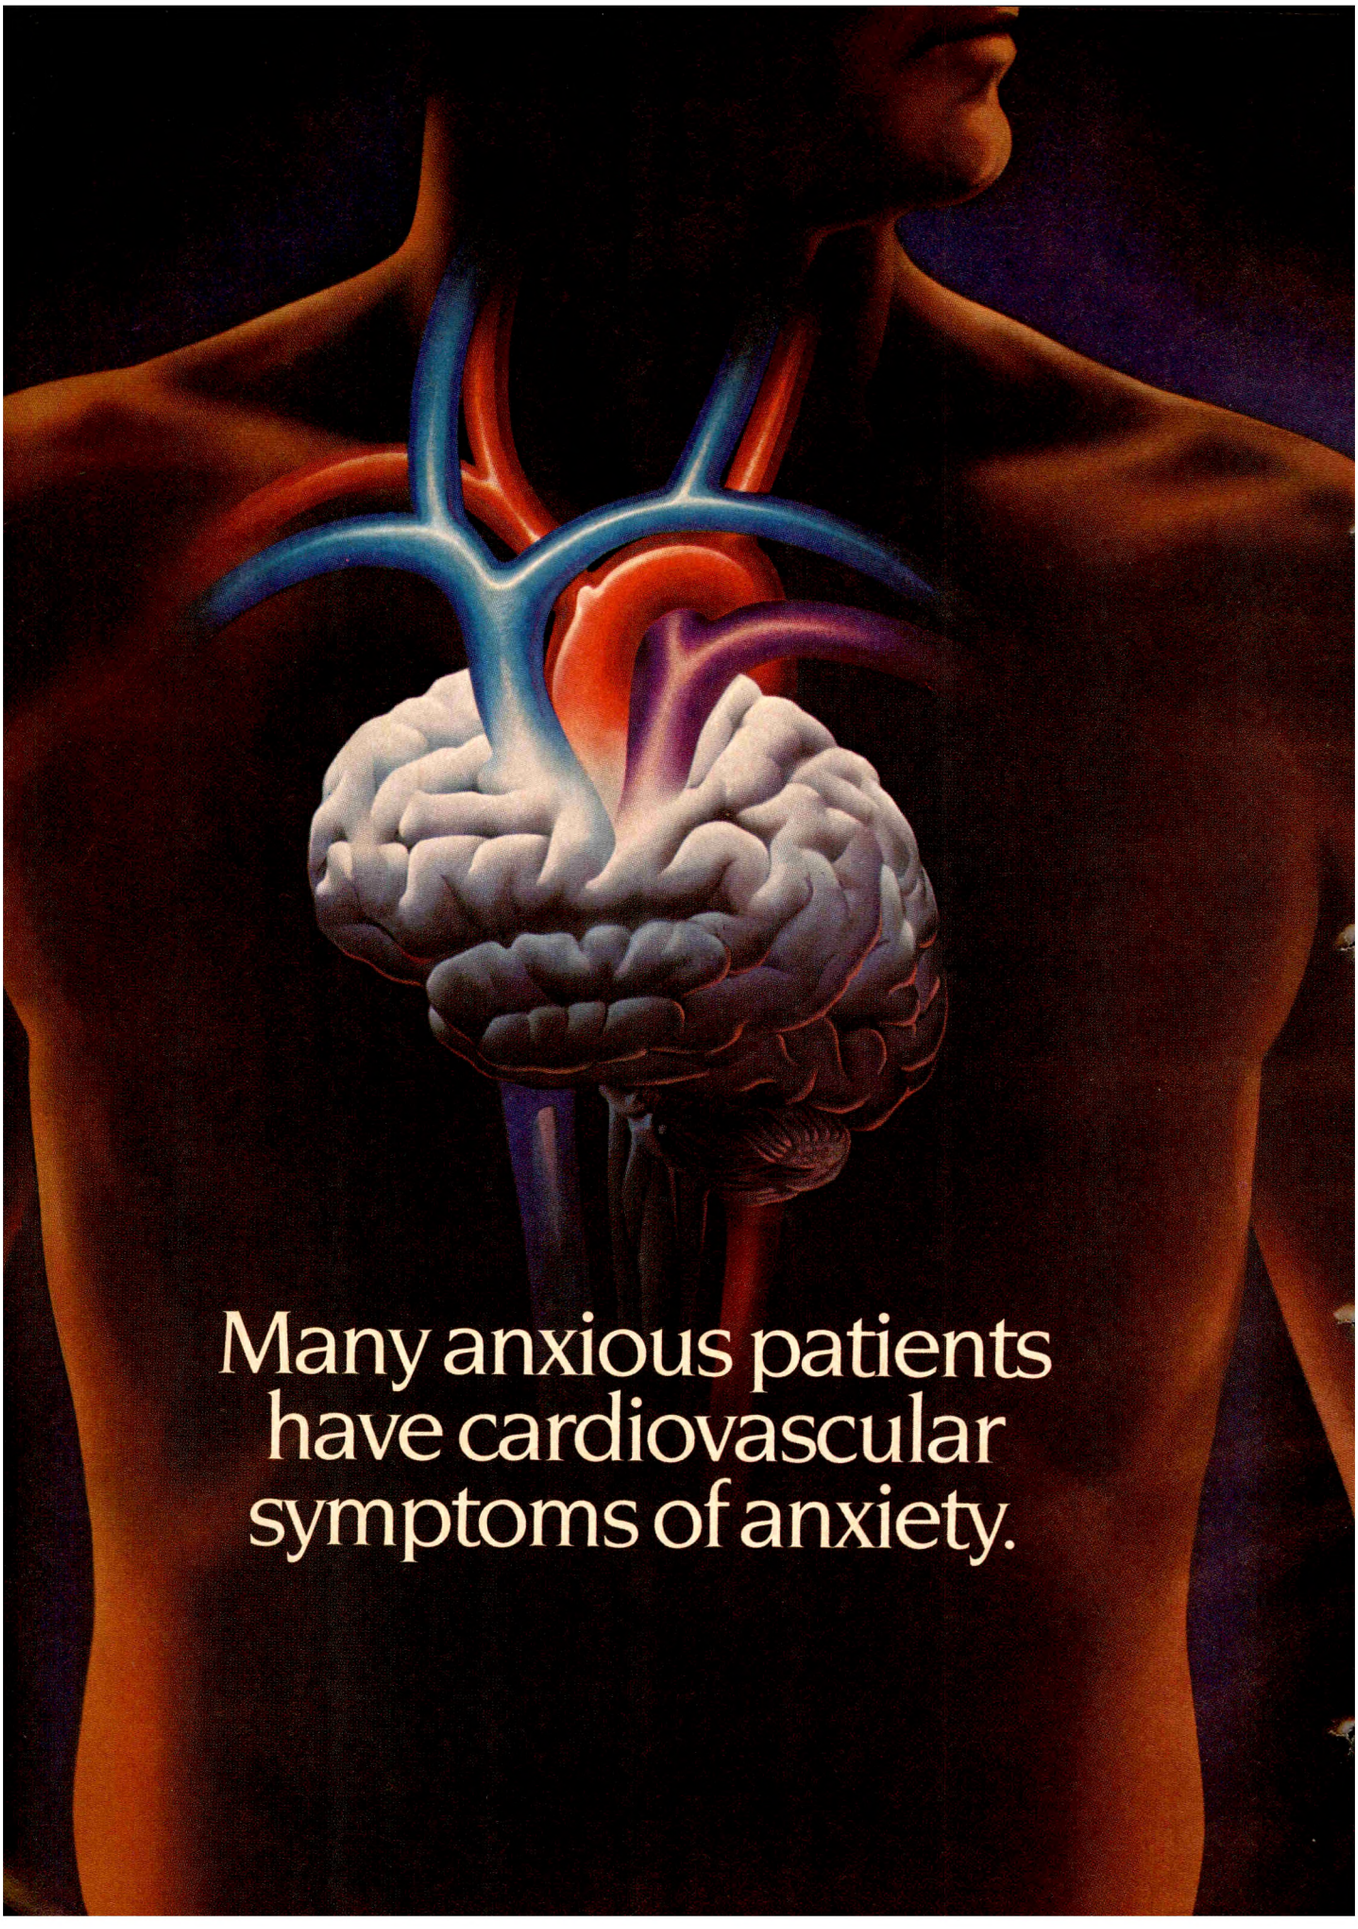
HEWLETT PACKARD

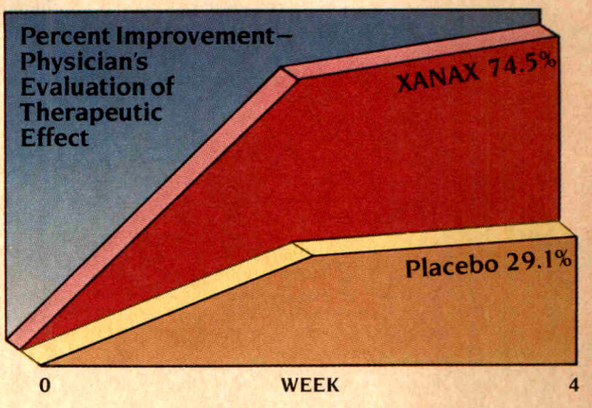


Many anxious patients
have cardiovascular
symptoms of anxiety.

Xanax effectively relieves anxiety...

In double-blind, four-week clinical trials in 976 patients with moderate to severe anxiety, therapy with XANAX was compared with placebo.[1]

XANAX was significantly more effective ($P<0.001$) than placebo in relieving the anxiety, with over half of the patients showing marked to moderate improvement by the first evaluation period (one week).



...including anxiety with associated cardiovascular symptoms...

Most patients in the study had cardiovascular symptoms even though cardiovascular disease was ruled out. XANAX was shown to effectively relieve anxiety with associated cardiovascular symptoms.

...and anxiety with associated depressive symptoms.

Over 70% of these patients experienced moderate to severe depressed mood. XANAX was shown to be significantly more effective ($P<0.014$) than placebo in improving depressed mood.

Xanax® 0.5 mg Tablets

alprazolam C-IV

Upjohn

©1988 The Upjohn Company
Kalamazoo, Michigan 49001, USA

Please see adjacent page for brief summary of prescribing information.

XANAX® Tablets
(alprazolam) ℞

INDICATIONS AND USAGE
Anxiety disorders, short-term relief of the symptoms of anxiety, and anxiety associated with depression. Anxiety or tension associated with the stress of everyday life usually does not require an anxiolytic. Effectiveness for more than four months has not been established; periodically reassess the usefulness of the drug for the individual patient.

CONTRAINDICATIONS
Sensitivity to XANAX or other benzodiazepines, and in acute narrow angle glaucoma.

WARNINGS
Benzodiazepines can cause fetal harm in pregnant women, hence women who may become pregnant should be warned. Avoid during the first trimester. Withdrawal seizures have been reported upon rapid dose reduction or abrupt discontinuation, thus reduce dose gradually. (See Drug Abuse and Dependence and Dosage and Administration.)

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsants, consider drug potentiation. (See Drug Interactions). Use the usual precautions in patients with renal or hepatic impairment and regarding prescription size in depressed and suicidal patients. In elderly and debilitated patients, use the lowest possible dose. (See Dosage and Administration.) Hypomania and mania has been reported in depressed patients.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Plasma levels of imipramine and desipramine are increased. Pharmacokinetic interactions with other drugs have been reported. Cimetidine can delay clearance of benzodiazepines. *Drug/Laboratory Test Interactions:* No consistent pattern for a drug or test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms, neonatal flaccidity and respiratory problems. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacologic activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness. *Gastrointestinal:* Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation. *Cardiovascular:* Tachycardia/palpitations, and hypotension. *Sensory:* Blurred vision. *Musculoskeletal:* Rigidity and tremor. *Cutaneous:* Dermatitis/allergy. *Other side effects:* Nasal congestion, weight gain, and weight loss.

Withdrawal seizures with rapid decrease or abrupt discontinuation. (See Warnings.)

The following adverse events have been reported with benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, transient amnesia or memory impairment, loss of coordination, fatigue, seizures, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence, and urinary retention.

Paradoxical reactions such as stimulation, agitation, rage, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

Liver enzyme elevations, gynecomastia and galactorrhea have been reported but no causal relationship was established.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms including seizures have occurred following abrupt discontinuance or rapid dose reduction of benzodiazepines. (See Warnings). Dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

OVERDOSAGE
Manifestations include somnolence, confusion, impaired coordination, diminished reflexes and coma. No delayed reactions have been reported.

DOSAGE AND ADMINISTRATION
Dosage should be individualized.

The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than 0.5 mg every three days.

HOW SUPPLIED
XANAX Tablets are available as 0.25 mg, 0.5 mg, and 1 mg tablets.

CAUTION:
FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. B-7-S

SPECIAL DISCOUNT OFFER
PLACE A STANDING ORDER TO RECEIVE EACH EDITION OF CARDIOLOGY ON 30 DAY APPROVAL, AND RECEIVE A 10% DISCOUNT ON THIS EDITION AND ON ALL FUTURE EDITIONS.

☐ **YES,** please enter my standing order for Cardiology. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval and I will receive a 10% discount on this edition and on all future editions. (1987 edition discount price $49.50)(00053)

☐ Please send me a copy of Cardiology 1987 at the full price of $55.00. I do not wish to place a standing order. (00053)

Please send me the following book(s): ☐ Cardiology 1984 (00039) $49.50 ☐ Cardiology 1982 (00025) $47.50 ☐ Cardiology 1985 (00043) $55.00 ☐ Cardiology 1983 (00032) $49.50 ☐ Cardiology 1986 (00048) $55.00

☐ Enclosed is my check for _____ which includes $1.50 for handling. Yorke pays postage. (same return privilege)
☐ Please bill by ☐ VISA ☐ MasterCard (same return privilege)

Card Number _____ Exp. Date _____
Interbank no. (M/C) _____
Signature _____

☐ Please bill me plus postage and handling. (U.S. and Canadian orders only)

Name _____
Address _____
City/State/Zip _____

Customers in the following states please include applicable sales tax: CA, CT, GA, IL, MA, MI, NY, OH, PA, TX. All foreign orders must be prepaid in U.S. funds with a check drawn on a U.S. bank or charged to a credit card. Please add $5.00 per book for all orders to be shipped outside the U.S. and Canada.

AJCD8

presence of ventricular tachycardia during exercise tolerance testing on the discharge antiarrhythmic drug program. When the left ventricular ejection fraction was >30%, controlling ventricular arrhythmia improved survival, but when the ejection fraction was <30%, arrhythmia control did not affect survival. Multivariate regression analysis identified rales and exercise-induced ventricular tachycardia during antiarrhythmic drug therapy as the strongest predictors of sudden death.

SYSTEMIC HYPERTENSION

798 Effect of Behavior State on Caffeine's Ability to Alter Blood Pressure

Gwendolyn A. Pincomb, William R. Lovallo, Richard B. Passey, and Michael F. Wilson

Caffeine is known to produce acute blood pressure elevations in man. Hemodynamic mechanisms underlying its pressor effects and their possible health consequences have been disputed for years. Most previous studies involving measurements of cardiac output and vascular resistance have not used a placebo condition or controlled for behavioral interactions. In the current study caffeine's pressor effect was produced by either of 2 opposite mechanisms: enhanced vascular resistance at rest and potentiated cardiac stimulation during behavioral challenge. Implications for hemodynamic models, health consequences and for methodologic improvements in behavioral or clinical studies are discussed.

803 Lisinopril Versus Lisinopril plus Hydrochlorothiazide in Essential Hypertension

Jawahar Mehta, Larry M. Lopez, and Alfred D. Thorman

A new converting enzyme inhibitor, lisinopril, was administered alone or in combination with hydrochlorothiazide to patients with essential hypertension as initial pharmacotherapy. Both regimens lowered blood pressure significantly without causing tachycardia. The antihypertensive dose of lisinopril was lower when combined with hydrochlorothiazide. Metabolic alterations caused by hydrochlorothiazide, such as a decrease in serum potassium, were blunted by concurrent use of lisinopril. Side effects from both regimens were acceptable.

807 Comparison of the Antihypertensive Effects of Betaxolol to Atenolol

William J. Mroczek, James F. Burris, Leo B. Hogan, Daniel C. Citron, Allan H. Barker, and Robert H. McDonald

A randomized double-blind multicenter study compared a new oral β_1-adrenergic antagonist, betaxolol (10 to 40 mg) with atenolol (25 to 100 mg) once daily for 24 weeks in 146 patients with mild to moderate hypertension. During the initial titration phase, betaxolol produced a significantly greater reduction in supine diastolic blood pressure than atenolol when measured 24 hours after dosing. Through the remainder of the study, no significant differences in blood pressure reduction were noted between treatment groups. Of those patients completing the trial, a significantly greater number (72% for betaxolol vs 52% for atenolol) achieved a supine disastolic blood pressure of ≤90 mm Hg. Both drugs were well tolerated.

812 Comparative Study of Primary Tissue Failure Between Porcine (Hancock and Carpentier-Edwards) and Bovine Pericardial (Ionescu-Shiley) Bioprostheses in the Aortic Valve Position at Five- to Nine-Year Follow-Up

Ignacio Gallo, Francisco Nistal, Emilio Arbe, and Edurne Artiñano

We studied the incidence of primary tissue valve failure after 5 to 9 years of follow-up in 461 valves: 184 Hancock, 131 Carpentier-Edwards (C-E) and 146 Ionescu-Shiley (I-S). Cumulative follow-up was 1,016 patient-years for patients with Hancock valve, 688 for the C-E and 767 for the I-S group. Of the 397 prostheses at risk (154 Hancock, 120 C-E and 123 I-S), 36 instances of primary tissue valve failure occurred (12 Hancock, 7 C-E and 17 I-S). On an actuarial basis, the calculated probability of freedom from primary tissue valve failure was 88 ± 4% for the Hancock group, 87 ± 6% for the C-E and 51 ± 17% for the I-S at 9 years of follow-up. This represents a linearized incidence of 1.2 for the Hancock, 1 for the C-E and 2.2 failing valves per 100 patient-years for the I-S group. In a cohort of patients older than 40 years at the time of surgery, the rate of freedom from primary failure was 98 ± 1%, 87 ± 9% and 44 ± 22% for the Hancock, C-E and I-S groups, respectively, at 9 years. Comparison of actuarial curves disclosed a meaningful difference between the pericardial valve and the Hancock and C-E porcine bioprostheses at 9 years of follow-up.

817 Noninvasive Assessment of Mitral Stenosis Before and After Percutaneous Balloon Mitral Valvuloplasty

Patricia C. Come, Marilyn F. Riley, Daniel J. Diver, James P. Morgan, Robert D. Safian, and Raymond G. McKay

Balloon dilatation of the mitral valve was performed in 37 patients with symptomatic mitral stenosis. The procedure resulted in significant increases in valve areas measured by catheterization (0.9 ± 0.3 to 1.8 ± 0.8 cm^2) and by the Doppler pressure half-time technique (0.9 ± 0.2 to 1.7 ± 0.5 cm^2). In contrast to our previously reported correlation between Doppler and catheterization mitral valve areas ($r = 0.84$, $p < 0.001$), the area correlations before valvuloplasty in this selected group of patients with severe, symptomatic mitral stenosis was only fair ($r = 0.51$, $p < 0.002$). In addition, the correlation after valvuloplasty was again only fair ($r = 0.47$, $p < 0.005$). The increases in mitral valve area were independent of valve thickness assessed by 2-dimensional echocardiography. Flail mitral leaflet movement was not observed and the degree of mitral regurgitation, assessed by pulsed Doppler mapping techniques, increased by >1 of 4 grades in only 1 patient. A greater increase in lateral than in anteroposterior mitral orifice diameter suggested commissural splitting as the mechanism of successful valvuloplasty. Significant increases (all $p < 0.0001$) were noted in mitral valve EF slope, mitral valve excursion and cardiac output. Significant decreases (all $p < 0.001$) were observed in left atrial diameter and in mean catheterization and Doppler gradients.

Continued on page A71

TONOCARD®
(TOCAINIDE HCl|MSD)

INDICATIONS AND USAGE

TONOCARD is indicated for the treatment of life-threatening ventricular arrhythmias.

TONOCARD is also indicated for the treatment of some patients with symptomatic ventricular arrhythmias.

Because TONOCARD has the potential to produce serious hematologic disorders (0.18 percent in clinical trials) particularly leukopenia or agranulocytosis (sometimes fatal), the use of TONOCARD should be reserved for patients in whom, in the opinion of the physician, the benefits of treatment outweigh the risks. (See WARNINGS.) For less serious arrhythmias alternative therapy with less severe toxicity, such as certain beta-blocking agents, should be considered.

Like all other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like all other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS

Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS

Blood Dyscrasias: Agranulocytosis, bone marrow depression, leukopenia, neutropenia, hypoplastic anemia, thrombocytopenia and sequelae such as septicemia and septic shock have been reported in patients receiving TONOCARD. Most of these patients received TONOCARD within the recommended dosage range. Fatalities have occurred (with approximately 25 percent mortality in reported agranulocytosis cases). Since most of these events have been noted during the first 12 weeks of therapy, it is recommended that complete blood counts, including white cell, differential and platelet counts be performed, optimally, at weekly intervals for the first three months of therapy, and periodically thereafter. Complete blood counts should be performed promptly if the patient develops any signs of infection (such as fever, chills, sore throat, or stomatitis), bruising, or bleeding. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation. Caution should be used in patients with pre-existing marrow failure or cytopenia of any type. (See ADVERSE REACTIONS.)

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS

General

Pulmonary Fibrosis: Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough, or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued. (See ADVERSE REACTIONS.)

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Information for Patients

Patients should be instructed to promptly report the development of bruising or bleeding; any signs of infections such as fever, chills, sore throat, or soreness and ulcers in the mouth; any pulmonary symptoms, such as exertional dyspnea, cough, or wheezing; rash.

Laboratory Tests

As with other antiarrhythmics, abnormal liver function tests, particularly in the early stages of therapy, have been reported. Periodic monitoring of liver function should be considered. Hepatitis and jaundice have been reported in some patients.

Drug Interactions

Tocainide and lidocaine are pharmacodynamically similar. The concomitant use of these two agents may cause an increased incidence of adverse reactions, including central nervous system adverse reactions such as seizure.

Specific interaction studies with cimetidine, digoxin, metoprolol, and warfarin have been conducted; no clinically significant interaction was seen with cimetidine, digoxin, or warfarin; but tocainide and metoprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

Pregnancy

Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TONOCARD commonly produces minor, transient nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were dizziness/vertigo (15.3 percent), nausea (14.5 percent), paresthesia (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by

TONOCARD® (Tocainide HCl|MSD)

taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or digestive system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
BODY AS A WHOLE		
Tiredness/drowsiness/fatigue/lethargy/lassitude/sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
CARDIOVASCULAR		
Hypotension	3.4	2.7
Bradycardia	1.8	0.4
Palpitations	1.8	0.4
Chest pain	1.6	0.4
Conduction disorders	1.5	0.0
Left ventricular failure	1.4	0.0
DIGESTIVE		
Nausea	15.2	14.5
Vomiting	8.3	4.6
Anorexia	1.2	1.9
Diarrhea/loose stools	0.0	3.8
NERVOUS SYSTEM/PSYCHIATRIC		
Dizziness/vertigo	8.0	15.3
Paresthesia	3.5	9.2
Tremor	2.9	8.4
Confusion/disorientation/hallucinations	2.1	2.7
Headache	2.1	4.6
Nervousness	1.5	0.4
Altered mood/awareness	1.5	3.4
Incoordination/unsteadiness/walking disturbances	1.2	0.0
Anxiety	1.1	1.5
Ataxia	0.2	3.0
SKIN		
Diaphoresis	5.1	2.3
Rash/skin lesion	0.4	8.4
SPECIAL SENSES		
Blurred vision/visual disturbances	1.3	1.5
Tinnitus/hearing loss	0.4	1.5
Nystagmus	0.0	1.1

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

	Percent of Patients Compassionate Use (n = 1,927)
CARDIOVASCULAR	
Increased ventricular arrhythmias/PVCs	10.9
CHF/progression of CHF	4.0
Tachycardia	3.2
Hypotension	1.8
Conduction disorders	1.3
Bradycardia	1.0
DIGESTIVE	
Nausea	24.6
Anorexia	11.3
Vomiting	9.0
Diarrhea/loose stools	6.8
MUSCULOSKELETAL	
Arthritis/arthralgia	4.7
Myalgia	1.7
NERVOUS SYSTEM/PSYCHIATRIC	
Dizziness/vertigo	25.3
Tremor	21.6
Nervousness	11.5
Confusion/disorientation/hallucinations	11.2
Altered mood/awareness	11.0
Ataxia	10.8
Paresthesia	9.2

TONOCARD® (Tocainide HCl|MSD)

	Percent of Patients Compassionate Use (n = 1,927)
SKIN	
Rash/skin lesion	12.2
Diaphoresis	8.3
Lupus	1.6
SPECIAL SENSES	
Blurred vision/vision disturbances	10.0
Nystagmus	1.1

Adverse reactions occurring in less than one percent of patients in either the controlled studies or the compassionate use program or since the drug was marketed are as follows:

Body as a Whole: Septicemia; septic shock; syncope; vaso-vagal episodes; edema; fever; chills; cinchonism; asthenia; malaise.

Cardiovascular: Ventricular fibrillation; extension of acute myocardial infarction; cardiogenic shock; pulmonary embolism; angina; AV block; hypertension; claudication; increased QRS duration; pleurisy/pericarditis; prolonged QT interval; right bundle branch block; cardiomegaly; sinus arrest; vasculitis; orthostatic hypotension; cold extremities.

Digestive: Hepatitis, jaundice (see PRECAUTIONS), abnormal liver function tests; pancreatitis; abdominal pain/discomfort; constipation; dysphagia; gastrointestinal symptoms (including dyspepsia); stomatitis; dry mouth; thirst.

Hematologic: Agranulocytosis; bone marrow depression; hypoplastic anemia; hemolytic anemia; anemia; leukopenia; neutropenia; thrombocytopenia; eosinophilia.

Metabolic and Immune: Hypersensitivity Reaction (including some of the following symptoms or signs: rash, fever, joint pains, abnormal liver function tests, eosinophilia); increased ANA.

Musculoskeletal: Muscle cramps; muscle twitching/spasm; neck pain; pain radiating from neck; pressure on shoulder.

Nervous System/Psychiatric: Coma; convulsions/seizures; myasthenia gravis; depression; psychosis; psychic disturbances; agitation; decreased mental acuity; dysarthria; impaired memory; increased stuttering/slurred speech; insomnia/sleeping disturbances; local anesthesia; dream abnormalities.

Respiratory: Respiratory arrest; pulmonary edema; pulmonary fibrosis; fibrosing alveolitis; pneumonia; interstitial pneumonitis; dyspnea; hiccough; yawning.

Skin: Stevens-Johnson syndrome; exfoliative dermatitis; erythema multiforme; urticaria; alopecia; pruritus; pallor/flushed face.

Special Senses: Diplopia; earache; taste perversion/smell perversion.

Urogenital: Urinary retention; polyuria/increased diuresis.

Agranulocytosis, bone marrow depression, leukopenia, neutropenia, hypoplastic anemia, and thrombocytopenia have been reported (0.18 percent) in patients receiving TONOCARD in controlled trials and the compassionate use program. Most of these events have been noted during the first 12 weeks of therapy. (See WARNINGS.)

Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. The incidence of pulmonary fibrosis (including interstitial pneumonitis and fibrosing alveolitis) was 0.11 percent in controlled trials and the compassionate use program. These events usually occurred in seriously ill patients. Symptoms of these pulmonary disorders and/or x-ray changes usually occurred following 3-18 weeks of therapy and two patients died. (See PRECAUTIONS.)

A number of disorders, in which a causal relationship with TONOCARD has not been established, have been reported in seriously ill patients. These include: renal failure, renal dysfunction, myocardial infarction, cerebrovascular accidents, and transient ischemic attacks. These disorders may be related to the patient's underlying condition.

HOW SUPPLIED

Scored tablets containing 400 mg or 600 mg in bottles of 100 and unit-dose packages of 100.

For more detailed information, consult your MSD Representative and the Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, PA 19486.

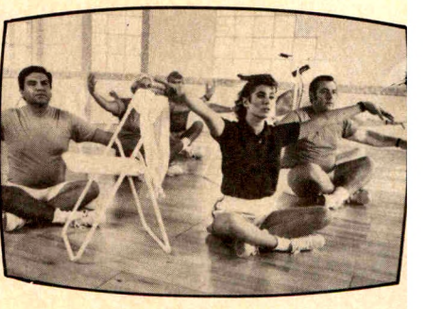
New Prescribed Video Program For Cardiac Patients.

Special Offer For AJC Readers



Now available, the first take-home education and exercise video for cardiac patients. These four 60-minute videos extend rehabilitative care and meet the current standards of AHA and ACSM.

- Exercise videos feature increasing levels of intensity. Select the tape that's best for each patient. These video home programs encourage patient compliance.
- Patient exercise and activity log helps you audit progress during office visits.
- Available only on physician recommendation.

Prescription video orders can be filled at your office or rehab center for as low as $69-$89 each, depending on the module you prescribe.

VideoCare National Advisory Panel on Cardiac Rehabilitation

Physicians: Bruno Balke; Samuel M. Fox, III; Victor Froelicher, Peter Hanson; Herman K. Hellerstein; Terence Kavanagh; Arthur S.Leon; Henry S. Miller, Jr.; L. Kent Smith; C. Barr Taylor; Steven P. Van Camp.
Nurses: Kathy Berra; Nancy Houston Miller; Erika S. Sivarajan.
Exercise Physiologists: Carl Foster; Barry A. Franklin; William L. Haskell; Neil B. Oldridge; Michael L. Pollock; Paul M. Ribisl; Ray W. Squires.
Behavioral Scientist: James A. Blumenthal.
Physical Therapist: Elizabeth J. Protas.

Special AJC Offer

Normally $346, a complete VideoCare™ set can be obtained by AJC readers for only $300. Satisfaction guaranteed, credit cards accepted. **Call 1-800-338-1927.** Mention AJC for special offer.

VIDEOCARE, INC.

Yes! Please send four (4) VideoCare VHS cassettes, video brochure, and all support materials at special AJC price — only $300.00. Satisfaction guaranteed. (Foreign orders write for more information.)

PRODUCT INFORMATION

NORMODYNE®

brand of labetalol hydrochloride

Tablets

BRIEF SUMMARY

INDICATIONS AND USAGE

NORMODYNE (labetalol HCl) Tablets are indicated in the management of hypertension. NORMODYNE Tablets may be used alone or in combination with other antihypertensive agents, especially thiazide and loop diuretics.

CONTRAINDICATIONS

NORMODYNE (labetalol HCl) Tablets are contraindicated in bronchial asthma, overt cardiac failure, greater than first degree heart block, cardiogenic shock, and severe bradycardia (see **WARNINGS**).

WARNINGS

Cardiac Failure Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure. Beta blockade carries a potential hazard of further depressing myocardial contractility and precipitating more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, labetalol HCl can be used with caution in patients with a history of heart failure who are well-compensated. Congestive heart failure has been observed in patients receiving labetalol HCl. Labetalol HCl does not abolish the inotropic action of digitalis on heart muscle.

In Patients Without a History of Cardiac Failure In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, NORMODYNE (labetalol HCl) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal Angina pectoris has not been reported upon labetalol HCl discontinuation. However, hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered NORMODYNE (labetalol HCl), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, NORMODYNE (labetalol HCl) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue NORMODYNE (labetalol HCl) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis and emphysema) Patients with bronchospastic disease should, in general, not receive beta-blockers. NORMODYNE may be used with caution, however, in patients who do not respond to, or cannot tolerate, other antihypertensive agents. It is prudent, if NORMODYNE is used, to use the smallest effective dose, so that inhibition of endogenous or exogenous beta-agonists is minimized.

Pheochromocytoma Labetalol HCl has been shown to be effective in lowering the blood pressure and relieving symptoms in patients with pheochromocytoma. However, paradoxical hypertensive responses have been reported in a few patients with this tumor; therefore, use caution when administering labetalol HCl to patients with pheochromocytoma.

Diabetes Mellitus and Hypoglycemia Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; it may therefore be necessary to adjust the dose of antidiabetic drugs.

Major Surgery The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial. Protracted severe hypotension and difficulty in restarting or maintaining a heart beat have been reported with beta-blockers. The effect of labetalol HCl's alpha-adrenergic activity has not been evaluated in this setting.

A synergism between labetalol HCl and halothane anesthesia has been shown (see **Drug Interactions**).

PRECAUTIONS

General *Impaired Hepatic Function* NORMODYNE (labetalol HCl) Tablets should be used with caution in patients with impaired hepatic function since metabolism of the drug may be diminished.

Jaundice or Hepatic Dysfunction On rare occasions, labetalol HCl has been associated with jaundice (both hepatic and cholestatic). It is therefore recommended that treatment with labetalol HCl be stopped immediately should a patient develop jaundice or laboratory evidence of liver injury. Both have been shown to be reversible on stopping therapy.

Information for Patients

As with all drugs with beta-blocking activity, certain advice to patients being treated with labetalol HCl is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. While no incident of the abrupt withdrawal phenomenon (exacerbation of angina pectoris) has been reported with labetalol HCl, dosing with NORMODYNE Tablets should not be interrupted or discontinued without a physician's advice. Patients being treated with NORMODYNE Tablets should consult a physician at any sign of impending cardiac failure. Also, transient scalp tingling may occur, usually when treatment with NORMODYNE Tablets is initiated (see **ADVERSE REACTIONS**).

Laboratory Tests

As with any new drug given over prolonged periods, laboratory parameters should be observed over regular intervals. In patients with concomitant illnesses, such as impaired renal function, appropriate tests should be done to monitor these conditions.

Drug Interactions

In one survey, 2.3% of patients taking labetalol HCl in combination with tricyclic antidepressants experienced tremor as compared to 0.7% reported to occur with labetalol HCl alone. The contribution of each of the treatments to this adverse reaction is unknown but the possibility of a drug interaction cannot be excluded.

Drugs possessing beta-blocking properties can blunt the bronchodilator effect of beta-receptor agonist drugs in patients with bronchospasm; therefore, doses greater than the normal anti-asthmatic dose of beta-agonist bronchodilator drugs may be required.

Cimetidine has been shown to increase the bioavailability of labetalol HCl. Since this could be explained either by enhanced absorption or by an alteration of hepatic metabolism of labetalol HCl, special care should be used in establishing the dose required for blood pressure control in such patients.

Synergism has been shown between halothane anesthesia and intravenously administered labetalol HCl. During controlled hypotensive anesthesia using labetalol HCl in association with halothane, high concentrations (3% or above) of halothane should not be used because the degree of hypotension will be increased and because of the possibility of a large reduction in cardiac output and an increase in central venous pressure. The anesthesiologist should be informed when a patient is receiving labetalol HCl.

Labetalol HCl blunts the reflex tachycardia produced by nitroglycerin without preventing its hypotensive effect. If labetalol HCl is used with nitroglycerin in patients with angina pectoris, additional antihypertensive effects may occur.

Drug/Laboratory Test Interactions

The presence of a metabolite of labetalol in the urine may result in falsely increased levels of urinary catecholamines when measured by a nonspecific trihydroxyindole (THI) reaction. In screening patients suspected of having a pheochromocytoma and being treated with labetalol HCl, specific radioenzymatic or high performance liquid chromatography assay techniques should be used to determine levels of catecholamines or their metabolites.

Carcinogenesis, Mutagenesis, Impairment of Fertility

Long-term oral dosing studies with labetalol HCl for 18 months in mice and for 2 years in rats showed no evidence of carcinogenesis. Studies with labetalol HCl, using dominant lethal assays in rats and mice, and exposing microorganisms according to modified Ames tests, showed no evidence of mutagenesis.

Pregnancy Category C

Teratogenic studies have been performed with labetalol in rats and rabbits at oral doses up to approximately 6 and 4 times the maximum recommended human dose (MRHD), respectively. No reproducible evidence of fetal malformations was observed. Increased fetal resorptions were seen in both species at doses approximating the MRHD. There are no adequate and well-controlled studies in pregnant women. Labetalol should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects

Infants of mothers who were treated with labetalol HCl for hypertension during pregnancy did not appear to be adversely affected by the drug. Oral administration of labetalol to rats during late gestation through weaning at doses of 2 to 4 times the MRHD caused a decrease in neonatal survival.

Labor and Delivery

Labetalol HCl given to pregnant women with hypertension did not appear to affect the usual course of labor and delivery.

Nursing Mothers

Small amounts of labetalol (approximately 0.004% of the maternal dose) are excreted in human milk. Caution should be exercised when NORMODYNE Tablets are administered to a nursing woman.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects are mild, transient and occur early in the course of treatment. In controlled clinical trials of 3 to 4 months duration, discontinuation of NORMODYNE (labetalol HCl) Tablets due to one or more adverse effects was required in 7% of all patients. In these same trials, beta-blocker control agents led to discontinuation in 8 to 10% of patients, and a centrally acting alpha-agonist in 30% of patients.

The incidence rates of adverse reactions listed in the following table were derived from multicenter controlled clinical trials, comparing labetalol HCl, placebo, metoprolol and propranolol, over treatment periods of 3 and 4 months. Where the frequency of adverse effects for labetalol HCl and placebo is similar, causal relationship is uncertain. The rates are based on adverse reactions considered probably drug-related by the investigator. If all reports are considered, the rates are somewhat higher (e.g., dizziness 20%, nausea 14%, fatigue 11%), but the overall conclusions are unchanged.

	Labetalol HCl (N = 227) %	Placebo (N = 98) %	Propranolol (N = 84) %	Metoprolol (N = 49) %
Body as a whole				
fatigue	5	0	12	12
asthenia	1	1	1	0
headache	2	1	1	2
Gastrointestinal				
nausea	6	1	1	2
vomiting	<1	0	0	0
dyspepsia	3	1	1	0
abdominal pain	0	0	1	2
diarrhea	<1	0	2	0
taste distortion	1	0	0	0
Central and Peripheral Nervous Systems				
dizziness	11	3	4	4
paresthesias	<1	0	0	0
drowsiness	<1	2	2	2
Autonomic Nervous System				
nasal stuffiness	3	0	0	0
ejaculation failure	2	0	0	0
impotence	1	0	1	3
increased sweating	<1	0	0	0
Cardiovascular				
edema	1	0	0	0
postural hypotension	1	0	0	0
bradycardia	0	0	5	12
Respiratory				
dyspnea	2	0	1	2
Skin				
rash	1	0	0	0
Special Senses				
vision abnormality	1	0	0	0
vertigo	2	1	0	0

The adverse effects were reported spontaneously and are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, i.e., a group excluding patients with bronchospastic disease, overt congestive heart failure, or other contraindications to beta-blocker therapy.

Clinical trials also included studies utilizing daily doses up to 2400 mg in more severely hypertensive patients. Certain of the side effects increased with increasing dose as shown in the table below which depicts the entire U.S. therapeutic trials data base for adverse reactions that are clearly or possibly dose related.

Labetalol HCl Daily Dose (mg)	200	300	400	600
Number of Patients	522	181	606	608
Dizziness (%)	2	3	3	3
Fatigue	2	1	4	4
Nausea	<1	0	1	2
Vomiting	0	0	<1	<1
Dyspepsia	1	0	2	1
Paresthesias	2	0	2	2
Nasal Stuffiness	1	1	2	2
Ejaculation Failure	0	2	1	2
Impotence	1	1	1	1
Edema	1	0	1	1

Labetalol HCl Daily Dose (mg)	800	900	1200	1600	2400
Number of Patients	503	117	411	242	175
Dizziness (%)	5	1	9	13	16
Fatigue	5	3	7	6	10
Nausea	4	0	7	11	19
Vomiting	<1	0	1	2	3
Dyspepsia	1	0	2	2	4

Labetalol HCl Daily Dose (mg) (cont.)	800	900	1200	1600	2400
Paresthesias	1	1	2	5	5
Nasal Stuffiness	2	2	4	5	6
Ejaculation Failure	3	0	4	3	5
Impotence	2	4	3	4	3
Edema	1	0	1	2	2

In addition, a number of other less common adverse events have been reported in clinical trials or the literature:

Cardiovascular Postural hypotension, including rarely, syncope.

Central and Peripheral Nervous Systems Paresthesias, most frequently described as scalp tingling. In most cases, it was mild, transient and usually occurred at the beginning of treatment.

Collagen Disorders Systemic lupus erythematosus; positive antinuclear factor (ANF).

Eyes Dry eyes.

Immunological System Antimitochondrial antibodies.

Liver and Biliary System Cholestasis with or without jaundice.

Musculo-Skeletal System Muscle cramps; toxic myopathy.

Respiratory System Bronchospasm.

Skin and Appendages Rashes of various types, such as generalized maculo-papular; lichenoid; urticarial; bullous lichen planus; psoriaform; facial erythema; Peyronie's disease; reversible alopecia.

Urinary System Difficulty in micturition, including acute urinary bladder retention.

Following approval for marketing in the United Kingdom, a monitored release survey involving approximately 6,800 patients was conducted for further safety and efficacy evaluation of this product. Results of this survey indicate that the type, severity, and incidence of adverse effects were comparable to those cited above.

Potential Adverse Effects

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents.

Central Nervous System Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular Intensification of AV block. See **CONTRAINDICATIONS.**

Allergic Fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic Agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura.

Gastrointestinal Mesenteric artery thrombosis; ischemic colitis.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with labetalol HCl.

Clinical laboratory tests: There have been reversible increases of serum transaminases in 4% of patients treated with labetalol HCl and tested, and more rarely, reversible increases in blood urea.

OVERDOSAGE

Overdosage with NORMODYNE (labetalol HCl) Tablets causes excessive hypotension which is posture sensitive, and sometimes, excessive bradycardia. Patients should be laid supine and their legs raised if necessary to improve the blood supply to the brain. The following additional measures should be employed if necessary: *Excessive bradycardia* — administer atropine (3.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. *Cardiac failure* — administer a digitalis glycoside and a diuretic. *Hypotension* — administer vasopressors, e.g., norepinephrine. There is pharmacological evidence that norepinephrine may be the drug of choice. *Bronchospasm* — administer a $beta_2$-stimulating agent and/or a theophylline preparation.

Gastric lavage or pharmacologically induced emesis (using syrup of ipecac) is useful for removal of the drug shortly after ingestion. Labetalol HCl can be removed from the general circulation by hemodialysis.

The oral LD_{50} value of labetalol HCl in the mouse is approximately 600 mg/kg and in the rat is greater than 2 gm/kg. The intravenous LD_{50} in these species is 50 to 60 mg/kg.

DOSAGE AND ADMINISTRATION

DOSAGE MUST BE INDIVIDUALIZED. The recommended initial dose is 100 mg twice daily whether used alone or added to a diuretic regimen. After 2 or 3 days, using standing blood pressure as an indicator, dosage may be titrated in increments of 100 mg bid every 2 or 3 days. The usual maintenance dosage of labetalol HCl is between 200 and 400 mg twice daily.

Since the full antihypertensive effect of labetalol HCl is usually seen within the first one to three hours of the initial dose or dose increment, the assurance of a lack of an exaggerated hypotensive response can be clinically established in the office setting. The antihypertensive effects of continued dosing can be measured at subsequent visits, approximately 12 hours after a dose, to determine whether further titration is necessary.

Patients with severe hypertension may require from 1200 mg to 2400 mg per day, with or without thiazide diuretics. Should side effects (principally nausea or dizziness) occur with these doses administered bid, the same total daily dose administered three times daily may improve tolerability and facilitate further titration. Titration increments should not exceed 200 mg twice daily.

When a diuretic is added, an additive antihypertensive effect can be expected. In some cases this may necessitate a labetalol HCl dosage adjustment. As with most antihypertensive drugs, optimal dosages of NORMODYNE Tablets are usually lower in patients also receiving a diuretic.

When transferring patients from other antihypertensive drugs, NORMODYNE Tablets should be introduced as recommended and the dosage of the existing therapy progressively decreased.

HOW SUPPLIED

NORMODYNE (labetalol HCl) Tablets, 100 mg, light-brown, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 244, and on the other side the number 100 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0244-04), 500 (NDC-0085-0244-05), and box of 100 for unit-dose dispensing (NDC-0085-0244-08).

NORMODYNE (labetalol HCl) Tablets, 200 mg, white, round, scored, film-coated tablets engraved on one side with Schering and product identification numbers 752, and on the other side the number 200 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0752-04), 500 (NDC-0085-0752-05), box of 100 for unit-dose dispensing (NDC-0085-0752-08), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0752-03).

NORMODYNE (labetalol HCl) Tablets, 300 mg, blue, round, film-coated tablets engraved on one side with Schering and product identification numbers 438, and on the other side the number 300 for the strength and "NORMODYNE"; bottles of 100 (NDC-0085-0438-03), 500 (NDC-0085-0438-05), box of 100 for unit-dose dispensing (NDC-0085-0438-06), and Patient Calendar Package of 56 (4 bottles of 14 tablets) (NDC-0085-0438-02).

NORMODYNE (labetalol HCl) Tablets should be stored between 2° and 30°C (36° and 86°F).

NORMODYNE (labetalol HCl) Tablets in the unit-dose boxes should be protected from excessive moisture.

For complete prescribing information, please consult package insert.

- ☐ Low incidence of impotence, fatigue, or cold extremities†
- ☐ Lipid and potassium levels are not adversely affected
- ☐ Minimizes risk of reflex tachycardia
- ☐ Maintains cardiac output
- ☐ Maintains exercise capacity
- ☐ Does not adversely affect heart rate
- ☐ Maintains blood flow to vital organs
- ☐ Renal function is unimpaired

*reduces double product (HR × SBP) and minimizes the risk of reflex tachycardia

†Most adverse effects are mild, transient, and occur early in the course of treatment. In controlled clinical trials of three to four months' duration, the most common side effects noted in treating mild to moderate hypertension with NORMODYNE (labetalol HCl) Tablets include dizziness (11%), nausea (6%), and fatigue (5%). Dyspepsia (3%), nasal stuffiness (3%), impotence (1%), and drowsiness (<1%) occurred to a lesser degree. Overall, reports of symptomatic postural hypotension have been uncommon and have included rare instances of syncope. For complete side effects profile, see Prescribing Information.

826 Angina Pectoris and Coronary Artery Disease in Severe Aortic Regurgitation

Philippe Timmermans, Jos L. Willems, Jan Piessens, and Hilaire De Geest

A consecutive series of 198 patients (148 men and 50 women) with pure, isolated, severe aortic regurgitation was retrospectively studied to determine the prevalence of angiographically significant coronary artery disease (CAD) and its relation to angina pectoris and coronary risk factors. Significant CAD (coronary diameter stenoses >50%) was found in 28 cases (14%). Typical angina was present in 18% and atypical chest pain in 16%. Angina alone had a sensitivity of 57% to detect significant CAD. By using multivariate logistic regression, a risk score could be calculated that increased the sensitivity to 74% at equal specificity. Almost 40% had a risk score of <-2.9 (only 1 patient in this group had CAD). It is concluded that coronary arteriography can safely be omitted in many patients with severe aortic regurgitation if they have no symptoms of myocardial ischemia or risk factors known to increase its incidence.

CARDIOMYOPATHY

830 Relation Between Serum Nifedipine Concentration and Hemodynamic Effects in Nonobstructive Hypertrophic Cardiomyopathy

Sandro Betocchi, Robert O. Bonow, Richard O. Cannon, III, Lawrence J. Lesko, Harold G. Ostrow, Rita M. Watson, and Douglas R. Rosing

The relation between the hemodynamic effects of sublingual nifedipine and nifedipine concentration was studied in 13 patients with nonobstructive hypertrophic cardiomyopathy (HC) during cardiac catheterization. Nifedipine resulted in reduced peripheral vascular resistance which correlated with drug concentration ($r = -0.63$), associated with increased heart rate and cardiac index. At low to medium drug concentrations ($\leq$120 ng/ml), these peripheral effects predominated, with increased left ventricular (LV) stroke volume and increased ejection fraction, with no change in the end-systolic pressure-volume relation and no change in pulmonary artery wedge pressure. However, at high concentrations (>120 ng/ml), negative inotropic effects predominated; despite greater reduction in peripheral resistance at these concentrations, stroke volume index decreased, both end-systolic and end-diastolic volumes increased, ejection fraction decreased and LV end-diastolic and pulmonary artery wedge pressures increased. Thus, low to medium concentrations of nifedipine augment LV ejection performance in nonobstructive HC, whereas high concentrations result in deleterious negative inotropic effects.

836 A Comparative Study of Thallium-201 Single-Photon Emission Computed Tomography and Electrocardiography in Duchenne and Other Types of Muscular Dystrophy

Shuhei Yamamoto, Hideo Matsushima, Akio Suzuki, Iwao Sotobata, Toshikatsu Indo, and Yukihiko Matsuoka

We compared thallium-201 single-photon emission computed tomography (SPECT) with electrocardiography in 47 patients with Duchenne, facioscapulohumeral, limb-girdle and myotonic dystrophies. SPECT showed (multiple) hypoperfusion (37 patients), malrotation (23), apical aneurysm (5) and dilatation (7) of the left ventricle. Electrocardiography frequently showed QRS wave abnormalities (36 patients). In the Du-

chenne type, SPECT hypoperfusion and QRS abnormalities were frequent in the posteroapical and the posterolateral walls, respectively. Both were scattered over the left ventricle in the 3 other types. In this disease, SPECT hypoperfusion was often shown despite minimal electrocardiographic changes and irrespective of clinical subtype and skeletal involvement.

CONGENITAL HEART DISEASE

844 Doppler Ultrasound Evaluation of Valvar Pulmonary Stenosis from Multiple Transducer Positions in Children Requiring Pulmonary Valvuloplasty

Elman G. Frantz and Norman H. Silverman

This study compares the estimates of peak pressure difference in children with valvar pulmonary stenosis admitted for valvuloplasty with continuous wave Doppler ultrasound using the modified Bernoulli equation from several different transducer positions. Because jet direction varies from the axial direction of normal pulmonary flow, only an appropriate alignment of the ultrasound will determine the highest velocity signal. We examined whether the conventional parasternal transducer position or an alternate transducer from the subcostal, suprasternal or apical transducer position produced the highest velocity signals in 24 children. In 12 of these children (50%) studied prior to, and in 8 (67%) studied during cardiac catheterization, a higher velocity was recorded from a nonparasternal position. The same transducer position produced the highest velocity after as it did before valvuloplasty although the numbers are too small to generalize. The study shows that in valvar pulmonary stenosis multiple transducer positions are required to determine peak transpulmonary velocity.

850 Anomalous Origin of a Pulmonary Artery from the Ascending Aorta: Associated Anomalies and Pathogenesis

Lynn M. Kutsche and L.H.S. Van Mierop

The pathologic anatomic features and associated cardiovascular anomalies of 99 cases of anomalous origin of 1 pulmonary artery from the aorta were analyzed. Anomalous origin of the right pulmonary artery (PA) was more common than that of the left PA. An anomalous right PA usually arose from the posterior aspect of the ascending aorta close to the aortic valve. Less commonly, it originated near the innominate artery. Patent ductus arteriosus and aorticopulmonary septal defect were common in anomalous origin of the right PA. Tetralogy of Fallot, aortic arch anomalies or both were always present in anomalous origin of the left PA. An association with DiGeorge syndrome was not seen. Anomalous origin of the right PA and anomalous origin of the left PA appear to be unrelated to each other pathogenetically. Moreover, the distal type of anomalous origin of the right PA appears to be pathogenetically distinct from that which arises close to the aortic valve. These pathogenetic relations should be considered in epidemiologic studies of congenital heart disease.

A87-W4803T

ONCE-A-DAY
Calan® SR
(verapamil HCl) 240mg
SUSTAINED-RELEASE CAPLETS

- **Convenient one-caplet, once-a-day dosing regimen:* Start with one 240—mg caplet in the morning with food. (Starting dosages of 120 mg/day, ½ caplet, may be suitable for the elderly or those of small stature.)**
- **Favorably priced—similar in cost to beta blockers**

*Some patients may require *b.i.d.* dosing.

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present).
Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with significant ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan SR is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.
Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.
Adverse Reactions— oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, cerebrovascular accident, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation.

New York, N.Y. 10011

XL T.I.D. The Prescription for Excellence

interspec XL

A Tremendous Success Today

Every day three more XL Ultrasound Systems are delivered and begin a lifetime of reliability and performance. Cardiologists, medical centers, and mobile scanning services buy the Interspec XL Ultrasound System because of its reputation:

- Superior image quality and exquisite Doppler sensitivity for diagnosing difficult cases.
- Versatility and portability for a wide range of applications in a variety of clinical settings.
- A commitment to service and education.
- An extraordinary price.

Now the XL's superb imaging and Doppler capabilities are better than ever. The XL has an even wider range of probes for greater clinical flexibility and new features like complete vascular capabilities, steerable CW, high-resolution zoom, 110° scanning, variable depth settings, and much more.

A Great System Tomorrow

Some buy the XL for its combination of value and performance. Others buy the XL for the future. We continually strive to make our systems better, because we're never satisfied to stand still. And *the Interspec Commitment* lets our customers upgrade, no matter how long their system has been in service.

If you're ready for today's state-of-the-art ultrasound system . . . and tomorrow's too . . . you're ready for the Interspec XL.

Call today for a demonstration or for more information about Interspec and its colorful future.

857 **An Echocardiagraphic Study of the Association of Ventricular Septal Defect and Right Ventricular Muscle Bundles with a Fixed Subaortic Abnormality**

Michael Vogel, Jeffrey F. Smallhorn, Robert M. Freedom, John Coles, William G. Williams, and George A. Trusler

Since 1983, 36 patients with ventricular septal defect and anomalous right ventricular muscle bundles have been evaluated by cross-sectional echocardiography to address the incidence of an associated subaortic abnormality. Of these, 32 had an indentifiable subaortic abnormality. Surgical confirmation of the presence or absence of an abnormality was available in 26. A recordable Doppler gradient across the left ventricular outflow tract of ≥10 mm Hg was present only in 10. It appears that the incidence of a subaortic abnormality in this setting is far greater than previously suspected.

861 **Cardiorespiratory Exercise Testing After Venous Switch Operation in Children with Complete Transposition of the Great Arteries**

Tony Reybrouck, Monique Dumoulin, and Lucas G. Van der Hauwaert

In 14 children who underwent a venous switch operation, exercise testing was performed 3 to 15 years (mean 8) after the operation. Exercise performance capacity was assessed by the determination of the ventilatory threshold during exercise, defined as the highest exercise intensity before which hyperventilation starts during graded exercise. The mean ventilatory threshold (72 ± 15%) was significantly lower ($p < 0.01$) in these patients than the age-predicted normal mean value. A lower than normal heart rate response to exercise was observed in nearly half of the patients, and was not associated with a high or normal value for ventilatory threshold (as would be expected in endurance-trained subjects). This blunted heart rate response during exercise suggests sinoatrial dysfunction secondary to extensive intraatrial operation.

QUINAGLUTE® (quinidine gluconate) DURA-TABS®

INDICATIONS AND USAGE: QUINAGLUTE® (quinidine gluconate) DURA-TABS® sustained-release tablets are indicated in the prevention and/or treatment of:

1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).

2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administation of quinidine.

2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.

3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication.

6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.

7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4 to 8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Information for Patients: As with all solid oral medications, QUINAGLUTE® DURA-TABS® tablets should be taken with an adequate amount of fluid, preferably in an upright position, to facilitate swallowing.

Drug Interactions: *Drug*	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Potential for reduction of quinidine plasma levels
Quinidine with cimetidine	Potential for elevation of quinidine plasma levels
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. QUINAGLUTE® DURA-TABS® tablets should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers: Caution should be exercised when QUINAGLUTE® DURA-TABS® tablets are administered to a nursing woman due to passage of the drug into breast milk.

Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of QUINAGLUTE® DURA-TABS® tablets in children.

ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.

Less frequently encountered adverse reactions:

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Rash, cutaneous flushing with intense pruritis, urticaria. Photosensitivity has also been reported.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although rare, there have been reports of lupus erythematosus in patients taking quinidine.

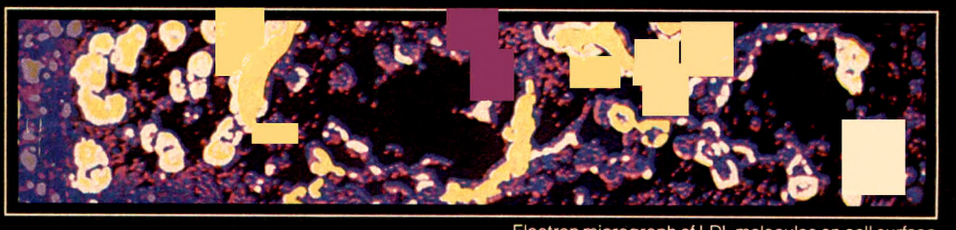
Heart patients place something vital into your hands. Their lives. Whether you're a cardiologist, radiologist, cath lab nurse or technologist, they trust you're using the very best cine imaging film. They trust you're using Cine 35. Offering maximum image resolution and contrast, excellent vessel visualization and an around the clock technical staff, Cine 35 makes the difference between "adequate" results and results your patients will appreciate— for the rest of their entire lives. **Cine Film Systems, Inc.**

YOU'LL NEVER HEAR A PATIENT SAY THANKS FOR USING CINE 35.

BUT IF THEY SAW THE DIFFERENCE IT COULD MAKE, THEY WOULD.

Seeing is Believing. (800) 237-0740. 3511 Locke, Fort Worth, Texas 76107.



Electron micrograph of LDL molecules on cell surface

When you consider Coronary Heart Disease (CHD) risk reduction,

The lipid effects of thiazide diuretics may negate their positive antihypertensive effect.

Electron micrograph of red blood cells against a vessel wall.

In Hypertension,

Initiate Positive Action with Minipress®

(prazosin HCl)

First-line control of hypertension without the negatives of diuretics

Minipress and diuretics both deliver effective first-line blood pressure control. But unlike thiazide diuretics, Minipress does not compromise lipid metabolism[1-4]; additionally, potassium balance[5] and diabetes control are not compromised.[6,7] And sexual dysfunction is seldom a problem with Minipress.[8] Impotence has been reported but in less than 1% of patients on Minipress.

With Minipress, most common adverse reactions, generally mild and transient, are: dizziness, headache, drowsiness, palpitations, and nausea. Syncope has been reported in about 0.15% of patients at the recommended 1 mg initial dose. Fluid retention may occur.

Minipress. The positive first-line approach to hypertension. Instead of diuretics.

	Minipress	Thiazide Diuretics
Controls Hypertension	+	+
No adverse effect on Blood Lipids	+[1-3]	−[4]
No adverse effect on Potassium Balance	+[5]	−[9]
Does not compromise Glucose Tolerance	+[6,7]	−[7]
Rarely compromises Sexual Function	+[8]	−[10]

+ = Yes − = No

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Please see MINIPRESS® (prazosin HCl) brief summary on adjacent page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

Brief Summary
MINIPRESS (prazosin hydrochloride) CAPSULES ***For Oral Use***

INDICATIONS AND USAGE: MINIPRESS (prazosin hydrochloride) is indicated in the treatment of hypertension. It is mild to moderate in activity and can be used as the initial agent or in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed.

CONTRAINDICATIONS: None known.

WARNINGS: MINIPRESS may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120–160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS. The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS therapy.

PRECAUTIONS: ***Information for Patients:*** Dizziness or drowsiness may occur after the first dose of this medicine. Avoid driving or performing hazardous tasks for the first 24 hours after taking this medicine or when the dose is increased. Dizziness, lightheadedness or fainting may occur, especially when rising from a lying or sitting position. Getting up slowly may help lessen the problem. These effects may also occur if you drink alcohol, stand for long periods of time, exercise, or if the weather is hot. While taking MINIPRESS, be careful in the amount of alcohol you drink. Also, use extra care during exercise or hot weather, or if standing for long periods. Check with your physician if you have any questions.

Drug Interactions: MINIPRESS has been administered without any adverse drug interaction in limited clinical experience to date with the following: (1) cardiac glycosides–digitalis and digoxin; (2) hypoglycemics–insulin, chlorpropamide, phenformin, tolazamide, and tolbutamide; (3) tranquilizers and sedatives–chlordiazepoxide, diazepam, and phenobarbital; (4) antigout–allopurinol, colchicine, and probenecid; (5) antiarrhythmics–procainamide, propranolol (see WARNINGS however), and quinidine; and (6) analgesics, antipyretics and anti-inflammatories–propoxyphene, aspirin, indomethacin, and phenylbutazone.

Addition of a diuretic or other antihypertensive agent to MINIPRESS has been shown to cause an additive hypotensive effect.

Drug/Laboratory Test Interactions: False positive results may occur in screening tests for pheochromocytoma in patients who are being treated with prazosin. If an elevated VMA is found, prazosin should be discontinued and the patient retested after a month.

Laboratory Tests: In clinical studies in which lipid profiles were followed, there were generally no adverse changes noted between pre- and post-treatment lipid levels.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No carcinogenic potential was demonstrated in an 18 month study in rats with MINIPRESS (prazosin hydrochloride) at dose levels more than 225 times the usual maximum recommended human dose of 20 mg per day. MINIPRESS was not mutagenic in *in vivo* genetic toxicology studies. In a fertility and general reproductive performance study in rats, both males and females, treated with 75 mg/kg (225 times the usual maximum recommended human dose), demonstrated decreased fertility while those treated with 25 mg/kg (75 times the usual maximum recommended human dose) did not.

In chronic studies (one year or more) of MINIPRESS in rats and dogs, testicular changes consisting of atrophy and necrosis occurred at 25 mg/kg/day (75 times the usual maximum recommended human dose). No testicular changes were seen in rats or dogs at 10 mg/kg/day (30 times the usual maximum recommended human dose). In view of the testicular changes observed in animals, 105 patients on long term MINIPRESS therapy were monitored for 17-ketosteroid excretion and no changes indicating a drug effect were observed. In addition, 27 males on MINIPRESS for up to 51 months did not have changes in sperm morphology suggestive of drug effect.

Usage In Pregnancy: Pregnancy Category C. There are no adequate and well controlled studies which establish the safety of MINIPRESS (prazosin HCl) in pregnant women. MINIPRESS should be used during pregnancy only if the potential benefit justifies the potential risk to the mother and fetus.

Nursing Mothers: MINIPRESS has been shown to be excreted in small amounts in human milk. Caution should be exercised when MINIPRESS is administered to a nursing woman.

Usage in Children: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Clinical trials were conducted on more than 900 patients. During these trials and subsequent marketing experience, the most frequent reactions associated with MINIPRESS therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

Less frequent adverse reactions which are reported to occur in 1–4% of patients are:

Gastrointestinal: vomiting, diarrhea, constipation; *Cardiovascular:* edema, orthostatic hypotension, dyspnea, syncope; *Central Nervous System:* vertigo, depression, nervousness; *Dermatologic:* rash; *Genitourinary:* urinary frequency; *EENT:* blurred vision, reddened sclera, epistaxis, dry mouth, nasal congestion.

In addition, fewer than 1% of patients have reported the following (in some instances, exact causal relationships have not been established):

Gastrointestinal: abdominal discomfort and/or pain, liver function abnormalities, pancreatitis; *Cardiovascular:* tachycardia; *Central Nervous System:* paresthesia, hallucinations; *Dermatologic:* pruritus, alopecia, lichen planus; *Genitourinary:* incontinence, impotence, priapism; *EENT:* tinnitus; *Other:* diaphoresis, fever.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported.

OVERDOSAGE: Should overdosage lead to hypotension, support of the cardiovascular system is of first importance. Restoration of blood pressure and normalization of heart rate may be accomplished by keeping the patient in the supine position. If this measure is inadequate, shock should first be treated with volume expanders. If necessary, vasopressors should then be used. Renal function should be monitored and supported as needed. Laboratory data indicate MINIPRESS is not dialysable because it is protein bound.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS should be adjusted according to individual blood pressure response.

Initial Dose: 1 mg two or three times a day.

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

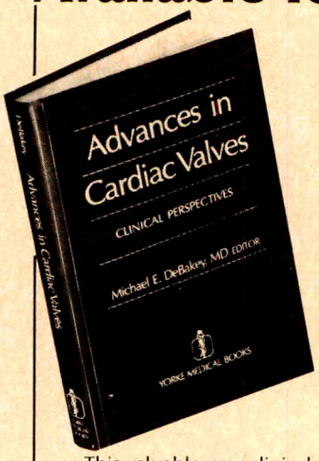
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

INSTRUCTOR OF INTERNAL MEDICINE

A position of Instructor is available in the Department of Internal Medicine, Division of Cardiology at The University of Texas Southwestern Medical Center at Dallas. Applications should have Ph.D. degree in Pharmacology or Physiology and two years of post-doctoral experience. The applicants should have experience in experimental cardiology and eicosanoid chemistry and biochemistry. He or she should be familiar with in vivo methods in open-chested dogs for measurement of coronary hemodynamics and cardiac function. In addition, applicants should have experience with in vitro methods for assessing coronary vascular tone, determining platelet function and culture of vascular cells. Regarding eicosanoid chemistry and biochemistry, applicants should be familiar with TLC and HPLC methods for isolation of eicosanoids, methods of preparing samples for mass spectrometric analysis and analytical methods as radioimmunoassay, HPLC or gas chromatography-mass spectrometry. Applicants should send a curriculum vitae and three letters of recommendation to Dr. James T. Willerson, University of Texas Southwestern Medical Center, Department of Internal Medicine, Division of Cardiology, 5323 Harry Hines Blvd., Dallas, TX 75235. THE UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL CENTER IS AN EQUAL OPPORTUNITY/AFFIRMATIVE ACTION EMPLOYER.

MILWAUKEE AREA: CARDIOLOGIST BC/BE for invasive and noninvasive practice. Rapidly expanding Cardiology Department has an immediate opening for a third Cardiologist to join the staff of a 55 physician multispecialty clinic located in a suburban setting within 20 minutes of downtown Milwaukee. Excellent salary and fringe benefits. Submit CV to Administrator, P.O. Box 427, Menomonee Falls, WI 53051 (Equal Opportunity Employer).

CARDIOLOGIST/NON-INVASIVE, BC/BE to practice in midwestern community with large multi-specialty group affiliation. Complete non-invasive skills and intensive care capabilities required. Excellent salary and fringe benefits. Send CV to Chief Executive Officer, Carle Clinic, Urbana, IL 61801.

Cardiologist

LOVELACE

MEDICAL CENTER

Lovelace Medical Center, a 230-bed hospital located in Albuquerque, New Mexico, is seeking a **Cardiologist** to join a group of 4 Cardiologists. Our institution provides a full range of cardiovascular health care including an active cardiac catheterization lab which is involved in diagnostic catheterization as well as urgent and elective coronary angioplasty, valvuloplasty, and electrophysiologic studies. We also have an active cardiac surgery program and have a strong affiliation with the University of New Mexico training program for cardiology fellows.

Lovelace Medical Center has opened a new hospital with an 8-bed Coronary Care Unit, a 2-bed open-heart recovery with an additional 10-bed Intensive Care Unit. State-of-the-art telemetry capabilities for arrhythmias detection are available in a step-down unit. The Cardiology Division also offers state-of-the-art echo and Doppler evaluations and the full range of cardiac nuclear studies.

The candidate we seek should be a fully trained cardiologist, specializing in noninvasive cardiology who is ABIM certified and board eligible or board certified in cardiology. Responsibilities will include supervising the noninvasive laboratory as well as the full range of clinical cardiovascular care and the education and training of Fellow within the Cardiology Department at the University of New Mexico. Attractive salary and benefits package is available. Please submit your curriculum vitae and letters of professional reference to: **Robert P. Croke, M.D. FACC, Chairman, Department of Cardiology, Lovelace Medical Center, 5400 Gibson Blvd SE, Albuquerque, NM 87108.**

Equal Opportunity Employer M/F/V/H

Professional Use Information

NITRO-BID® Plateau CAPS®

(nitroglycerin) 2.5 mg, 6.5 mg, and 9 mg

DESCRIPTION: Each NITRO-BID® Controlled-Release Capsule contains:
2.5 mg nitroglycerin: Light purple and clear capsule with white beads; identification imprint MARION/1550.
6.5 mg nitroglycerin: Dark blue and yellow capsule with white beads; identification imprint MARION/1551.
9 mg nitroglycerin: Green and yellow capsule with white beads; identification imprint MARION/1553.

ACTION: The mechanism of action of nitroglycerin in the relief of angina pectoris is not as yet known. However, its main pharmacologic action is to relax smooth muscle, principally in the smaller blood vessels, thus dilating arterioles and capillaries, especially in the coronary circulation. In therapeutic doses, nitroglycerin is thought to increase the blood supply to the myocardium which may, in turn, relieve myocardial ischemia, the possible functional basis for the pain of angina pectoris. The sublingual administration of nitroglycerin is normally rapid and transient, but nitroglycerin in controlled-release NITRO-BID® 2.5, NITRO-BID® 6.5, and NITRO-BID® 9 produces a prolonged action.

* **INDICATIONS:** Based on a review of this drug and a related drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective:
For the management, prophylaxis, or treatment of anginal attacks.
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS: Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure, and idiosyncrasy to the drug.

WARNINGS: Capsules must be swallowed. FOR ORAL, NOT SUBLINGUAL, USE. NITRO-BID® 2.5, NITRO-BID® 6.5, and NITRO-BID® 9 Controlled-Release Capsules are not intended for immediate relief of anginal attacks.

PRECAUTIONS: Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth, or lack of benefit occurs, the drug should be discontinued.

ADVERSE REACTIONS: Severe and persistent headaches, cutaneous flushing, dizziness, and weakness. Occasionally, drug rash or exfoliative dermatitis and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

DOSAGE AND ADMINISTRATION: Administer the smallest effective dose two or three times daily at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Patient should be titrated to anginal relief or hemodynamic response. Hemodynamic response can be measured by drop in systolic blood pressure. Discontinue if not effective.

HOW SUPPLIED: NITRO-BID® (nitroglycerin) 2.5, 6.5, and 9 Controlled-Release Capsules are available in 60- and 100-count bottles.

CAUTION: Federal law prohibits dispensing without prescription.

STORAGE: Store at a controlled room temperature. Dispense only in the original unopened container.

Issued 3/83

CORONARY ARTERY DISEASE

Determinants and Protective Potential of Coronary Arterial Collaterals as Assessed by an Angioplasty Model

K. PETER RENTROP, MD, JOHN C. THORNTON, PhD, FREDERICK FEIT, MD, and MARK VAN BUSKIRK, MS

Two indexes of collateral blood flow, the ratio of distal coronary occlusion pressure/aortic pressure (DCOP/Pao) and angiographic collateral class were determined during elective angioplasty in 36 patients with normal left ventricular function. The association between collateral indexes and 8 anatomic and clinical variables was assessed. A reduction in luminal diameter by ≥70% predicted angiographically demonstrable collaterals with 100% specificity and 85% sensitivity. Lesion severity (stenosis) correlated with both collateral class and DCOP/Pao: DCOP/Pao = 2.8809 − 0.0729 × stenosis + 0.00049 × stenosis^2. The data suggest a quantitative relation between lesion severity and collateral development beyond a threshold value of 70% stenosis. Left ventricular ejection fraction during ischemia caused by balloon occlusion (EFo) was found to be primarily determined by lesion location; however, collateral flow modified EFo significantly. For mid-left anterior descending and right coronary artery: EFo = 59 + 26 × (DCOP/Pao); for proximal left anterior descending artery: EFo = 24 + 89 × (DCOP/Pao). A model predicting the hemodynamic and clinical consequences of abrupt coronary closure based on lesion location and severity was developed. In the second study phase, this model was tested retrospectively in a different group of 23 patients who experienced coronary occlusion as a complication of angioplasty. The data of both study phases suggest that left ventricular function and clinical outcome after abrupt coronary closure are determined by an interaction between location of the coronary artery obstruction and the amount of collateral flow. Lesion severity and the extent of functional impairment resulting from abrupt coronary closure are inversely related.

(Am J Cardiol 1988;61:677–684)

Human hearts have <100-μ diameter congenital collateral channels, which can enlarge in the presence of a critical coronary lesion.[1-6] A quantitative relation between collateral development and the factors that might promote it—including lesion severity—has not been established. The functional relevance of collaterals in humans who experience abrupt coronary closure is controversial. In previous studies the relation between the degree of collateralization and the extent of myocardial necrosis[1,3] or wall motion abnormality[7,10] has been assessed days or weeks following coronary closure. In the experimental animal abrupt coro-

nary closure has been found to cause an increase of tangential wall stress in collaterals leading to a rapid luminal expansion of these channels.[11] After 24 hours there was mitotic activity resulting in active collateral growth.[12] Thus, the degree of collateralization at the time of acute coronary closure may be less than that found days or weeks after the event. Contradictory results of prior human studies may be explained by their retrospective nature.

With the development of coronary angioplasty it became possible to determine the immediate consequences of abrupt coronary closure in humans with simultaneous assessment of indexes of collateral flow. Two such indexes can be determined during controlled obstruction of a coronary artery by the inflated balloon used in percutaneous transluminal coronary angioplasty: distal coronary occlusion pressure and degree of angiographic visualization of collaterals.[13] Both indexes have been found to correlate with the amount of retrograde coronary blood flow determined during coronary artery bypass surgery.[14] In the animal model, coronary occlusion pressure is an accepted index of collateral flow.[15-17] In the present study, the association between indexes of collateral flow and lesion severity (as well as clinical variables) was assessed. Furthermore, the indexes of collateral flow were correlated with ejection fraction determined during angioplasty. Two models were developed to predict the degree of impairment of left ventricular function after abrupt coronary closure based on variables determined before or during angioplasty. In phase II, 1 of these models was validated clinically.

Methods

Phase I. Development of the model: Thirty-six patients who had successful elective angioplasty for 1-vessel disease of the left anterior descending or right coronary artery comprise the study population. Exclusion criteria have been published previously.[13] Informed consent was obtained from all patients. The consequences of abrupt coronary closure were assessed in the 29 patients whose coronary artery obstruction was not complete at baseline. Baseline ejection fraction was normal in all patients included in this portion of the study.

Cardiac catheterization and angioplasty: Patients were premedicated with oxazepam, 2 mg intramuscularly and 2 mg orally; aspirin, 325 mg orally; dipyridamole, 75 mg orally; nifedipine, 10 mg sublingually. Nitroglycerin was administered via a continuous intravenous infusion to maintain a systolic blood pressure between 105 and 120 mm Hg. Coronary angioplasty was performed using a standard brachial or femoral approach. A second arterial access was gained by placing a 5Fr sheath percutaneously in a femoral artery. Heparin sulfate, 10,000 units was administered intraarterially. Angioplasty was performed with standard, double lumen balloon catheters (USCI, ACS), en-

abling the determination of distal coronary occlusion pressure at the tip of the balloon. Pressures were determined with fluid-filled tubing and Statham P231D pressure transducers.

Acquisition of baseline data: A 5Fr pigtail catheter was advanced into the left ventricle and the angioplasty guiding catheter into the ascending aorta; left ventricular and aortic pressures were recorded. This was followed by baseline left ventriculography in the 30° right anterior oblique projection by injection of 40 ml of Renografin 38%. Subsequently, the pigtail catheter was removed and selective angiography of the contralateral coronary artery was performed by manual injection of 5 to 10 ml of Renografin-76.® Then, the guiding catheter was placed into the ostium of the vessel to be dilated and the lesion was visualized in several projections. Finally, the guidewire and angioplasty balloon were placed across the lesion and pressures at the tip of the balloon and in the aorta were recorded simultaneously.

Acquisition of intervention data: The lesion was dilated by 2 or 3 balloon inflations, sufficient to achieve prompt distal filling of the vessel around the deflated balloon. Following a rest period of 4 minutes, 3 additional balloon inflation cycles with a duration of 60 to 90 seconds each were performed during which data acquisition occurred. Three minutes of recovery were allowed between each of these inflations. Immediately before and during cycle 1, pressures were recorded continuously in the aorta, the left ventricle and at the tip of the balloon. During cycle 2, at 40 to 60 seconds of balloon inflation, a second left ventriculogram was acquired (Figures 1 and 2). During cycle 3, at 40 to 60 seconds, dye was injected manually into the contralateral coronary artery, to assess collateral status.

Data analysis: Lesion location and severity were assessed by a panel of 2 cardiologists who were not aware of any other patient findings. Lesions were grouped into 3 categories by location: right coronary artery, proximal left anterior descending artery and mid-left anterior descending artery.[18] The lesion and adjacent normal segment were traced using a magnified projection of the cineangiographic view demonstrating maximal severity. The diameters of the stenosed and adjacent normal segments were measured and lesion severity was expressed as percent reduction in lumen diameter.

Collateral classification: A panel of 2 cardiologists blinded to all other angiographic and clinical data qualitatively assessed collateral filling to the artery being dilated. Collateral filling of the obstructed vessel was classified based on presence and extent of epicardial filling by contralateral coronary artery injection at baseline and during balloon inflation, as follows: class 0 = no epicardial filling at baseline or during occlusion; class I = no epicardial filling at baseline with partial epicardial filling during balloon inflation; class II = partial epicardial filling at baseline with partial or complete filling during occlusion; class III = complete epicardial filling at baseline.

Pressures were measured at baseline and during balloon inflation in the first study cycle. The mean pressure measured at the tip of the angioplasty cathe-

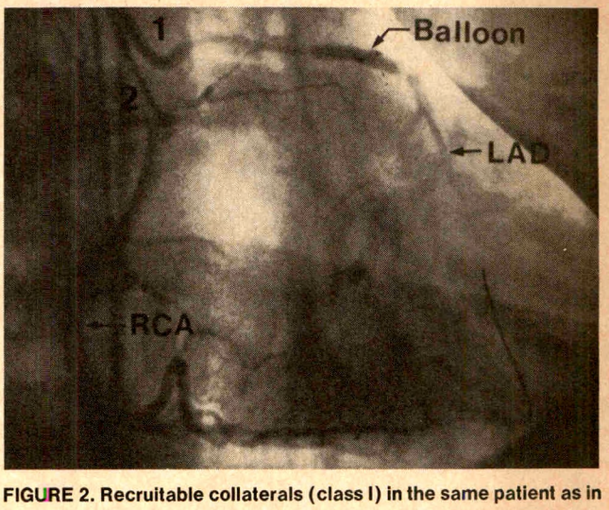

FIGURE 2. Recruitable collaterals (class I) in the same patient as in Figure 1. Dye injection into the right coronary artery (RCA) via catheter (*2*) during obstruction of the left anterior descending artery (LAD) by the inflated balloon results in filling of the mid-LAD beyond the site of occlusion via collateral channels. No collaterals were visible prior to ballon inflation. 1 = guiding catheter.

ter at 50 seconds of occlusion was called distal coronary occlusion pressure (DCOP). In the analysis of DCOP, a correction for mean aortic pressure was applied since these 2 pressures are related in a linear fashion and the majority of investigators assess the ratio DCOP/Pao.[16]

Left ventricular function: The left ventriculograms were acquired and analyzed with the Diasonics-Fischer digital subtraction imaging system. Calculation of ejection fraction was based on the area-length method.[19]

Statistics: The data went into an IBM XT computer. The SAS statistical software package was used to perform all statistical calculations. Comparisons among groups were made using chi-square tests for categorical variables and analysis of variance, and analysis of covariance for continuous variables. Differences in occlusion ejection fraction among collateral classes were assessed taking the 3 lesion location categories into consideration and adjusting for baseline ejection fraction. Linear regression methods were used to develop the model relating occlusion ejection fraction and DCOP/Pao.

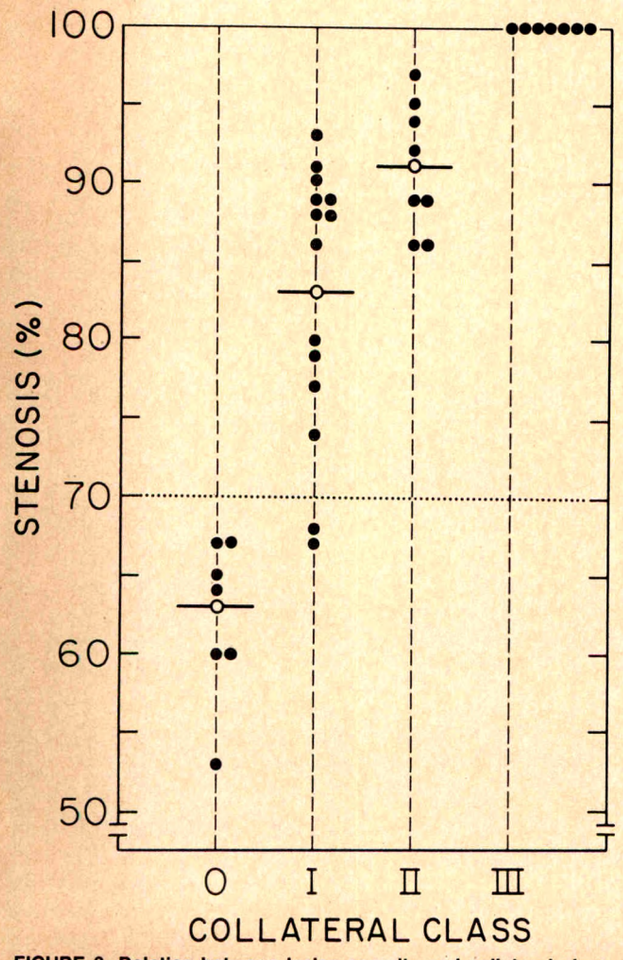

FIGURE 3. Relation between lesion severity and collateral class. ***Open circles*** **indicate mean values.**

Phase II. Clinical validation of the model: Based on the findings of phase I, the hypothesis was derived that the risk of hemodynamic collapse after abrupt coronary closure can be predicted by location and severity of the lesion prior to closure. Risk was predicted to be high with a proximal left anterior descending artery lesion <70%, intermediate with a proximal left anterior descending artery lesion >70%, low if there was a mid-left anterior descending artery or right coronary artery lesion. This hypothesis was tested in phase II in a second group of patients who experienced abrupt coronary closure as an angioplasty complication.

The study group included all 23 patients in a consecutive series of 1,300 procedures whose elective angioplasty of an isolated left anterior descending or right coronary artery lesion was complicated by total occlusion at the dilatation site. Preintervention lesion location and severity were assessed as in phase I of this study by investigators blinded to clinical outcome. The consequences of abrupt coronary occlusion were assessed in 2 categories: clinical outcome and treatment. Clinical outcome was defined by in-hospital vital status and immediate hemodynamic consequences of coronary artery occlusion. Treatment comprised the need for immediate interventions, such as intraaortic balloon counterpulsation due to severe ischemia with hemodynamic instability and emergency revascularization by either coronary artery bypass surgery or repeat angioplasty. Emergent bypass surgery was performed only in those patients who had ischemic pain persisting for more than 10 minutes after abrupt coronary closure.

ables was assessed (Table I). Seven patients were classified as collateral class 0, 14 as class I, 8 as class II and 7 as class III. There was a significant difference between all 4 collateral classes in degree of lesion severity ($p < 0.05$) (Figure 3). Collateral class 0 was associated with a mean lesion severity of 63% (range 53 to 67%), class I with 83% (62 to 93%), class II with 91% (85 to 97%) and class III with 100% in all patients (Table I and II). The findings suggest that a lesion of >70% severity predicts the presence of angiographically demonstrable collaterals with a specificity of 100% and a sensitivity of 85% (Figure 3).

Patients of collateral class 0 had significantly less severe angina pectoris as assessed by Canadian Heart Association criteria than patients with angiographically demonstrable collaterals ($p = 0.02$). There was a trend toward an association between collateral class and duration of angina pectoris ($p = 0.13$).

With each increment in collateral class for either left or right coronary artery, the DCOP/Pao rose significantly (Tables II and III). The relation between DCOP/Pao and lesion severity was described by a quadratic equation: DCOP/Pao = $2.8809 - 0.0729 \times \text{stenosis} + 0.00049 \times \text{stenosis}^2$; $R^2 = 0.68$; $p = 0.0001$ (Figure 4).

Left ventricular ejection fraction: During balloon occlusion, the left ventricular ejection fraction was found to be significantly related to lesion location ($p < 0.01$) and both indexes of collateral flow ($p < 0.05$). When DCOP/Pao was considered, the regression equations for mid-left anterior descending artery and right coronary artery did not differ: occlusion ejection fraction = $59 + 26 \times$ (DCOP/Pao). For patients with proximal left anterior descending artery the equation was: occlusion ejection fraction = $24 + 89 \times$ (DCOP/Pao). The R^2 for the model was 0.59 (Figure 5).

When collateral class was considered, 4 significantly different groups were identified (Figure 6): (1) proximal left anterior descending/collateral class 0: mean occlusion ejection fraction = 39%; (2) proximal left anterior descending/collateral class I: occlusion ejection fraction = 54%; (3) mid-left anterior descending/

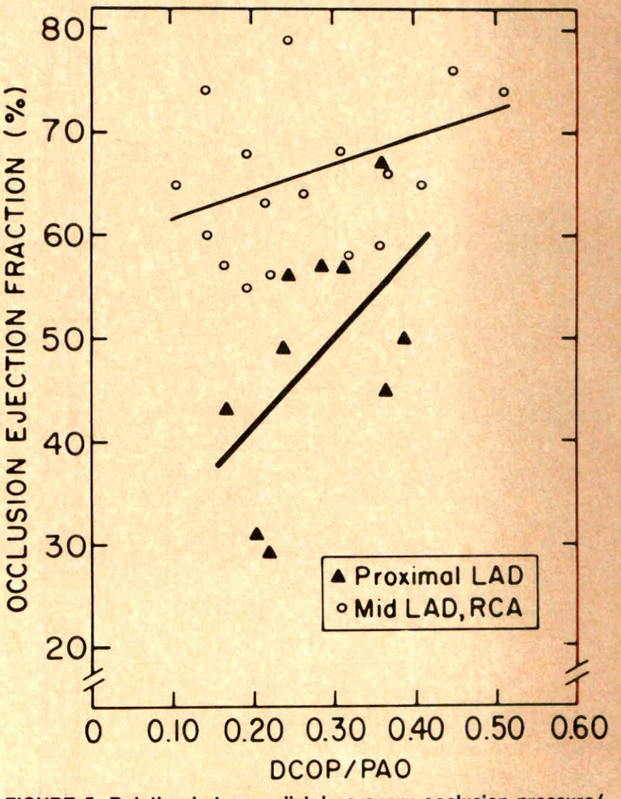

FIGURE 5. Relation between distal coronary occlusion pressure/aortic pressure ratio (DCOP/Pao), left ventricular ejection fraction during balloon inflation and lesion location. LAD = left anterior descending; RCA = right coronary artery.

collateral classes 0–II and right coronary artery/collateral classes 0–I: occlusion ejection fraction = 62%; (4) right coronary artery/collateral class II: occlusion ejection fraction = 73%. This was the only group in which the ejection fraction did not decrease during coronary closure.

Phase II: After abrupt coronary closure occurring as an angioplasty complication, both treatment and clinical outcome correlated with risk group assignment (Figure 7). The only deaths occurred in 2 of the 3 patients in the high-risk group. Cardiogenic shock occurred in all 3 patients of the high-risk group and in the 1 patient with the least severe lesion in the intermediate-risk group. Intraaortic balloon counterpulsation was used in 7 of 9 high- and intermediate-risk patients but in only 2 of the 14 low-risk patients. Emergency revascularization was performed in 8 of the 9 high- and intermediate-risk patients; 1 patient refused revascularization. Four of 14 low-risk patients did not evidence signs or symptoms of myocardial ischemia as a result of coronary obstruction and, therefore, did not undergo emergency revascularization.

Discussion

Threshold for collateral development: Although lesions with stenotic diameters ranging from 50 to 75% have occasionally been found in vessels receiving collateral flow,[20,21] lesion severity in collateralized vessels usually is at least 90% in most studies.[9,22] Our finding of a lesion severity of at least 86% in class II patients is in agreement with these reports. However, collaterals could be demonstrated during inflation of the angioplasty balloon in the majority of patients in whom they were not visible at baseline angiography. These collaterals, constituting class I in our classification, have been called "recruitable collaterals" in the literature.[13] The presence of such recruitable collaterals indicates that the frequency of collateral development in patients with coronary artery disease has been underestimated by standard angiographic techniques.

The existence of at least class I collaterals in all patients with a lesion having a diametric narrowing of >70% and the absence of any collateral filling during controlled coronary closure in almost all patients with <70% lesions suggest that this lesion severity may represent a threshold value for the development of collaterals in human hearts which are demonstrable by angiography during occlusion. The positive association between lesion severity and both indexes of collateral flow as assessed during coronary occlusion indicates that, beyond the threshold value, lesion severity and collateral development are quantitatively related. This relation probably applies only to patients with stable angina, such as those included in this study, who presumably have a chronic fixed coronary lesion.

Distal coronary occlusion pressure in humans and experimental animals: In dogs with chronic fixed constriction of the coronary artery, collateral flow was completely protective at the time of abrupt coronary ligation if the DCOP/Pao exceeded 0.5.[23] In the present study, we have demonstrated that patients with severe fixed coronary lesions may develop DCOP/Pao ratios comparable to those found in completely protected animals. This finding complements our previously published observation of complete preservation of local wall motion and absence of electrocardiographic signs of ischemia during balloon occlusion in patients with well-developed collaterals.[24]

Clinical importance of collateral flow: The findings of the present study suggest that the clinical conse-

quences of abrupt coronary closure result from an interaction between the location of the obstruction and the amount of collateral flow. The site of coronary obstruction determines the extent of myocardium at risk while the amount of collateral flow at the time of obstruction determines the degree of protection of that area.

In the case of right coronary artery or mid-left anterior descending obstruction, we observed DCOP/Pao values covering the entire spectrum of values reported in experimental studies. High DCOP/Pao values during occlusion in these patients were associated with complete or nearly complete preservation of global left ventricular function, indicating that the development of completely protective collaterals can be stimulated by a chronic subtotal lesion in humans. This hypothesis is supported by the lack of clinical signs of ischemia observed in some patients who experienced complete coronary occlusion of a high-grade lesion of the right coronary artery or the mid-left anterior descending branch as a complication of angioplasty in the second phase of this study. In those patients in whom the collateral indexes indicated minimal or absent collateral flow during right coronary artery or mid-left anterior descending balloon occlusion, the reduction of ejection fraction was moderate, reflecting the area of myocardium at risk. In the corresponding low-risk group of the second study phase, catastrophic events did not occur when percutaneous transluminal coronary angioplasty was complicated by coronary artery occlusion.

Collateral flow appears to be most important in patients with proximal left anterior descending occlusion, i.e., those patients who have a larger area at risk. Ejection fraction values during balloon occlusion were severely depressed in those patients in whom the collateral indexes indicated very low or absent collateral flow. Deaths occurred only in the corresponding high-risk group of the second study phase. Patients with recruitable collaterals had significantly higher ejection fraction values during proximal left anterior descending balloon inflation than those without collaterals. The corresponding intermediate-risk group of phase II was characterized by a more favorable clinical outcome than the high-risk group.

Limitations and conclusions: It is conceivable that the linear regression model shown in Figure 5 would not describe the relation between occlusion ejection fraction and DCOP/Pao accurately over a wider range of values. A leveling off toward a horizontal line at the high and low extremes of the spectrum would be expected.

It is possible that the nitrates and calcium antagonists uniformly applied during our studies affected collateral flow differently in the different collateral classes.[25-27]

Left ventricular function and collateral flow might not be the same 45 to 60 seconds after coronary closure and several hours thereafter.[11,28,29] The relation between left ventricular function immediately following coronary closure and clinical course over the subsequent hours is not known. In phase II of this study we have begun to address this problem by a retrospective analysis of clinical outcome in patients who experienced abrupt coronary closure as a complication of angioplasty. Conclusive testing of the model would require a prospective study of an analogous design.

In spite of their limitations, these models add to our understanding of the consequences of abrupt coronary closure in the natural history of symptomatic 1-vessel coronary artery disease. Clinical decisions are often based on the assumption that the prognostic importance of a lesion parallels its severity; however, the relation between lesion severity and collateral development shown with our model indicates an inverse relation between lesion severity and clinical consequences of abrupt coronary closure.

TABLE III Distal Coronary Pressure/Aortic Pressure by Collateral Class and Lesion Location

	Collateral Class			
Location	0	1	2	3
Right		18 (7)	38 (8)	56 (6)
LAD	21 (6)	29 (8)	39 (10)	56 (10)

Mean values (standard deviation).

Usefulness of Serial Radionuclide Monitoring During Graded Nitroglycerin Infusion for Unstable Angina Pectoris for Determining Left Ventricular Function and Individualized Therapeutic Dose

WARREN M. BREISBLATT, MD, NESTOR A. VITA, MD, MARCOS ARMUCHASTEGUI, MD, LAWRENCE S. COHEN, MD, and BARRY L. ZARET, MD

Using serial invasive hemodynamics in concert with noninvasive radionuclide monitoring of left ventricular (LV) function, 20 patients with unstable angina were evaluated during incremental infusion of intravenous nitroglycerin. Of 20 patients, 17 demonstrated a favorable hemodynamic response and dose responses could be determined for individual patients. There was excellent agreement between hemodynamic and noninvasive radionuclide measurements, and patient responses could be inferred from the radionuclide data alone. Cardiac output improved by 29% (mean 4.7 ± 1.2 to 6.0 ± 1.3), LV ejection fraction increased an average of 0.11 (0.39 ± 0.14 to 0.50 ± 0.16) and diastolic function as assessed by peak filling rate improved from 1.80 ± 0.60 end-diastolic volumes/s to 2.70 ± 0.90. Changes in systolic blood pressure and heart rate were not predictive of hemodynamic response. The dose of nitroglycerin necessary to produce maximal hemodynamic benefit was variable (mean 98 μg/min, range 48 to 144). In 7 patients, nitroglycerin caused excessive decreases in pulmonary arterial wedge pressure and adverse hemodynamics that corrected with intravenous fluids, allowing continued administration of intravenous nitroglycerin with improvement in hemodynamic status. In 15 patients, peak systolic pressure–end-systolic volume relations were assessed to define possible changes in LV contractility induced during nitroglycerin infusion. In 12 of these patients, this relation was linear, suggesting altered loading rather than augmented contractility as nitroglycerin's mechanism of action. In 3 patients a downward and rightward shift of the systolic relation was seen, suggesting that significant underloading with nitroglycerin was associated with depressed contractility.

(Am J Cardiol 1988;61:685–690)

The use of intravenous nitroglycerin as a potential therapeutic modality in patients with coronary artery disease was first reported in 1962.[1,2] However, it is only relatively recently that intravenous nitroglycerin has been used widely in the treatment of patients with acute myocardial infarction and unstable angina.[3–6] Several studies have emphasized its therapeutic utility when added to conventional antianginal therapy in patients with unstable angina.[7–9] Nevertheless, questions remain concerning the optimal therapeutic dose of intravenous nitroglycerin in such patients, its effect (either positive or negative) on left ventricular (LV) performance in this circumstance and the optimal means of monitoring patients during therapy. The present study was undertaken to provide a framework within which to deal with these issues. Invasive hemodynamic measurement was both compared and used in concert with noninvasive serial radionuclide monitoring of LV function in a series of patients with unstable angina receiving incremental dose infusions of intravenous nitroglycerin. We attempted to: (1) compare

the results of invasive and noninvasive monitoring in each patient and (2) assess the relation of changes in LV function to changes in contractility as inferred from evaluation of LV systolic pressure-volume relations.

Methods

Patient population: The study population consisted of 20 patients hospitalized with unstable angina pectoris: in 7 patients the unstable syndrome occurred in the peri-infarction period and in the remaining 13 patients there was either a marked change in a preexisting stable anginal pattern or the new onset of angina requiring hospitalization in a coronary care unit. All patients had been treated with 1 or more of the following: nonparenteral nitrate preparations (13 patients, 66%) β-blocking agents (14 patients, 70%), and calcium antagonist agents (9 patients, 45%) before initiation of intravenous nitroglycerin. Fourteen patients were receiving 2 or more antianginal agents before intravenous nitroglycerin. Patients ranged in age from 42 to 78 years (mean 59); 12 were men and 8 women. Eighteen of 20 patients were evaluated with coronary angiography. Eleven had 3-vessel disease, 4 had 2-vessel disease and 2 had 1-vessel disease (both involving high grade proximal left anterior descending coronary artery stenosis). Based on initial physical examination 6 patients were thought to have some manifestation of congestive heart failure.

Hemodynamic-radionuclide protocol: Nitroglycerin for parenteral use (400 μg/cc) was administered by infusion pump, starting at a dose of 10 μg/min. The dose was increased at 10 μg/min increments every 5 minutes. Patients were titrated to a maximal tolerated dose that was defined by either a 20% reduction in systolic blood pressure, a decrease in systolic blood pressure to a level of 90 mm Hg irrespective of the baseline value or development of intolerance to proto-

col duration or intolerable drug side effects. In 15 patients the study was performed at the bedside in the coronary care unit; in 5 it was obtained in the cardiac catheterization laboratory.

Before the institution of intravenous nitroglycerin all patients had a balloon-tip catheter placed in the pulmonary artery. In 14 patients blood pressure was monitored by arterial line. In the remaining 6 patients, a sphygmomanometer was used. Radionuclide monitoring of function was obtained with a nonimaging nuclear probe (Nuclear Stethoscope, Bios). Nuclear studies were obtained following equilibrium blood pool labeling with technetium-99m (25 mCi) according to a modified in vitro technique.[10] Standard probe positioning algorithms were used to define LV and background regions. Acquisition of individual electrocardiographic gated nuclear probe studies required 60 seconds. Radionuclide-determined parameters included LV ejection fraction, LV peak filling rate normalized to end-diastolic volume and radionuclide relative stroke volume. Background measurement was rechecked every 20 minutes. Hemodynamic measurements included heart rate, blood pressure, cardiac output, right atrial pressure, pulmonary artery pressure and pulmonary arterial wedge pressure. Cardiac output was determined in duplicate by thermodilution. LV volumes were derived from the relation between LV ejection fraction (by nuclear probe) and stroke volume (by thermodilution).

For each patient, hemodynamic and radionuclide data were obtained during the last minute at each dose level. In this manner individual dose-responses could be determined. Monitoring was continued when intravenous fluid therapy was administered because of the initial hemodynamic response to nitroglycerin.

In 15 patients LV peak systolic pressure-end systolic data were defined at each dose level of nitroglycerin. These points were plotted to define a systolic pressure-volume relation for each patient. Analysis of pressure-volume plots allowed assessment of changes in LV contractility possibly induced during nitroglycerin infusion.[11]

Statistical methods: Data are given as mean ± standard deviation. Linear correlations between parameters were derived in a standard manner. Differences between baseline and treatment effects within patient groups were assessed by paired *t* test.

Results

Hemodynamic responses: Intravenous nitroglycerin resulted in substantial improvement in hemodynamic status in the majority of patients studied (Table I). Within the confines of our protocol, 17 of 20 patients demonstrated a favorable hemodynamic response defined by an increase in cardiac output of at least 10%.[12] In these 17 patients, cardiac output improved by 29% (range 14 to 55). Mean baseline cardiac output increased from 4.7 ± 1.2 to 6.0 ± 1.3 liters/min ($p < 0.004$) at the time of maximal augmentation. Heart rate remained unchanged (72 ± 16 at baseline versus 71 ± 18 beats/min at the time of peak effect). Systolic blood pressure decreased by 11 ± 12 mm Hg at the time of maximal hemodynamic effect. Baseline systolic blood pressure averaged 121 ± 16 mm Hg and was 110 ± 13 at the time of peak effect. Peak hemodynamic improvement occurred over a wide range of wedge pressures in individual patients. The nitroglycerin dose necessary to produce maximal hemodynamic benefit within the protocol constraints likewise was quite variable. The mean dose at the time of maximal improvement in cardiac output was 98 μg/min (range 48 to 144).

Radionuclide parameters demonstrated comparable levels of improvement in the 17 responders. LV ejection fraction improved, with an average increase of 0.11 ± 0.05. This increase is far in excess of the

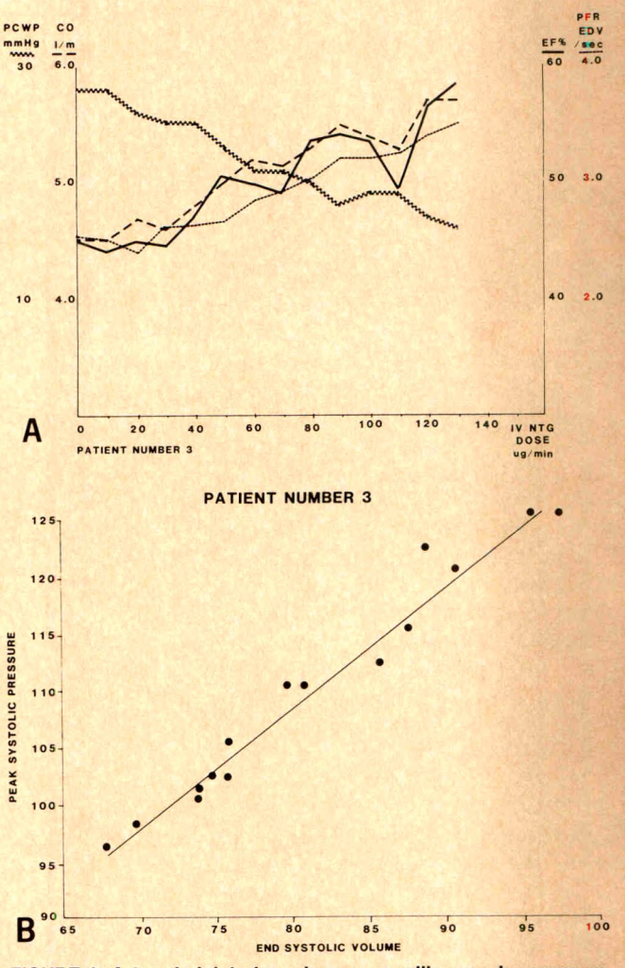

FIGURE 1. *A*, trended data for pulmonary capillary wedge pressure (PCWP), cardiac output (CO), ejection fraction (EF) and peak filling rate (PFR) during the incremental dose infusion of intravenous nitroglycerin (IV NTG). Data were obtained at each dose. The dose of IV NTG is plotted on the horizontal axis and the hemodynamic parameters on the vertical axis. Note that with the incremental dose of nitroglycerin there is a progressive increase in EF (*solid lines*) and PFR, associated with an increase in CO and a decrease in PCWP. *B*, the peak systolic pressure–end-systolic volume plot in the same patient is shown. Note that this relation remains linear, indicating that the changes encountered are related to altered loading conditions.

SV = stroke volume (measured by thermodilution); other abbreviations as in Table I.

intrinsic variability of the measurement.[13,14] Mean baseline LV ejection fraction was 0.39 ± 0.14 and this increased to 0.50 ± 0.16 at the time of maximal hemodynamic effect ($p < 0.05$). The individual range of improvement was 0.05 to 0.24. Relative radionuclide stroke volume increased from 0.43 ± 0.18 to 0.64 ± 0.23 (52%). End-diastolic volume did not change significantly: 165 ± 52 cc at baseline and 162 ± 48 at time of peak effect, whereas end-systolic volume decreased from 105 ± 43 to 80 ± 13 cc ($p < 0.05$). LV diastolic function, as assessed by peak filling rate also improved, increasing from 1.80 ± 0.60 to 2.70 ± 0.90 end-diastolic volumes/s at peak dose ($p < 0.004$). Changes in filling rate correlated closely with changes in LV ejection fraction in individual patients (Table II). The r value averaged 0.87 and ranged from 0.70 to 0.98 in individual patients.

Favorable responses also were seen in the 10 patients in whom filling pressures were elevated (wedge pressure ≥18 mm Hg). In these patients wedge pressure decreased from 24 ± 4 to 16 ± 3 mm Hg at peak effect. In these same patients systolic blood pressure decreased from 120 ± 34 to 104 ± 7 mm Hg. As in the group as a whole, there was no change in heart rate in these patients (73 vs 73 beats/min). In this subgroup cardiac output increased from 4.4 ± 0.9 to 5.7 ± 1.2 liters/min and LV ejection fraction increased from 0.35 ± 0.17 to 0.46 ± 0.19. There were no significant differences between responses to nitroglycerin in patients with significant elevation in wedge pressure and those 10 patients without such elevation. Improvement in LV ejection fraction and cardiac output also were similar. However, those patients with lower LV filling pressure often needed an elevated wedge pressure, achieved through fluid administration, to obtain maximal hemodynamic effect. Neither changes in blood pressure nor heart rate predicted hemodynamic responses. Comparable trends were also seen in the 7 patients with peri-infarction angina.

Comparison of serial radionuclide and hemodynamic data: In general, there was excellent agreement between hemodynamic and radionuclide measurements in this protocol (Table II). The correlation between thermodilution cardiac output and LV ejection fraction in each patient averaged r = 0.85. In 16 of 20 patients, r was >0.80. Thermodilution stroke volume correlated well with radionuclide relative stroke volume, with r averaging 0.90. The r value was 0.80 in 18 of 20 patients. The parallel nature of the responses of invasive and noninvasive parameters is illustrated in Figures 1 and 2.

Use of intravenous fluids with nitroglycerin: In 7 patients (patients 7 through 11, 15, 17) nitroglycerin

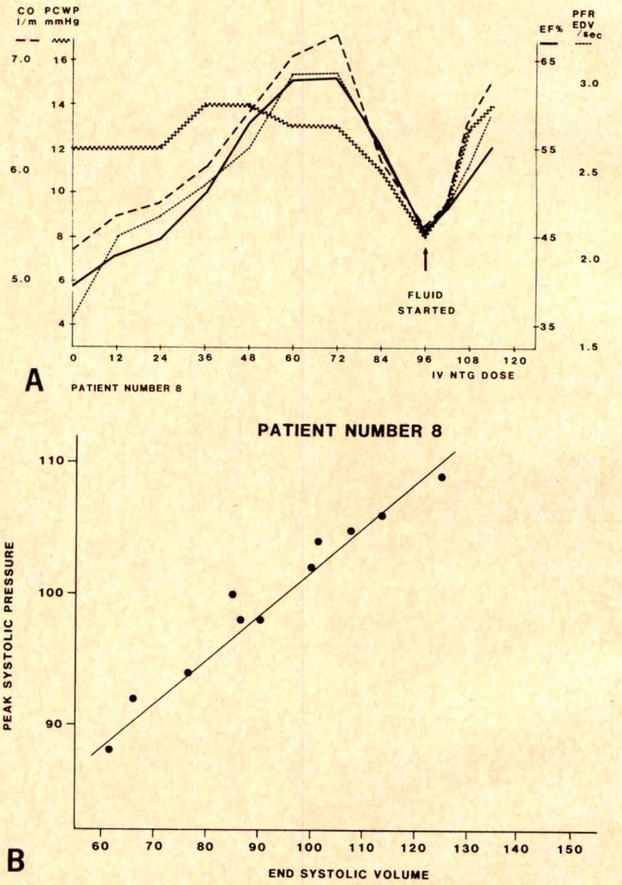

FIGURE 2. *A*, relation between cardiac output (CO), pulmonary capillary wedge pressure (PCWP), ejection fraction (EF) and peak filling rate (PFR) during an incremental nitroglycerin infusion in a patient requiring intravenous volume to maintain effective forward output. The format is the same as in Figure 1. Note the tracking of the radionuclide and invasive parameters as well as the substantial improvement achieved after fluid infusion. *B*, the peak systolic pressure–end-systolic volume plot in the same patient is shown. Despite significant increments and decrements in ejection fraction, this pressure-volume relation remains linear. One can infer from this that no change in contractility has occurred.

TABLE III The Role of Volume Expansion During Intravenous Therapy*

	Systolic BP (mm Hg)	HR (bpm)	EF	PCWP (mm Hg)	PFR	CO (liters/min)	RSV
Baseline	114	66	0.44	22	1.87	4.5	0.45
Peak (initial)	105	68	0.56	16	2.72	6.3	0.65
Trough	95	69	0.47	11	2.05	5.1	0.53
After intravenous fluids	107	68	0.54	17	2.56	6.1	0.62

* Data from 7 patients (7 through 11,15,17) receiving a mean of 340 cc intravenous fluids (range 200 to 500). Abbreviations as in Table I.

caused excessive decreases in wedge pressure associated with decreases in systemic blood pressure and symptoms, but no appreciable change in heart rate (Table III). In these patients, intravenous fluids were used to increase filling pressures and allow continued administration of intravenous nitroglycerin (Figure 2 and Table III). In these patients, 200 to 500 cc of intravenous fluid (normal saline) was administered (mean 340). With the falling pressure there was a decrease in cardiac output, blood pressure, ejection fraction, filling rate and relative stroke volume. Hemodynamic status was reversed with fluids and there was good tracking between invasive and noninvasive measures.

Systolic pressure-volume relations: Linear peak systolic pressure–end-systolic volume relations were demonstrated in each of the 15 patients so evaluated. An average of 10 pressure-volume points were obtained for each patient. The correlation coefficient for the 15 patients averaged 0.87 (range 0.56 to 0.98). In 11 of 15 patients r was >0.80. The linearity of the relation suggests that although LV ejection fraction was increasing during therapy, this was the result of altered loading rather than augmented contractility. As noted previously, when nitroglycerin resulted in excessive decreases in filling pressures, there was an associated decrease in cardiac output and LV ejection fraction. In most instances the decrease in ejection fraction occurred with no alteration in the linear nature of the systolic pressure-volume relation. However, in 3 patients (Figure 3) this was accompanied by a shift of the systolic pressure-volume relation downward and to the right. In 2 of these 3 patients there was either associated recurrent chest pain or ST-segment alteration. In these 3 patients, we postulate that underloading after intravenous nitroglycerin resulted in a sufficient decrease in coronary perfusion pressure to result in ischemia-related altered left ventricular contractility. It should be emphasized that this was seen in relatively few patients.

Discussion

Use of intravenous nitroglycerin is an important aspect of contemporary care. This therapy has been applied to patients with acute myocardial infarction, congestive heart failure and acute hypertension after cardiac surgery. Perhaps its most important application lies in the management of patients with unstable angina. Although this therapy currently is employed widely, there still is no general agreement concerning definition of both optimal therapy and objective monitoring criteria. The present study demonstrates that under carefully monitored conditions, substantial hemodynamic improvement can be demonstrated in most patients receiving graded nitroglycerin infusion. Although serial observation with pulmonary artery catheters still remains the appropriate current standard for therapeutic monitoring, this study also illustrates the potential of serial noninvasive monitoring. The measured noninvasive parameters both complement as well as correlate with invasively derived data.

Within the confines of our protocol, maximal improvement in hemodynamic status as judged by cardiac output was not predicated by achieving either a single dose of nitroglycerin or a specific decrement in systolic blood pressure. A decrease in mean systemic blood pressure of 10% has been advocated as a means of effectively and safely titrating intravenous nitroglycerin.[12] Only 35% of patients in our series would have noted a maximal hemodynamic effect if such a

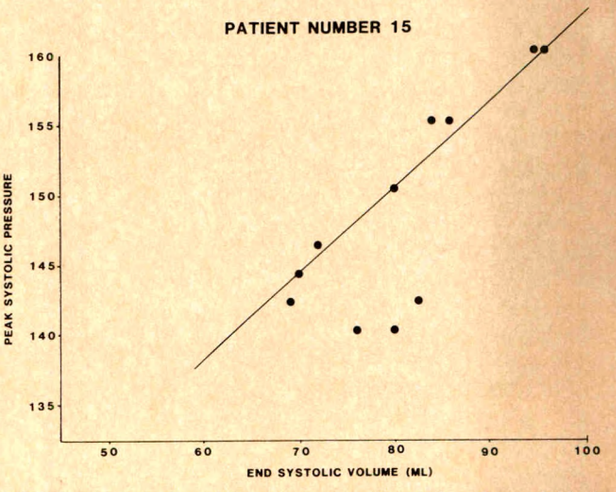

FIGURE 3. The peak systolic pressure–end-systolic volume plot in 1 of 3 patients requiring intravenous volume during intravenous nitroglycerin and also manifesting an abnormal systolic pressure-volume relation. In contrast to the previous example, in this patient there are several points in the systolic pressure-volume relation that are below and to the right of the linear relation. This suggests decreased contractility, presumably due to coronary underperfusion associated with a marked decrease in filling pressures and forward output due to intravenous nitroglycerin.

protocol had been followed. On the other hand, it is clear that a protocol of continuing graded increments in nitroglycerin dose can result in deleterious hemodynamic effects, with substantial reduction in filling pressures and subsequent decrease in cardiac output and LV performance. For these reasons, detailed but nevertheless simple monitoring of hemodynamic status should be considered. In this series, noninvasive parameters tracked and paralleled hemodynamic data quite well, thereby suggesting a possible future role in monitoring therapy. Significant correlations between invasive and noninvasive data were obtained in each patient. The concept of noninvasive monitoring for optimization of therapy clearly merits further prospective evaluation.

Radionuclide monitoring was obtained with a nonimaging nuclear probe. This instrument is relatively compact when compared with conventional scintillation cameras.[13,14] However, when considered as a means of serial monitoring of the acutely ill patient, its size and positioning pose potential logistic problems. These problems conceivably can be solved with miniaturized detector apparatus that can either be affixed directly on the chest wall or worn by the patient.[15-18]

From a mechanistic standpoint, changes in LV function were generally related to altered loading circumstances. This was inferred from observation of the systolic pressure-volume relations. Nevertheless, in a small subset of patients actual changes in contractility did occur. Although in this study ventricular volumes were measured by combining ejection fraction and thermodilution stroke volume measurements, actual ventricular volume measurements can be obtained with radionuclide data when appropriate attenuation correction is used. The use of systolic pressure-volume relations to differentiate changes in loading from those due to altered contractility clearly is an important issue that can be addressed directly by this approach. The use of peripheral systolic pressure to obtain an estimate of peak systolic pressure is well accepted.[19]

It was somewhat surprising that in our patients, despite a decrease in end-systolic volume, end-diastolic volume did not decrease. This suggests that under these circumstances, the effects of intravenous nitroglycerin were more evident on the resistance than capacitance circulation. The concomitant administration of other vasoactive drugs may have contributed to this somewhat paradoxical event. Changes in diastolic performance, as measured by peak filling rate, paralleled closely those in LV ejection fraction. This suggests that nitroglycerin effects on diastolic function were not necessarily independent, but rather linked, at least in part, to changes in systolic performance.

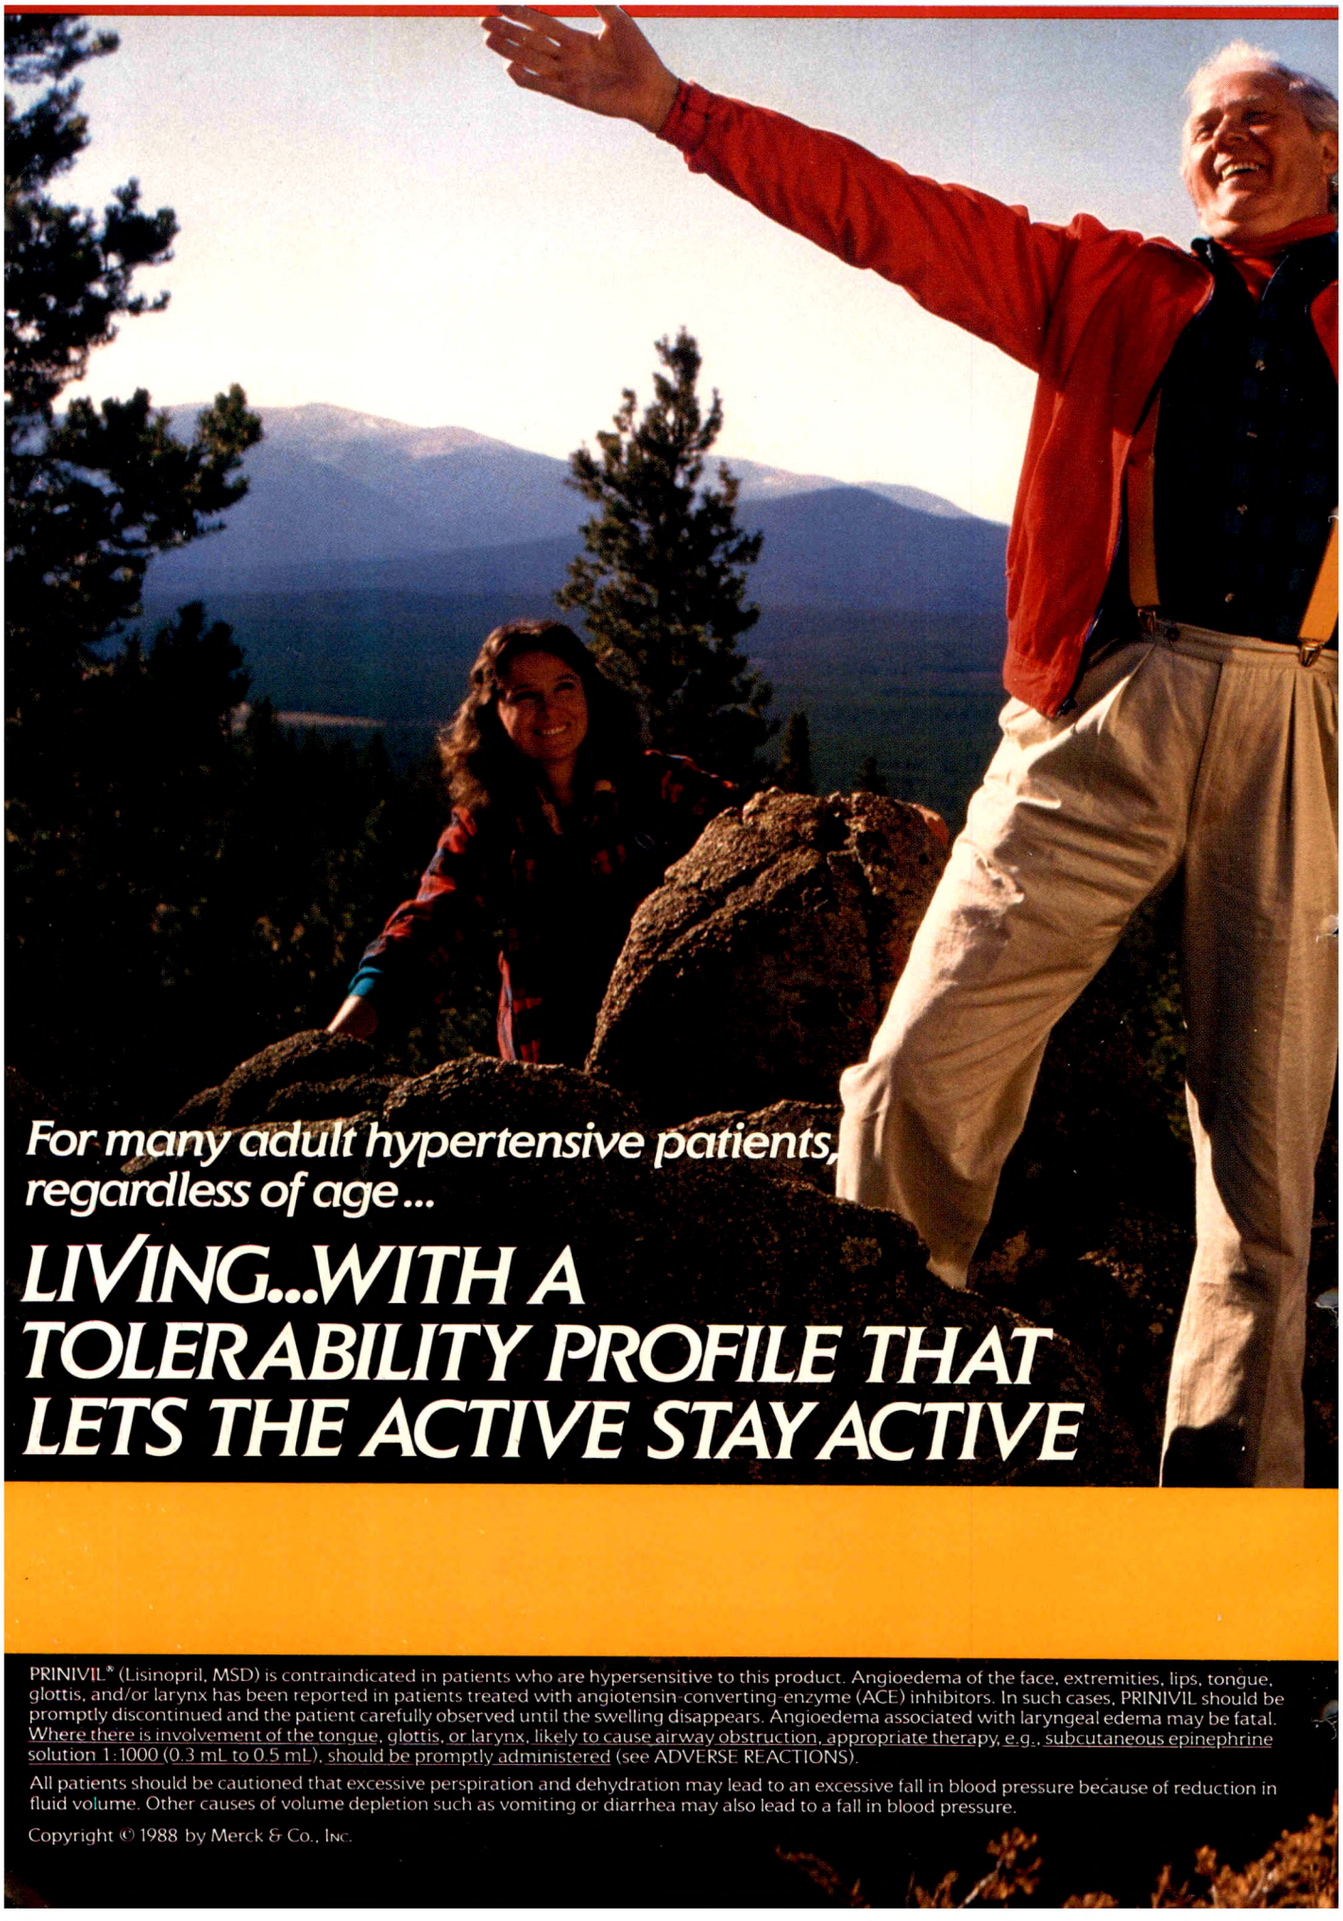
MSD
MERCK SHARP & DOHME
A NEW WAY OF LIVING WITH ANTIHYPERTENSIVE THERAPY...
ONCE-DAILY
New PRINIVIL®
(LISINOPRIL/MSD)
A New ACE Inhibitor Discovered and Developed by Merck Sharp & Dohme Research Laboratories
For a Brief Summary of Prescribing Information, please see the last page of this advertisement.



PRINIVIL® (Lisinopril, MSD) is contraindicated in patients who are hypersensitive to this product. Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with angiotensin-converting enzyme (ACE) inhibitors. In such cases, PRINIVIL should be promptly discontinued and the patient carefully observed until the swelling disappears. Angioedema associated with laryngeal edema may be fatal. Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered (see ADVERSE REACTIONS).

All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure.

MSD
MERCK SHARP & DOHME
Keeping physically active is one of the important recommendations made to most hypertensive patients. ACE inhibitors, such as **PRINIVIL**, can be particularly valuable in these patients.
LIVING... free from many activity-limiting side effects
ACE inhibitors, including **PRINIVIL**, are not characteristically associated with:
☐ decreased exercise capacity
☐ malaise or drowsiness
☐ muscle cramps
☐ reduced cardiac output
☐ decreased heart rate
☐ depressed myocardial contractility
LIVING... free from other lifestyle-limiting side effects
ACE inhibitors, including **PRINIVIL**, are not characteristically associated with:
☐ impotence—incidence 0.7% in clinical trials
☐ constipation
☐ peripheral edema, weight gain
Adverse reactions observed most frequently in controlled trials were dizziness (6.3%), headache (5.3%), fatigue (3.3%), diarrhea (3.2%), upper respiratory symptoms (3.0%), and cough (2.9%). For more information on adverse reactions, please see the Brief Summary of Prescribing Information on the next page.
Tablet
10 mg
Usual starting dose is 10 mg in patients with uncomplicated hypertension not on diuretic therapy.
New ONCE-DAILY PRINIVIL®
(LISINOPRIL/MSD)
LIVING... AS YOUNG AS THEY FEEL
For a Brief Summary of Prescribing Information, please see the last page of this advertisement.

Contraindications:
PRINIVIL® (Lisinopril, MSD) is contraindicated in patients who are hypersensitive to this product.

Warnings:
Angioedema: Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with ACE inhibitors, including PRINIVIL. In such cases, PRINIVIL should be promptly discontinued and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips, the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered** (see ADVERSE REACTIONS).
Hypotension: Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of the use of PRINIVIL in salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis (see PRECAUTIONS, *Drug Interactions* and ADVERSE REACTIONS). In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first 2 weeks of treatment and whenever the dose of PRINIVIL and/or diuretic is increased. Similar considerations apply to patients with ischemic heart or cerebrovascular disease in whom an excessive fall in blood pressure could result in a myocardial infarction or cerebrovascular accident.
If hypotension occurs, the patient should be placed in a supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses, which usually can be given without difficulty once the blood pressure has increased after volume expansion.
Neutropenia/Agranulocytosis: Another ACE inhibitor has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease. Available data from clinical trials of PRINIVIL are insufficient to show that PRINIVIL does not cause agranulocytosis at similar rates. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered.

Precautions:
General: Impaired Renal Function: As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors, including PRINIVIL, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death.
In hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine may occur. Experience with another ACE inhibitor suggests that these increases are usually reversible upon discontinuation of PRINIVIL and/or diuretic therapy. In such patients renal function should be monitored during the first few weeks of therapy.
Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when PRINIVIL has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction of PRINIVIL and/or discontinuation of the diuretic may be required.
Evaluation of the hypertensive patient should always include assessment of renal function (see DOSAGE AND ADMINISTRATION).
Hyperkalemia: In clinical trials, hyperkalemia (serum potassium > 5.7 mEq/L) occurred in approximately 2.2% of hypertensive patients and 4.0% of patients with congestive heart failure. In most cases, these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in approximately 0.1% of hypertensive patients. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with PRINIVIL (see *Drug Interactions*).
Surgery/Anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, PRINIVIL may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.
Information for Patients:
Angioedema: Angioedema, including laryngeal edema, may occur, especially following the first dose of PRINIVIL. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to take no more drug until they have consulted with the prescribing physician.
Symptomatic Hypotension: Patients should be cautioned to report lightheadedness, especially during the first few days of therapy. If actual syncope occurs, patients should be told to discontinue the drug until they have consulted with the prescribing physician.
All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with their physician.
Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.
Neutropenia: Patients should be told to report promptly any indication of infection (e.g., sore throat, fever) which may be a sign of neutropenia.
NOTE: As with many other drugs, certain advice to patients being treated with PRINIVIL is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.
Drug Interactions:
Hypotension: Patients on Diuretic Therapy: Patients on diuretics and especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with PRINIVIL® (Lisinopril, MSD). The possibility of hypotensive effects with PRINIVIL can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with PRINIVIL. If it is necessary to continue the diuretic, initiate therapy with PRINIVIL at a dose of 5 mg daily, and provide medical supervision after the initial dose for at least 2 hours and until blood pressure has stabilized for at least an additional hour (see WARNINGS and DOSAGE AND ADMINISTRATION). When a diuretic is added to the therapy of a patient receiving PRINIVIL, an additional antihypertensive effect is usually observed. Studies with ACE inhibitors in combination with diuretics indicate that the dose of the ACE inhibitor can be reduced when it is given with a diuretic (see DOSAGE AND ADMINISTRATION).
Indomethacin: In a study in 36 patients with mild to moderate hypertension where the antihypertensive effects of PRINIVIL alone were compared to PRINIVIL given concomitantly with indomethacin, the use of indomethacin was associated with a reduced effect, although the difference between the two regimens was not significant.
Other Agents: PRINIVIL has been used concomitantly with nitrates and/or digoxin without evidence of clinically significant adverse interactions. No clinically important pharmacokinetic interactions occurred when PRINIVIL was used concomitantly with propranolol or hydrochlorothiazide. The presence of food in the stomach does not alter the bioavailability of PRINIVIL.
Agents Increasing Serum Potassium: PRINIVIL attenuates potassium loss caused by thiazide-type diuretics. Use of PRINIVIL with potassium-sparing diuretics (e.g., spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated because of demonstrated hypokalemia, they should be used with caution and with frequent monitoring of serum potassium.
Pregnancy Category C: Lisinopril was not teratogenic in mice treated on days 6 to 15 of gestation with up to 1,000 mg/kg/day (625 times the maximum recommended human dose). There was an increase in fetal resorptions at doses down to 100 mg/kg; at doses of 1,000 mg/kg, this was prevented by saline supplementation. There was no fetotoxicity or teratogenicity in rats treated with up to 300 mg/kg/day (188 times the maximum recommended dose) of lisinopril at days 6 to 17 of gestation. In rats receiving lisinopril from day 15 of gestation through day 21 postpartum, there was an increased incidence in pup deaths on days 2 to 7 postpartum and a lower average body weight of pups on day 21 postpartum. The increase in pup deaths and decrease in pup weight did not occur with maternal saline supplementation.
Lisinopril, at doses up to 1 mg/kg/day, was not teratogenic when given throughout the organogenic period in saline-supplemented rabbits. Saline supplementation (physiologic saline in place of tap water) was used to eliminate maternotoxic effects and enable evaluation of the teratogenic potential at the highest possible dosage level. The rabbit has been shown to be extremely sensitive to ACE inhibitors (captopril and enalapril) with maternal and fetotoxic effects apparent at or below the recommended therapeutic dosage levels in man. Fetotoxicity was demonstrated in rabbits by an increased incidence of fetal resorptions at a dose of lisinopril at 1 mg/kg/day and by an increased incidence of incomplete ossification at the lowest dose tested (0.1 mg/kg/day).
There are no adequate and well-controlled studies in pregnant women. PRINIVIL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nursing Mothers: It is not known whether this drug is secreted in human milk. Because many drugs are secreted in human milk, caution should be exercised when PRINIVIL is given to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.

Adverse Reactions:
PRINIVIL has been found to be generally well tolerated in controlled clinical trials involving 2,003 patients and subjects.
The most frequent clinical adverse experiences in controlled trials with monotherapy with PRINIVIL were: dizziness (6.3%), headache (5.3%), fatigue (3.3%), diarrhea (3.2%), upper respiratory symptoms (3.0%), and cough (2.9%), all of which were more frequent than in placebo-treated patients. For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6% of patients. In clinical trials, the overall frequency of adverse experiences could not be related to total daily dosage within the recommended therapeutic dosage range.
Other adverse experiences occurring in greater than 1% of patients and subjects treated with monotherapy with PRINIVIL in controlled clinical trials were: nausea (2.3%), hypotension (1.8%), rash (1.5%), orthostatic effects (1.4%), asthenia (1.3%), chest pain (1.3%), vomiting (1.3%), and dyspnea (1.1%). For information on adverse experiences occurring in greater than 1% of patients and subjects treated with PRINIVIL plus hydrochlorothiazide in controlled clinical trials, see Prescribing Information.
Clinical adverse experiences occurring in 0.3% to 1% of patients treated with monotherapy with PRINIVIL in the controlled trials and rarer, serious, possibly drug-related events reported in uncontrolled studies or marketing experience included: *Body as a Whole:* Chest discomfort, fever, flushing. *Cardiovascular:* Angina pectoris, orthostatic hypotension, rhythm disturbances, tachycardia, peripheral edema, palpitation. *Digestive:* Abdominal pain, anorexia, constipation, flatulence. *Metabolism:* Gout. *Musculoskeletal:* Joint pain, shoulder pain. *Nervous System/Psychiatric:* Depression, somnolence, insomnia, stroke. *Respiratory System:* Bronchitis, sinusitis, pharyngeal pain. *Urogenital:* Oliguria, progressive azotemia, acute renal failure. *Other:* Blurred vision, pruritus, urinary tract infection, vasculitis of the legs. *Angioedema:* Angioedema has been reported in patients receiving PRINIVIL® (Lisinopril, MSD) (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with PRINIVIL should be discontinued and appropriate therapy instituted immediately (see WARNINGS). *Hypotension:* In hypertensive patients, hypotension occurred in 1.2% and syncope occurred in 0.1% of patients. Hypotension or syncope was a cause for discontinuation of therapy in 0.5% of hypertensive patients (see WARNINGS). In patients with congestive heart failure, hypotension occurred in 5% and syncope occurred in 1% of patients. These adverse experiences were cause for discontinuation of therapy in 1.3% of these patients.
Clinical Laboratory Test Findings:
Serum Electrolytes: Hyperkalemia (see PRECAUTIONS).
Creatinine, Blood Urea Nitrogen: Minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 2% of patients with essential hypertension treated with PRINIVIL alone. Increases were more common in patients receiving concomitant diuretics and in patients with renal artery stenosis (see PRECAUTIONS). Reversible minor increases in blood urea nitrogen and serum creatinine were observed in approximately 9.1% of patients with congestive heart failure on concomitant diuretic therapy. Frequently, these abnormalities resolved when the dosage of the diuretic was decreased.
Hemoglobin and Hematocrit: Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.4 g % and 1.3 vol %, respectively) occurred frequently in patients treated with PRINIVIL but were rarely of clinical importance in patients without some other cause of anemia. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia.
Other (Causal Relationship Unknown): Rarely, elevations of liver enzymes and/or serum bilirubin have occurred.
Overall, 2.0% of patients discontinued therapy due to laboratory adverse experiences, principally elevations in blood urea nitrogen (0.6%), serum creatinine (0.5%), and serum potassium (0.4%).

Dosage and Administration:
Initial Therapy: In patients with uncomplicated essential hypertension not on diuretic therapy, the recommended initial dose is 10 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 20 to 40 mg per day administered in a single daily dose. The antihypertensive effect may diminish toward the end of the dosing interval regardless of the administered dose, but most commonly with a dose of 10 mg daily. This can be evaluated by measuring blood pressure just prior to dosing to determine whether satisfactory control is being maintained for 24 hours. If it is not, an increase in dose should be considered. Doses up to 80 mg have been used but do not appear to give a greater effect. If blood pressure is not controlled with PRINIVIL alone, a low dose of a diuretic may be added. Hydrochlorothiazide 12.5 mg has been shown to provide an additive effect. After the addition of a diuretic, it may be possible to reduce the dose of PRINIVIL.
Diuretic-Treated Patients: In hypertensive patients who are currently being treated with a diuretic, symptomatic hypotension may occur occasionally following the initial dose of PRINIVIL. The diuretic should be discontinued, if possible, for 2 to 3 days before beginning therapy with PRINIVIL to reduce the likelihood of hypotension (see WARNINGS). The dosage of PRINIVIL should be adjusted according to blood pressure response. If the patient's blood pressure is not controlled with PRINIVIL alone, diuretic therapy may be resumed as described above.
If the diuretic cannot be discontinued, an initial dose of 5 mg should be used under medical supervision for at least 2 hours and until blood pressure has stabilized for at least an additional hour (see WARNINGS and PRECAUTIONS, *Drug Interactions*).
Concomitant administration of PRINIVIL with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium (see PRECAUTIONS).
Use in Elderly: In general, blood pressure response and adverse experiences were similar in younger and older patients given similar doses of PRINIVIL. Pharmacokinetic studies, however, indicate that maximum blood levels and area under the plasma concentration time curve (AUC) are doubled in older patients so that dosage adjustments should be made with particular caution.
Dosage Adjustment in Renal Impairment: The usual dose of PRINIVIL (10 mg) is recommended for patients with a creatinine clearance > 30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance ≥ 10 mL/min and ≤ 30 mL/min (serum creatinine ≥ 3 mg/dL), the first dose is 5 mg once daily. For patients with creatinine clearance < 10 mL/min (usually on hemodialysis), the recommended initial dose is 2.5 mg. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily.

Acute Effects of Felodipine in Exertional Angina Pectoris

SABINO SCARDI, MD, CLAUDIO PANDULLO, MD, FULVIO PIVOTTI, MD, GIULIANO CESCHIA, MD, and GIORGIO POLLAVINI, MD

To investigate the antianginal efficacy, duration of action and tolerability of 2 doses of the new calcium antagonist felodipine, 15 patients (14 men and 1 woman, mean age 62 years) with stable exertional angina pectoris and angiographically demonstrated coronary artery disease were randomly given felodipine, 5 and 10 mg, and placebo on 3 different days. A bicycle ergometer exercise test was performed 3 and 10 hours after dosing. In comparison with placebo, felodipine 5 and 10 mg significantly increased resting heart rate and decreased resting systolic and diastolic blood pressure 3 hours after administration ($p < 0.001$). Ten hours after administration, only supine systolic blood pressure was still significantly lower ($p < 0.001$). Anginal (time to mild chest pain) and ischemic (time to 1 mm ST depression) thresholds, as well as duration of exercise and total work at peak exercise, were higher in comparison with placebo at 3 and 10 hours ($p < 0.001$). In comparison with the lower dose, 10 mg felodipine induced a decrease in supine ($p < 0.05$) and sitting ($p < 0.01$) systolic blood pressure at rest and an increase in total work to anginal threshold ($p < 0.01$), as well as in total work and duration of exercise at peak exercise ($p < 0.05$). These results suggest that a single administration of felodipine, 5 and 10 mg, may improve exercise capacity over a 10-hour period in patients with stable exercise-induced angina due to atherosclerotic heart disease.

(Am J Cardiol 1988;61:691–695)

Felodipine, a recently developed dihydropyridine derivative, is a calcium antagonist that selectively reduces smooth muscle contractile activity, particularly in resistance vessels.[1,2] Reduction in peripheral vascular resistance and, consequently, in arterial blood pressure account for the decrease in left ventricular systolic pressure, which is one of the 2 major determinants of cardiac afterload. The drug does not seem to have any effect on preload[1]: left ventricular end-diastolic pressure, revealed by pulmonary arterial wedge pressure measurements, remains unchanged after the oral administration of 0.1 mg/kg of felodipine to patients with coronary artery disease and exertional angina pectoris.[3] Hemodynamic effects of felodipine on coronary blood flow have also been demonstrated.[4] Coronary vasodilatation and, therefore, an increase in myocardial oxygen supply have been documented during cardiac catheterization as shown by an increase in coronary sinus flow, an increase in oxygen saturation of coronary sinus blood and a decrease in myocardial arteriovenous oxygen difference.[3,5] The present study evaluates the antianginal efficacy, duration of action and tolerability of 2 doses of felodipine (5 and 10 mg) after acute oral administration in patients with chronic, stable, exercise-induced angina pectoris.

Methods

Patient selection: Outpatients with a history of exercise-induced angina pectoris that was stable over a period of at least 6 months, and in whom angina was relieved by rest and sublingual nitroglycerin, were considered for the study. Patients had to have angiographic evidence of coronary artery disease. However, only those patients who had previously performed an exercise test, which was stopped because of typical chest pain associated with ST-segment depression ≥1 mm, were included in the study.

Exclusion criteria: Exclusion criteria included exertional angina pectoris with variable threshold, mixed angina and angina at rest, evidence of coronary spasm during angiography, acute myocardial infarction during the previous 6 months, heart failure, congenital or valvular heart disease, cardiomyopathy, Lown class 3 to 4 ventricular arrhythmias, atrioventricular or intraventricular conduction disturbances, left

Abbreviations as in Table I.

ventricular hypertrophy, previous myocardial infarction of the anterior wall, Wolff-Parkinson-White syndrome, use of digitalis, antiarrhythmic, anticoagulant or psychotropic drugs and any abnormalities in the electrocardiogram at rest that might mislead the interpretation of ST-segment changes. Patients older than 70 years or with insulin-dependent diabetes, anemia (red cell count <3,000,000/ml) and serious hepatic or renal disease were also excluded.

Study design: The trial plan consisted of an acute, double-blind, within-patient, randomized study comparing felodipine, 5 and 10 mg, and placebo, each given once, according to a 3 × 3 latin square design, and replicated 5 times. Blindness was preserved by means of the double-dummy technique. After informed consent was obtained, previous antianginal therapy was withdrawn (1 week for β blockers, 3 days for nitrates and calcium antagonists). During the study, sublingual nitroglycerin was allowed to interrupt, but not to prevent, anginal attacks.

One week before entering the study, the patients performed 2 exercise tests on 2 consecutive days (at the same time of day) to verify reproducibility. The tests were considered reproducible (and the patient admitted to the study) if ischemic (time to 1 mm ST-segment depression) and anginal (time to mild chest pain) thresholds did not vary by >15%. During these sessions, the patients were instructed on how to recognize anginal pain and to classify it according to the method of Borg,[6] and were made familiar with the instruments and the laboratory staff. Eligible patients were then randomly given the 3 treatments in 3 different sessions, with a 24-hour interval between them. Study medications (placebo or felodipine 5 or 10 mg, orally)

TABLE III Heart Rate, Systolic Blood Pressure and Pressure-Rate Product Under the Same Load (Exercise Stopped with Placebo)

were administered at 7 A.M. and exercise testing was performed at 10 A.M. and 5 P.M., 3 and 10 hours after administration, respectively.

Exercise testing: Exercise testing was always performed on the same electromagnetically braked bicycle ergometer, following the protocol of Redwood et al.[7] The initial workload was 30 watts below the mean maximal workload reached during the 2 preliminary tests, with increases of 30 watts every 3 minutes. Systolic and diastolic blood pressure (cuff sphygmomanometer), heart rate and electrocardiogram recordings were taken at rest (supine and sitting) before the test. The same recordings were made every minute during exercise and the recovery phase, which lasted until all the parameters returned to baseline. Three electrocardiogram leads (V_2, V_5, and aVF) were also continuously monitored during the entire test. The test was stopped if typical chest pain of mild intensity (Borg class 4 to 5), horizontal or downsloping ST depression ≥3 mm and lasting at least 0.08 seconds from the J point, fatigue or physical exhaustion occurred. ST-segment depression and heart rate were monitored and calculated by a computer-assisted system (CASE II, Marquette Electronics Inc.). The study was carried out in accordance with the Declaration of Helsinki.

Evaluation of results: Results were evaluated on the basis of variations in heart rate, systolic and diastolic blood pressure and pressure-rate product measured at rest, at ischemic threshold (1 mm ST depression), at maximal workload reached during placebo and at peak exercise. Duration of exercise and total work were considered at the onset of pain (anginal threshold), at ischemic threshold and at peak exercise.

Statistical analysis: One-way analysis of variance and nonparametric tests were performed to check the homogeneity of patient distribution in the 3 sequences of treatment. Analysis of variance for latin square design was used to compare the 3 treatments. Orthogonal comparisons were performed when appropriate.

Patients: Fifteen outpatients, selected from a population of 53, were admitted to the study, and none was withdrawn after randomization. There were 14 men and 1 woman. Mean age was 62 years (range 55 to 70). Angina had been stable over a period ranging from 6 to 10 months, with an average of 3.1 weekly attacks. Ten patients had had a previous myocardial infarction. Coronary angiography showed 1-vessel disease in 1 patient, 2-vessel in 10 and 3-vessel in 4 patients.

Results

As the analysis of variance did not show either period or sequence effects, results are given according to the drug, irrespective of the sequence of treatment.

Effect on hemodynamic parameters at rest: As shown in Table I, felodipine both 5 mg and 10 mg induced a significant increase in heart rate and a decrease in systolic and diastolic blood pressure, 3 hours after administration ($p < 0.001$) in both supine and sitting positions compared with placebo. Systolic blood pressure in the supine position was still significantly lower after 10 hours ($p < 0.001$). As far as comparisons between the 2 dosages were concerned, the 10 mg dose significantly decreased supine systolic blood pressure and systolic and diastolic blood pressure in sitting position at 3 hours. No significant differences were found at 10 hours after administration.

Effects on hemodynamic parameters during exercise: Three hours after administration, both doses of felodipine induced a significant increase in heart rate and pressure-rate product at the anginal and the ischemic thresholds and at peak exercise. There were no differences between doses. No significant differences were found after 10 hours (Table II). Furthermore, during felodipine treatment, heart rate, systolic blood pressure and pressure-rate product, measured at the same workload reached during placebo, did not change significantly (Table III).

Effects on exercise capacity: Changes in exercise capacity, 3 and 10 hours after dosing, are listed in Table IV. In comparison with placebo, both doses of felodipine induced a highly significant improvement in duration of exercise and in total work ($p < 0.001$) at 3 and 10 hours after administration. No significant differences were found between the 2 doses. A significant increase in the duration of exercise to the onset of angina as well as in total work was observed, at both 3 and 10 hours. At 10 hours, the amount of work was significantly higher with felodipine 10 mg than with the 5 mg dose ($p < 0.01$). In comparison with placebo, duration of exercise and total work significantly in-

TABLE IV Duration of Exercise and Total Work Performed at Ischemic (ST-Segment Depression = 1 mm) and Anginal (Mild Severity) Thresholds and at Peak Exercise

Variable	Hours After Dosing	Placebo (1)	Felodipine 5 mg (2)	Felodipine 10 mg (3)	Analysis of Variance p	Orthogonal Comparisons (2) (3) vs (1) p	Orthogonal Comparisons (2) vs (3) p
Ischemic threshold	3	220 ± 77	327 ± 99	330 ± 99	<0.001	<0.001	NS
(s)	10	166 ± 74	229 ± 97	255 ± 88	<0.001	<0.001	NS
Anginal threshold	3	305 ± 80	440 ± 91	418 ± 79	<0.001	<0.001	NS
(s)	10	261 ± 87	338 ± 92	361 ± 114	<0.001	<0.001	NS
Duration of exercise	3	375 ± 89	479 ± 83	470 ± 76	<0.001	<0.001	NS
to peak exercise (s)	10	303 ± 86	367 ± 89	418 ± 109	<0.001	<0.001	<0.05
Total work to ST↓	3	1,193 ± 674	1,927 ± 1,042	2,004 ± 1,131	<0.001	<0.001	NS
1 mm (Kpm)	10	797 ± 530	1,189 ± 835	1,407 ± 943	<0.001	<0.001	NS

(Kpm)	10	1,436 ± 777	1,911 ± 854	2,305 ± 1,071	<0.001	<0.001	<0.01
Total work to peak	3	2,366 ± 1,102	3,533 ± 1,286	3,277 ± 955	<0.001	<0.001	NS
exercise (Kpm)	10	1,718 ± 794	2,288 ± 830	2,716 ± 1,024	<0.001	<0.001	<0.05

Data are mean ± standard deviation.

creased 3 and 10 hours after administration, with both felodipine 5 mg and 10 mg. A significant difference ($p < 0.05$) was also found between the 2 doses at 10 hours.

During placebo, the test was always stopped because of angina associated with ST depression ≥3 mm. In contrast, during felodipine therapy (both doses), the test was stopped because of physical exhaustion, in 3 patients at 3 hours and in 1 patient at 10 hours. In the remaining patients, the reasons for stopping the test were angina associated with ST depression ≥1 mm or angina or ST depression ≥3 mm alone.

Adverse effects: One patient taking placebo, 3 patients taking felodipine 5 mg and 1 taking felodipine 10 mg experienced mild headache. One patient complained of asthenia and 1 of skin rash; both were taking felodipine 10 mg. None of the reported side effects caused the patients to withdraw. PR and QRS intervals, measured by electrocardiographic tracings, remained unchanged.

Discussion

The net effect of calcium antagonists on the cardiovascular system is the result of a complex set of interactions. Previous investigations have demonstrated that felodipine has a pronounced arteriolar vasodilator activity,[2,4] which results in an increase in cardiac output, stroke volume and coronary blood flow. This type of response has been described in patients with hypertension and coronary artery disease, with either normal or abnormal left ventricular wall motion.[8,9] In patients with congestive heart failure, the drug increases cardiac index, stroke volume and coronary flow without increasing myocardial oxygen consumption.[10]

Only preliminary data concerning the antianginal efficacy of felodipine are available. It has been shown that felodipine improves coronary blood flow. In particular, Emanuelson et al[11] reported an increase in luminal diameter of 7% in that portion of a coronary artery proximal to a stenosis, of 9% at the site of the stenosis and of 7% in the poststenotic portion after the intravenous administration of felodipine. Detry et al[12] examined the hemodynamic and antianginal effects of 0.1 mg/kg of felodipine after oral administration in patients with exercise-induced angina pectoris. At rest and during submaximal exercise, felodipine increased heart rate and decreased systemic blood pressure and vascular resistance. In comparison with baseline values, the patients showed an improvement in exercise capacity (20%), which was associated with a decrease in mean pulmonary wedge pressure and an increase in maximal cardiac output (20%), whereas the pressure-rate product remained unchanged. Recently Sheridan et al,[13] comparing the effects of felodipine with those of placebo in patients with stable angina pectoris treated with β-adrenoceptor blockers, showed that, at a plasma concentration of 15.5 nmol liter^{-1}, felodipine significantly increases exercise duration but fails to attenuate the degree of ST-segment depression during exercise.

The hemodynamic changes induced by felodipine, observed in our study, are similar to those reported by other investigators. Our data also indicate that felodipine has a favorable effect on exercise capacity. In comparison with placebo, exercise duration and total work at the appearance of angina, at the onset of 1 mm ST depression and at peak exercise were significantly higher with felodipine, both 3 and 10 hours after administration. The improvement in exercise capacity was associated with a significant increase in heart rate and pressure-rate product at peak exercise, suggesting a felodipine-related improvement in coronary blood flow. The absence of angina and of ST changes in patients given felodipine, at the workload reached with placebo, gives further support to this hypothesis. No significant differences between the 2 dosages were found at 3 hours after administration. However, 10 mg seemed to have a more prolonged duration of action than 5 mg; we observed a longer lasting improvement in duration of exercise and in total work at peak exercise ($p < 0.05$), as well as in total work until the onset of angina ($p < 0.01$). These findings are supported by the pharmacokinetic data obtained by Hedner et al,[14] who

showed that the mean elimination half-life of felodipine 10 mg, in steady-state conditions, is 23 ± 11 hours.

Clinical implications: The results of the present study show that felodipine, 5 and 10 mg, significantly increase exercise tolerance and prolong the ischemic and anginal thresholds up to 10 hours after oral administration in patients with chronic, stable, exercise-induced angina pectoris. At 3 hours after administration, the 2 doses are equally effective, but the 10 mg dose seems to produce more prolonged effects. Moreover, the drug is well tolerated. These properties indicate a useful role for felodipine in the management of outpatients with exertional angina pectoris. Further investigations are needed to determine its efficacy in long-term treatment.

Acknowledgment: We are grateful to Ciba-Geigy, Italy, for supplying felodipine and matching placebo tablets.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. Please include the corresponding author's phone number. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work also may be submitted, and this request is honored.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article (page not numbered); (3) abstract; (4) text; (5) acknowledgment; (6) references; (7) figure legends; (8) miniabstract for Table of Contents that includes the full title and names (without academic degrees) of the authors (page not numbered); and (9) tables. Number the title page as 1, abstract page as 2, and so forth. (Leave the second title page and the miniabstract page unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25-mm (1-inch) margins.

The second title page, on which the names and institutions of the authors are omitted, gives the Editor in Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is honored.

TITLE PAGE, TABLE OF CONTENTS, ABSTRACT AND MINIABSTRACT: For the **complete title page**, include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. If the work described is supported by a grant from a pharmaceutical company, that fact should be stated on the title page. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code. Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 3 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Abbreviations are best limited to phrases in the article's title. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical Journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association.*

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present", a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no" or "more."

BRIEF REPORTS: Brief Reports must be limited to no more than 4 text pages (including the title page) and 6 references. Longer ones may be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor in Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

PERMISSIONS: Permission to reproduce figures published in the Journal is obtained by writing to: Managing Editor, THE AMERICAN JOURNAL OF CARDIOLOGY, 249 West 17th St., New York, NY 10011.

Correlation of Minimum Coronary Lumen Diameter with Left Ventricular Functional Impairment Induced by Atrial Pacing

JONATHAN TOBIS, MD, DAVID SATO, MD, ORHAN NALCIOGLU, PhD, WARREN D. JOHNSTON, MD, JOHN MALLERY, MD, JACKIE SEE, MD, LIAN QU, MS, TIM REESE, BS, JIM PAYNTER, RCPT, STEVE MONTELLI, CRT, and WALTER L. HENRY, MD

To understand whether quantitative measurement of minimal coronary luminal diameter is a better method than percent diameter narrowing for assessing the functional impairment of myocardial contractility produced by coronary artery stenoses, measurements were made from 37 stenotic segments in 27 patients with coronary artery disease and from corresponding segments in 10 subjects without coronary artery narrowing. An assessment of the reliability of the 2 types of measurements was made by correlating them with the physiologic parameters of both segmental wall motion and global ejection fraction response induced by atrial pacing. Digitally acquired coronary angiograms were used to facilitate quantitative analysis. Measurements by edge detection and videodensitometry correlated closely ($r = 0.94$). Percent diameter narrowing correlated moderately with the change in ejection fraction ($r = -0.41$) or with the change in segmental wall motion ($r = -0.44$). The measurement of minimal lumen diameter correlated with the change in global ejection fraction ($r = 0.61$) and did so even better with the change in segmental wall motion ($r = 0.78$, $p < 0.05$). A minimal lumen diameter of ≤ 1.5 mm identified patients likely to have a functional impairment during atrial pacing as assessed by either global ejection fraction or segmental wall motion defects. We conclude that minimal coronary luminal diameter provides a better method than percent diameter narrowing calculations to measure the anatomic severity of coronary artery narrowing.

(Am J Cardiol 1988;61:697–703)

The severity of coronary artery disease (CAD) is usually graded from angiograms by the percent narrowing between the stenotic segment and a more proximal normal portion.[1,2] Therefore, percent diameter narrowing is a relative number that depends both on the size of the narrowed as well as the presumed normal segments. One problem with this method of measurement is that identification of the presumed normal region is arbitrary. In addition, pathologic studies indicate that atherosclerosis is present to a variable degree in a large portion of so-called normal segments.[3] An alternative method of performing quantitative analysis of coronary angiograms is to measure the minimal lumen diameter instead of the percent diameter narrowing at the region of maximal arterial narrowing.[4] Theoretically, this minimal lumen diameter would be a more accurate way of comparing studies or interpreting the results of coronary angioplasty. However, there have been no clinical studies demonstrating that measurements of minimal lumen diameter correlate better than percent diameter narrowing with functional determinations of the severity of disease. The purpose of this study was to assess the correlation of both percent diameter narrowing and minimal lumen diameter with functional measurements of global ejection fraction and segmental wall motion during ischemia induced by atrial pacing.

From the Division of Cardiology and Department of Radiological Sciences, University of California, Irvine, California. This study was supported in part by grant RO1 HL31440-01A1 from the National Institutes of Health, Bethesda, Maryland. Methods

Angiographic technique: Coronary angiograms were obtained by on-line digital acquisition. Images were exposed on a 7-inch image intensifier at a nominal focal spot of 1.2 mm. The images were converted by an on-line video image processor (Fischer DA-100)

into a 512 × 512 × 8 bit matrix and stored digitally on a 475 megabyte rapid parallel transfer disk (Fujitsu). Selective coronary angiograms were obtained in orthogonal right and left anterior oblique projections with cranial and caudal angulation. A more detailed description of our digital coronary acquisition and validation method as compared with 35-mm film cineangiography has been reported.[5]

Cardiac catheterization was performed by retrograde cannulation from the femoral artery and coronary angiograms were obtained and reviewed. A baseline digital subtraction left ventriculogram was then performed.[6,7] If there were no contraindications, an atrial pacing study was carried out. Contraindications to atrial pacing included significant left main disease, unstable angina, recent myocardial infarction (<3 months), cardiomyopathy or valvular heart disease. Left ventriculograms were performed in the 30° right anterior oblique projection to identify wall motion abnormalities in the distribution of the left anterior descending and right coronary arteries. To compare results of global ejection fraction and segmental wall motion in the right anterior oblique projection, no patients were included with predominant lesions in the circumflex artery (which would require left ventriculograms in the left anterior oblique projection to visualize lateral wall motion abnormalities).

Pacing protocol: After the resting digital left ventriculogram was obtained, 6Fr pacemaker electrode was inserted into the femoral vein and passed under fluoroscopic control to the lateral wall of the right atrium. The right atrium was stimulated at 2 mA initially at a rate of 10 beats/min above the patient's heart rate at rest. The rate was increased in increments of 10 beats/min every minute until chest pain developed or until a heart rate of 150 beats/min was reached. If atrioventricular Wenckebach block developed, 1 mg of atropine was administered intravenously and the pacing study continued. When the endpoint was achieved, another digital left ventriculogram was performed and the pacemaker was then turned off.

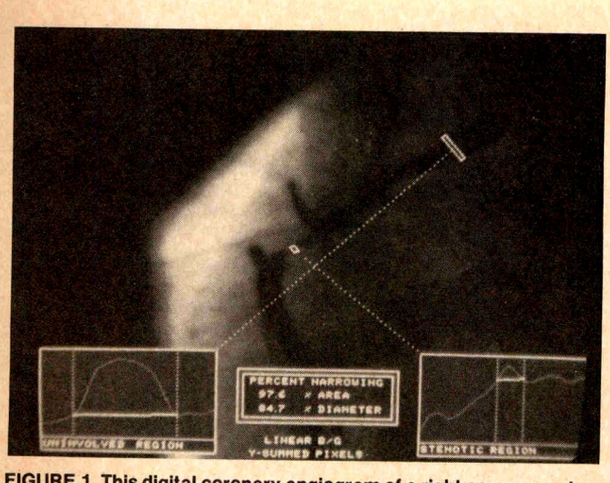

FIGURE 1. This digital coronary angiogram of a right coronary artery demonstrates a severe obstruction in the middle segment. Two regions of interest are defined at the obstruction and at a more proximal (assumed normal) segment. Because the image is already in a computerized format, the density of contrast within the lumen is calculated and plotted with the Y axis representiing relative density and the X axis corresponding to a 50-pixel wide segment perpendicular to the long axis of the artery. The densitometric boundary of the artery is then chosen and the percent area stenosis is calculated.

Quantitative analysis: After the catheterization was completed, the coronary angiographic images were recalled from computer memory. An individual frame was chosen from either the right anterior oblique or left anterior oblique projection which most clearly demonstrated the stenotic segment. Studies were chosen for analysis if the stenosis involved the proximal half of the right coronary artery or the left anterior descending coronary artery. This digital image was in an unsubtracted format, all calculations of the severity of coronary artery narrowing being made from the unsubtracted image so that measurement errors due to misregistration would not be introduced. The observer chose the stenotic portion of the image and the computer digitally magnified the area of interest 4-fold. Two different methods of quantifying the stenosis were used. The first was an edge-detection method with the operator choosing the diameter boundaries of the presumed normal and stenotic arterial segments. The image was magnified so that the catheter was displayed on the monitor screen and the edges of the catheter were defined by the operator. The routine angiographic catheters had been measured by Vernier calipers and these known measurements were used to calibrate the pixel dimensions of the digital image. Because the image was already in a digital X-Y coordinate matrix, the measurements of relative percent stenosis as well as absolute lumen dimensions could be quickly derived.

The second method of measurement of the stenosis was by videodensitometry (Figure 1). Because the unsubtracted digital images were logarithmically amplified to correct for exponential x-ray absorption, the digital number in each pixel corresponded to the thickness of the contrast material that the x-rays traversed. The observer chose the normal and stenotic segments by placing a rectangular region of interest over portions of the coronary image. The underlying background densities not due to contrast media in the arterial lumen were subtracted out by a linear averaging method, with the densities at the 4 corners of the region of interest used to estimate the underlying background.[8] In order to assure that a reasonable background measurement was obtained, the computer displayed the density profile of the arterial segment across the width of the artery. The observer could then alter the width of the region of interest so that it was just beyond the densitometric edge of the image as determined by the sharp inflection of the density profile. After subtracting out background densities, the density within each region of interest corresponded to the volume of contrast within the lumen. When divided by the height of the region of interest, this number corresponds to the cross-sectional area. The ratio of the densities at the stenotic and presumed normal segments was used to compute the percent area stenosis.

In order to compare videodensitometric results with the edge detection method, the percent diameter narrowing was derived from the percent area stenosis by assuming a circular cross section for the 2 segments. The minimum lumen diameter was then derived by using the width of the catheter to calibrate the distances in the image. The measurements of all the stenoses were performed by 2 independent observers. The first observer identified the regions of the artery to be measured and recorded their location with Polaroid® film so that both observers would derive measurements from approximately the same segments.

The digital left ventriculograms were analyzed by standard area-length methods for calculating volumes and ejection fraction.[9] The images were recalled from computer memory and processed by mask mode subtraction using a 10 to 15 frame blurred mask to enhance contrast.[10] The operator outlined the boundary of the end-diastolic and end-systolic images using the cursor of the computer graphics system. A separate wall motion analysis was performed on the ventricular boundaries using the method developed by Alderman et al.[11] In this analysis, the perimeter of the left ventricle in the right anterior oblique projection was divided into 5 segments (anterobasal, anterior, apical, diaphragmatic and posterobasal). The wall motion in these segments along radians was calculated and a percent of area segmental motion derived.

The relative amount of radial area shortening can be compared to a graph of wall motion based on normal subjects. For the purpose of this study, the percent of segmental area shortening was calculated at rest and during atrial pacing. The value at rest was subtracted from the value during pacing so that an increase in contractility during pacing would appear as a positive number and a decrease in contractility as a negative number. Similarly, the change in global ejection fraction was calculated as the value at rest subtracted from the value during pacing; thus, a fall in ejection fraction during pacing would appear as a negative value.

Statistical analysis: The measurements of percent diameter narrowing by the edge detection and videodensitometric techniques were compared by a linear regression analysis. The measurements of percent diameter narrowing and minimal lumen diameter were correlated to the change in global ejection fraction as well as to the change in segmental wall motion by separate linear regression analyses. Volumetric parameters at rest were compared with the values during pacing by a paired *t* test. Differences between groups of patients were compared with an unpaired *t* test.

Results

There were 41 patients who underwent atrial pacing studies. Four of these studies were excluded because either the resting or pacing left ventriculogram was not sufficiently opacified or it had multiple premature ventricular contractions which could have affected the wall motion analysis. There were 10 patients with chest pain syndromes who were found to have normal coronary angiograms and had atrial pacing studies performed. In the 27 patients with coronary artery narrowing, 22 were men and 5 women. The mean age was 54 ± 10 years. There were 35 narrowed coronary segments measured. There were 19 patients with 1-vessel disease and 8 with narrowed segments in both the left anterior descending and right coronary arteries; however, the second stenosis measured <50% and was judged not to be significant angiographically. Patients with complete occlusions or those with evidence of collateral blood supply were excluded. Of the 27 primary stenoses analyzed, 18 were in the left anterior descending, 8 in the right coronary artery and 1 was in a large diagonal artery. In the 27 patients with stenoses, the atrial pacing study induced chest pain in 15 (56%) and positive electrocardiographic criteria for ischemia was induced in only 8 (35%).

TABLE I Patients with Coronary Artery Disease

Clinical Variables	Rest (n = 27)	Atrial Pacing (n = 27)
Heart rate (beats/min)	69 ± 9	137 ± 13*
End-diastolic volume (ml)	153 ± 43	103 ± 33*
End-systolic volume (ml)	59 ± 37	51 ± 36†
Stroke volume (ml)	90 ± 30	52 ± 20*
Ejection fraction (%)	64 ± 15	54 ± 20*
Segmental wall radial shortening (%)	60 ± 22	48 ± 28†

* $p < 0.001$; † $p < 0.02$.

The mean percent diameter narrowing of the 27 primary lesions was 60 ± 16% when measured by the edge detection technique and it was not significantly different when measured by videodensitometry (60 ± 18%). The minimal lumen diameter was calculated to be 1.4 ± 0.6 mm by the edge detection method and 1.4 ± 0.7 mm by the densitometric technique (p = not significant). There was a close correlation (r = 0.94) between measurements of individual stenoses by edge detection and videodensitometry over the 0.4 to 2.8 mm range. In addition, interobserver variability was very close with either edge detection (r = 0.90) or videodensitometric technique (r = 0.89). There was no difference in the mean measurement of minimal lumen diameter for the left anterior descending artery obstructions (1.2 ± 0.4 mm) versus the right coronary artery obstructions (1.6 ± 0.6 mm).

The mean age of the 10 patients without CAD was 53.6 years (range 36 to 65), which was not different than the mean age of the patients with CAD. The mean ejection fraction at rest was 66 ± 7% and increased to 72 ± 5% at peak pacing ($p < 0.001$). The results of the ventricular volumetric measurements for the 27 patients with CAD are listed in Table 1. The mean resting global ejection fraction was 64 ± 15%. At the peak heart rate achieved during atrial pacing, the mean ejection fraction fell to 54 ± 20% ($p < 0.001$).

Segmental wall motion was quantified for the portion of the ventricular perimeter in the right anterior oblique projection expected to be affected by the ste-

notic artery; the anterobasal or anterior wall for lesions in the left anterior descending and diaphragmatic or posterobasal segments for patients with right CAD. For the wall section affected by the stenotic artery, the mean segmental radial area shortening was 60 ± 22% at rest; during pacing, this value decreased to 48 ± 28% ($p < 0.01$). This segmental wall motion response to pacing was significantly different from the increase observed in the segmental area shortening of patients without CAD (from 61 ± 11% at rest to 79 ± 9% during peak pacing, $p < 0.001$).

The correlations between percent diameter narrowing or minimal lumen diameter and global ejection fraction or segmental radial wall motion are demonstrated in Figures 2 through 6. The percent diameter narrowing correlated moderately with the change in global ejection fraction from rest to peak pacing rate ($r = -0.41$). There was a similar correlation between percent diameter narrowing and the change in segmental radial wall motion ($r = -0.44$) (Figure 2). The determination of minimal lumen diameter yielded a closer correlation with the change in global ejection fraction ($r = 0.61$). However, the closest correlation was between the minimal lumen diameter and the change in segmental radial wall motion: $r = 0.78$ (Figure 3). The effect of atrial pacing in patients with CAD was compared with the effect of anterior and diaphragmatic segmental wall motion in the 10 normal subjects (Figure 4).

The relation between minimal lumen diameter and change in ejection fraction due to atrial pacing also was categorized as shown in Figure 5. In this figure, the results in the 10 normal subjects are compared with the patients whose primary stenoses were divided between those with a minimal diameter ≤1.5 mm (17 patients) and those with >1.5 mm (10). A minimal lumen diameter ≤1.5 mm tended to separate those patients who had a positive outcome in their atrial pacing study (defined as >4% fall in ejection fraction) from those who had a normal response ($p < 0.001$). A similar analysis of the relation between minimal lumen diameter and change in segmental radial wall motion is

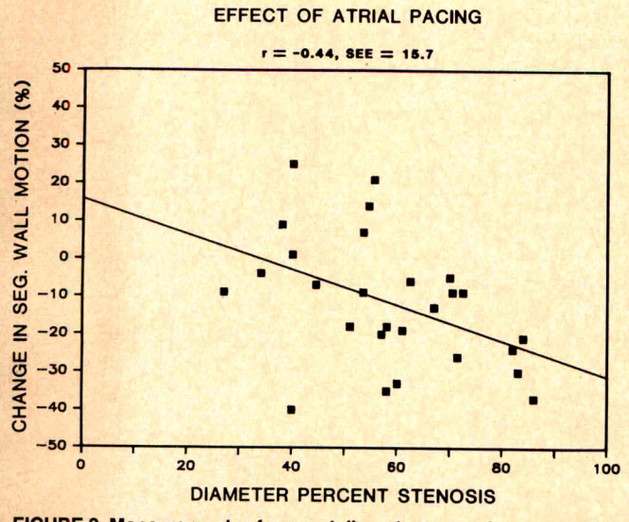

FIGURE 2. Measurements of percent diameter narrowing correlated moderately ($r = -0.44$) with the change in segmental (SEG) wall motion from rest to peak pacing. The primary stenosis in each of the 27 patients with coronary disease was measured and compared with the effect of atrial pacing on the corresponding wall segment. SEE = standard error of the estimate.

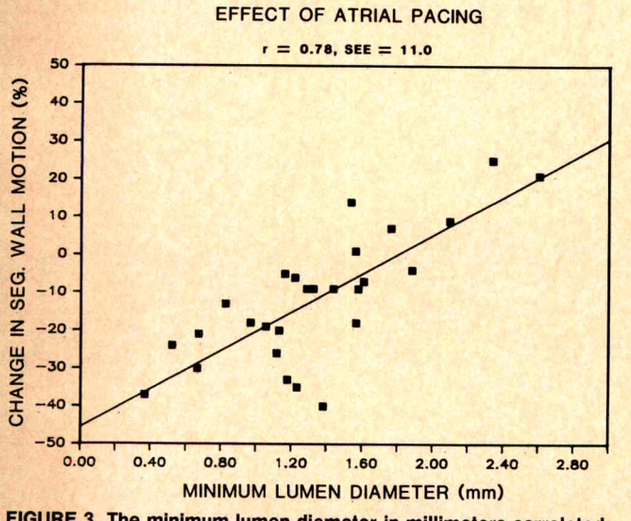

FIGURE 3. The minimum lumen diameter in millimeters correlated more closely with the change in segmental (SEG) wall motion ($r = 0.78$) than did measurements of percent diameter narrowing over a wide range of mild to severe stenoses. SEE = standard error of the estimate.

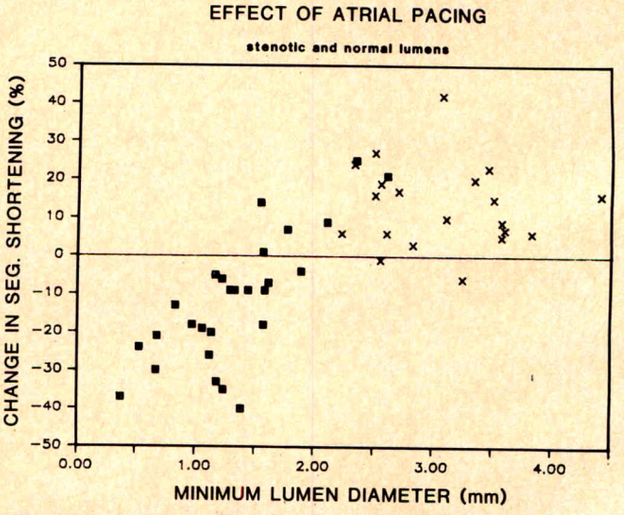

FIGURE 4. The effect of atrial pacing in 27 patients with coronary disease (■) and in 10 subjects with angiographically normal coronary arteries (×) is demonstrated. The measurement of the stenotic lumen or the normal arterial diameter in normal subjects is compared with the effect of pacing on the change in segmental (SEG) wall motion shortening.

shown in Figure 6 for the segmental areas perfused by the left anterior descending coronary artery and in Figure 7 for the areas perfused by the right coronary artery. A minimal arterial diameter of ≤1.5 mm tended to identify those patients likely to have an abnormal response in segmental wall motion during atrial pacing. The normal response to pacing revealed a mean increase in segmental area shortening of 18 ± 11% in the area perfused by the left anterior descending arery and 8 ± 9% in the area perfused by the right coronary artery ($p < 0.05$). The minimal lumen diameter of ≤1.5 mm significantly separated the patients with abnormal responses for both the right coronary artery and left anterior descending artery. However, there was some overlap among patients with left anterior descending artery narrowing between 2.2 and 1.6 mm. Moreover, there was no difference from normal segmental motion in the patients with right coronary artery narrowing between 2.2 and 1.6 mm.

Discussion

Assessment of the severity of coronary artery narrowing is made primarily by angiographic determination of the percent of diameter narrowing relative to an assumed normal portion of the artery. This determination may be misleading for several reasons. Of greatest importance, pathologic studies have demonstrated that atherosclerosis is a diffuse process and even when the angiogram only demonstrates a single stenosis, <25% of the length of the arteries will be free of disease and truly normal.[3,12] In addition, stenoses commonly occur at bifurcations so that it may be difficult to identify a normal proximal portion of the same arterial segment. Consistent with these observations, the study of White et al[13] reported that measurements of percent diameter narrowing correlate very poorly with a physiologic assessment of stenosis severity determined by hyperemic flow response after temporary coronary occlusion during open heart surgery. Legrand and coworkers[14] found a similar poor correlation between mea-

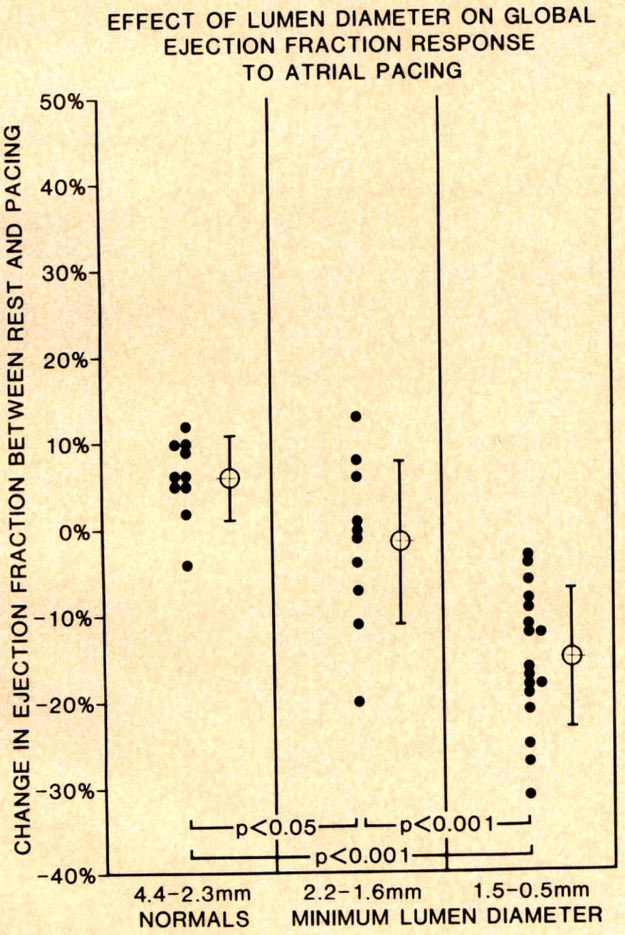

FIGURE 5. The 27 primary stenoses were separated into 2 groups—those with lumens from 0.5 to 1.5 mm and those from 1.6 to 2.2 mm. All were compared with normal lumen dimensions (2.3 to 4.4 mm) to assess the effect of atrial pacing on global ejection fraction. Coronary arteries with minimal lumen diameters <1.5 mm manifested a significant reduction in ejection fraction during pacing.

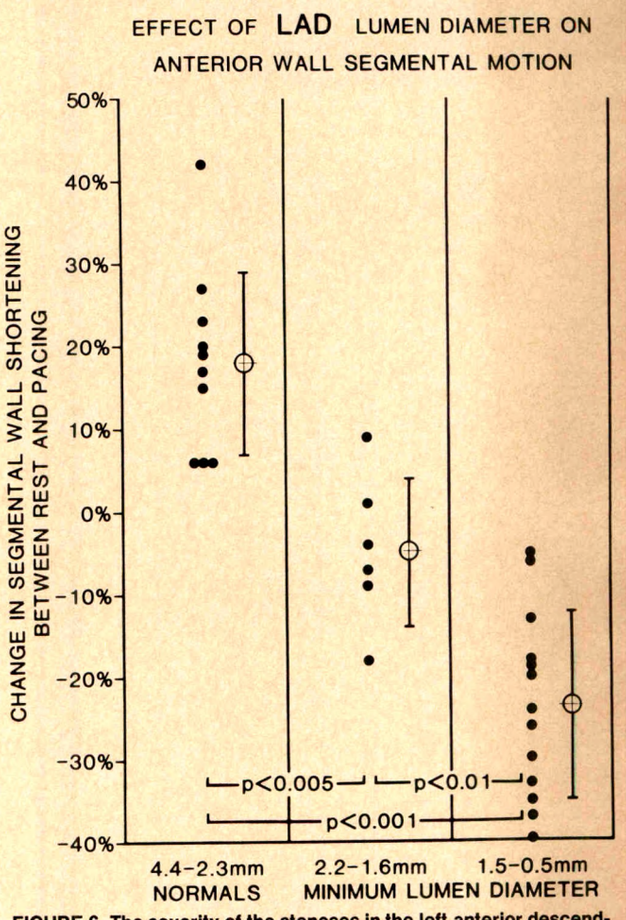

FIGURE 6. The severity of the stenoses in the left anterior descending (LAD) artery demonstrated a progressively impaired response to atrial pacing as measured by the change in segmental anterior wall shortening. The group of patients with a minimal lumen diameter of 1.5 mm or less had a more severe functional response to stress induced by atrial pacing.

surements of percent stenosis and coronary blood flow reserve, as measured by digital flow maps after a hyperemic stimulus.

For these reasons, percent diameter narrowing measurements are flawed as a quantitative method of assessing the severity of CAD. In addition, there is frequent disagreement between observers about the severity of a stenosis[15,16] and it has been suggested that minimum lumen dimensions (either cross-sectional area or linear diameter) would be preferable to using percent diameter narrowing to assess the severity of CAD.[17] Harrison et al found that the minimal lumen diameter correlated better with the hyperemic flow velocity response after 20 seconds of occlusion of the left anterior descending artery.[17] Our data, using the changes in wall motion during atrial pacing in conscious patients, are very similar to their results. In addition, both studies found that an arterial diameter of <1.5 mm was predictive of an abnormal physiologic response. Our data extend these findings to the right coronary artery as well as the left anterior descending. In addition, the data show that measurements of minimal lumen dimensions predict clinical results better than does percent diameter narrowing.

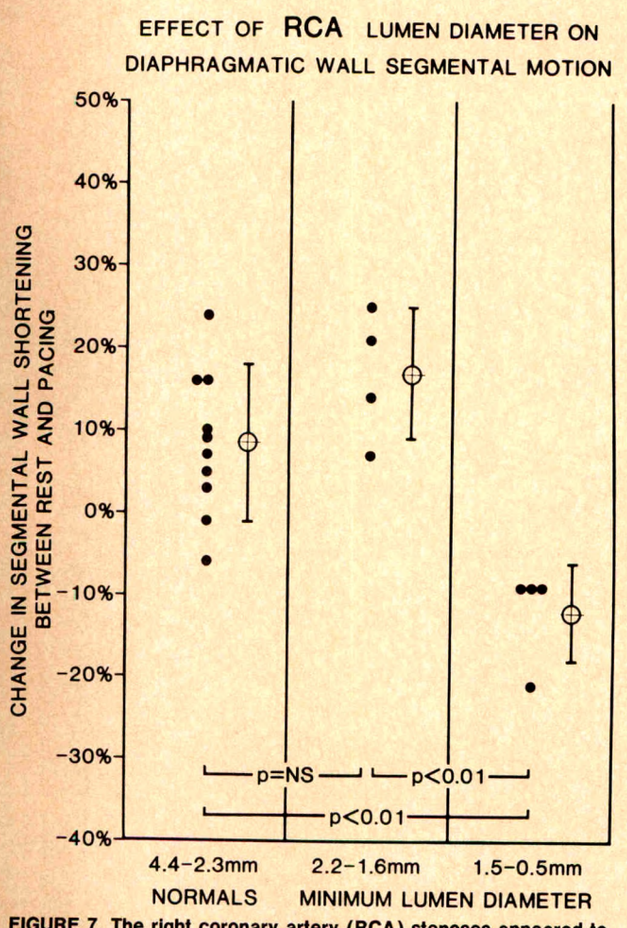

FIGURE 7. The right coronary artery (RCA) stenoses appeared to have a higher threshold than the left anterior descending stenoses for demonstrating a functional impairment to atrial pacing as manifested by a reduction in segmental wall motion. Only stenoses of 1.5 mm or less had a significant response to atrial pacing.

In the present study, atrial pacing stress tests were used as a functional assessment of stenosis severity for comparison with coronary angiographic determinations of stenosis severity.[18,20] In the 27 patients with CAD, measurements of percent diameter narrowing and lumen diameter by edge detection or videodensitometry correlated closely (r = 0.94). Both percent diameter narrowing and minimal lumen diameter correlated with the change in global ejection fraction (r = −0.41 and r = 0.61, respectively). However, it was recognized that the correlation may have been reduced when using global ejection fraction as the measured parameter because the myocardial wall supplied by the normal nonstenotic segments may compensate for diminished motion in the affected myocardium. Localized segmental wall motion was analyzed to isolate the effect of ischemia due to a specific stenosis. The result was a correlation of percent diameter narrowing with segmental wall motion (r = −0.44), similar to that obtained with global ejection fraction (r = −0.41). This result may be explained because percent diameter narrowing is a relative number that does not truly represent the functionally effective resistance to coronary flow. The Pouiselle equation for laminar flow indicates that resistance to flow is inversely proportional to the fourth power of the radius. Thus, a 50% reduction of a 2-mm vessel will have a much greater resistance to flow than a 50% reduction in a 4-mm vessel. When the effect of atrial pacing on segmental radial wall motion was analyzed, there was a clear difference between the 2 methods of measurement of CAD. Whereas percent diameter narrowing was correlated with segmental wall motion with a coefficient of r = −0.44, minimum lumen diameter correlated much more closely (r = 0.78, p <0.05). The improved correlation suggests that the lumen diameter predicts more accurately the functional impairment induced by pacing because the absolute diameter is more directly related to the resistance to flow than percent narrowing.

With regard to the amount of narrowing, our data indicated that the narrowing of an epicardial coronary artery to a diameter <1.5 mm increased the likelihood of a functional impairment induced by atrial pacing in the myocardium supplied by the narrowed artery. Narrowing of the artery to <1.5 mm in diameter increased the probability of a positive study both by global ejection fraction and segmental wall motion. Thus, a minimum lumen diameter <1.5 mm may be useful as a predictor of which patients will be symptomatic during stress.

As demonstrated in Figure 3, there was a close linear correlation between the minimal lumen diameter and the affected segmental wall motion for the patients with CAD. As the stenotic lumen diameter increased, the effect on wall motion leveled off into the range of normal subjects. Our data emphasize the finding that patients with mild disease may not have a functional impairment induced during stress. An exact linear relation between lumen diameter and functional impairment should not be expected because other

influences such as the length of coronary narrowing, vasomobility and the presence of sequential stenoses also impede blood flow.[21-23]

Recruitment and Baseline Description of Patients in the Cardiac Arrhythmia Pilot Study

THE CARDIAC ARRHYTHMIA PILOT STUDY (CAPS) INVESTIGATORS*

The Cardiac Arrhythmia Pilot Study tested the feasibility of performing a large-scale study to evaluate the effect of therapy of ventricular arrhythmias after acute myocardial infarction (AMI). Ten clinical sites identified patients with ≥10 ventricular premature complexes (VPCs)/hour, recorded 6 to 60 days after AMI in patients with an ejection fraction >0.20. Patients were randomized to receive 1 of 5 agents: encainide, flecainide, imipramine, moricizine or placebo. Successful therapy was defined as ≥70% suppression of VPCs and >90% suppression of runs of ventricular tachycardia. Randomization to a second agent occurred if a patient did not achieve adequate suppression with the initial agent. Patients initially randomized to placebo continued to receive placebo. Patients were evaluated at 3-month intervals for the next year. Of 30,763 patients screened, 10,734 (35%) were younger than 70 years old and had a qualifying AMI. A Holter recording was obtained in 3,957 patients, of whom 871 (22%) had qualifying arrhythmias and 687 were eligible. Of the 687 eligible patients, 502 (73%) were randomized. Mean age of enrolled patients was 59 years. One-half of patients were randomized within 1 month after AMI. Mean ejection fraction was 0.45, with 175 (35%) patients having an ejection fraction <0.40. On baseline drug-free recording, 173 (35%) patients had <30 VPCs/hour; 149 (30%) between 30 and 100/hour and 180 (36%) ≥100/hour. At least 1 run of ventricular tachycardia was seen in 172 (34%) patients. Drugs taken at baseline were similar in all groups with 116 (23%) patients taking digitalis, 161 (32%) taking diuretics, 203 (41%) taking β blockers and 200 (40%) taking calcium antagonists. Slightly more patients, 53 (51%), randomized to flecainide were taking calcium antagonists. No significant relation was noted between baseline VPC frequency and ejection fraction, but baseline VPC frequency was correlated with heart rate, arrhythmia noted before AMI and right bundle branch block. As expected, a high ejection fraction correlated with lower peak creatine kinase values, an inferior location of the infarct and fewer signs of congestive heart failure. At baseline, at least 1 adverse symptom was volunteered by 192 (39%) patients. The most common symptoms were unusual tiredness or fatigue, heart beating fast or skipping beats or headache. In this study, over 20 age- and AMI-eligible patients were identified to obtain each randomized patient. The randomization process successfully distributed baseline variables across drug groups.

(Am J Cardiol 1988;61:704–713)

One patient group identified as having a high risk of sudden cardiac death in the U.S. is the post-acute myocardial infarction (AMI) group.[1-3] There are approximately 350,000 patients discharged from the hospital with an AMI as the primary diagnosis each year in this country. The cumulative risk for cardiac death in the year after AMI is about 10%. Early studies suggested that the major factor in determining the risk of death in the year after AMI is left ventricular function,[4] but it has become apparent that ventricular arrhythmias constitute an independent predictor of death.[1,5,6]

Despite attempts to show that suppression of ventricular premature complexes (VPCs) after AMI might be beneficial, no study to date has achieved this goal.[7] The Cardiac Arrhythmia Pilot Study (CAPS) was implemented to address a number of issues important for the optimal conduct of such a trial, and, indeed, provide information as to whether such a trial is even feasible. Important issues included: (1) determining screening processes that would allow sufficient quantities of eligible patients to be identified and recruited; (2) evaluating day-to-day arrhythmia variability, as well as trends over time; (3) determining the feasibility of using arrhythmias detected and quantified by means of 24-hour ambulatory electrocardiograms[8] as measures of drug efficacy for dose titration; (4) assessing whether an appropriate (sufficiently effective and safe) drug existed; (5) determining the natural course of arrhythmias in untreated (placebo) patients; and (6) measuring stress and behavior in order to make recommendations for use of selected instruments in a full-scale trial.

This study was supported by contract NO1-HC 28004 from the National Heart, Lung, and Blood Institute, U.S. Department of Health and Human Services, Bethesda, Maryland. Manuscript received September 2, 1987; revised manuscript received December 24, 1987, and accepted December 26.

The design of the pilot study was described elsewhere.[9] Briefly, CAPS comprised 10 centers (Figure 1) that enrolled 502 patients in the early post-AMI period (6 to 60 days) who had ≥10 VPCs/hour and left ventricular ejection fractions of >20%. Patients were stratified by ejection fraction (≤40% and >40%) and randomized to 1 of 5 treatment arms (4 active and 1 placebo). This article describes the recruitment process and characteristics of the patient population enrolled.

Recruitment

The CAPS patients were recruited primarily from coronary care units at participating hospitals, but patients referred from other hospitals, clinics and private physicians were also included. All potential patients were entered on screening logs at enrolling CAPS hospitals. Because of the investigational nature of 3 of the CAPS drugs, numerous criteria could exclude a patient from the randomized study (Table I). The limited experience with these agents in patients with severe ventricular dysfunction led to the exclusion of patients with ejection fraction ≤0.20.

The screening process to determine patient eligibility included several steps. The first was a patient interview, physical examination and laboratory tests to determine that the patient was not ineligible because of any general exclusions (Table I). If no general exclusions applied, documentation of the myocardial infarction as a CAPS myocardial infarction by electrocardiogram, enzyme results or both was the next step. If a CAPS AMI was documented, the third step was a 24-hour ambulatory electrocardiogram obtained at least 6 days, and not more than 60 days, after the AMI. Minimal qualifying arrhythmia (≥10 VPCs/hour, ≥5 runs of 3 to 9 ectopic beats at a rate ≥100/min or both) with no excluding arrhythmia criteria must have been present. Finally, the ejection fraction was measured, either by radionuclide studies or angiography, no sooner than 48 hours after the AMI, with an ejection fraction of ≤0.20 excluding the patient. The steps in screening could proceed in a different order, but all 4 steps were necessary.

Because ectopy may continue to increase during the first 6 weeks or longer after AMI, if a screened patient did not have qualifying arrhythmia on the first 24-hour ambulatory electrocardiogram, the electrocardiogram could be repeated once, within 60 days of the qualifying AMI, with a second 24-hour ambulatory electrocardiogram. However, no patient could be randomized if 2 or more 24-hour electrocardiograms showed less than the minimal qualifying arrhythmia.

For all patients ineligible for enrollment, the reason or reasons for exclusion were recorded on screening logs at each enrolling hospital, with a separate log recording detailed information on the subset of patients eligible for randomization. This log included reasons that eligible patients were not randomized.

Early in the study it was assumed that ineligible patients were excluded because of multiple exclusion criteria. Usually only 1 reason for ineligibility was recorded on the screening log for each patient not enrolled. In order to ensure identification of any criteria that might be excluding a significant number of patients and to determine the prevalence of multiple criteria for exclusion, a special screening project was carried out. Seven sites participated, recording all reasons for exclusion for at least the first 50 patients who were age eligible and had a CAPS-defined AMI. Of the sample of 669 screened patients not excluded because of age or no AMI, 585 patients (87.4%) had only 1 exclusion recorded, 68 (10.2%) had 2 exclusions and only 16 (2.4%) had 3 or more exclusions listed.

At the end of the recruitment period, 30,763 patients had been screened at 27 hospitals represented by the 10 clinical sites. Figure 2 depicts the number of patients excluded at each step in the screening process. Of the 30,763 patients screened, 17% were excluded because they were age 75 or older, and 48% were excluded because they did not have an AMI according to the CAPS criteria. Thus, 35% of the original number screened were not excluded by 1 or the other of these 2 major criteria. Because of other clinical exclusions, patient/physician reticence or logistical problems, 67% of age- and AMI-eligible patients were not monitored by 24-hour electrocardiogram while 3,957 (37%) were. Of the latter, 18% had at least 10 VPCs/hour on the initial screening 24-hour ambulatory electrocardiogram. From this pool of 717 patients, 23% were excluded, leaving 554 (77%) eligible for enrollment. A total of 391, or 71%, of these eligible patients with ≥10 VPCs on the first screening electrocardiogram were randomized.

Of 3,240 patients with <10 VPCs/hour on their initial screening 24-hour electrocardiogram, 701 (22%) were rescreened, and of these, 154 (22%) had ≥10 VPCs/hour. Of the rescreened patients 133 (86%) were eligible for randomization, and 111 (83%) of the eligi-

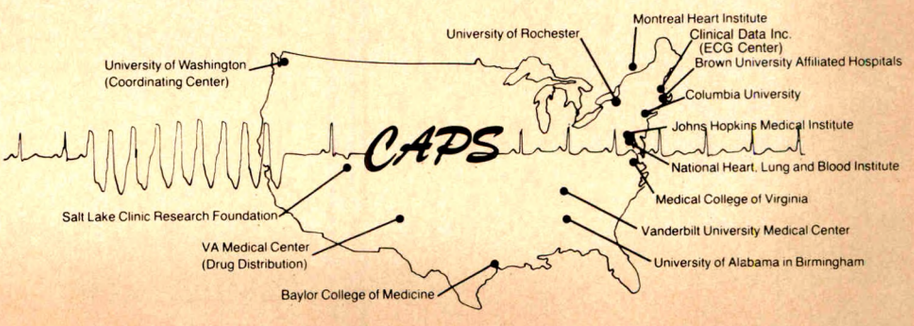

FIGURE 1. Sites for the Cardiac Arrhythmia Pilot Study.

TABLE I Exclusion Criteria for Patients Who Were Not Excluded by Age, Myocardial Infarction or Ejection Fraction

History and clinical
Female with child-bearing potential
Any significant malignancies or other life-threatening disease(s) (other than congestive heart disease) that are likely to be fatal within a 2-year period
Persistent systolic blood pressure ≥180, diastolic blood pressure ≥120 mm Hg, or both
Systolic blood pressure ≤80 and/or a diastolic blood pressure ≤50
NYHA classification class IV (either angina or congestive heart failure)
Clinically significant preexisting nonischemic cardiac condition which is symptomatic or requires treatment (i.e., rheumatic valvular disease, primary cardiomyopathy, mitral valve prolapse syndrome)
Known nonatherosclerotic cause of myocardial infarction
Clinically significant cerebrovascular disease
Creatinine ≥2.5 mg/dl
History of portal hypertension, ascites, portal caval shunt or variceal bleeding
Biopsy-proven cirrhosis
Chronic active hepatitis
Serum glutamic pyruvic transaminase (alanine aminotransferase) or alkaline phosphatase ≥ twice the upper limit of normal
Seizure disorder
Hyperthyroidism
History of narrow-angle glaucoma
Symptomatic urinary tract obstruction (if male)
Electrocardiogram criteria
Ventricular tachycardia ≥10 consecutive beats at a rate of >100 beats/min noted ≥6 days post-myocardial infarction onset
Ventricular fibrillation noted ≥6 days post-myocardial infarction onset
Ventricular tachycardia ≥10 complexes or ventricular fibrillation on graded exercise test done post-myocardial infarction
QRS >0.14 seconds noted ≥6 days post-myocardial infarction onset
Wolff-Parkinson-White syndrome at any time or atrial fibrillation at time of screening requiring treatment by other than digoxin or precluding 18 hours of interpretable ventricular electrocardiogram recording
Sinus pause ≥2.5 seconds noted ≥6 days post-myocardial infarction onset
Second-degree Mobitz II block or third-degree AV block noted ≥6 days post-myocardial infarction onset
PR interval >0.30 seconds noted ≥6 days post-myocardial infarction onset
Symptomatic sinus node dysfunction
Heart rate ≤30 asleep or ≤40 awake for a period lasting >1 minute noted ≥6 days post-myocardial infarction onset
Myocardial infarction ≤8 days after coronary artery bypass graft
Left bundle branch block pattern
Drug therapy
Previous serious adverse effect from 1 of the drugs under investigation
Use of drugs that are potentially arrhythmogenic, e.g., monoamine oxidase inhibitors, inhalant bronchodilators
Taking drugs with antiarrhythmic effect, such as anticonvulsants or tricyclic antidepressants
Use of drugs that interfere with study drug excretion
Angina likely to require manipulation of β blocker or calcium antagonist during Cardiac Arrhythmia Pilot Study dosing
Any phenothiazine preparation needed (except sporadic use of chlorpromazine, prochlorperazine or promethazine)
Parkinsonism being treated with anti-Parkinson drugs
Miscellaneous
Psychologically unfit to participate in the study
Alcoholic or other "noncomplier," or unable to participate effectively in the evaluation of potential side effects and symptoms
Permanently functioning ventricular pacemaker
Geographically inaccessible

AV = atrioventricular; NYHA = New York Heart Association.

ble patients were randomized. Had only 1 screening 24-hour ambulatory electrocardiogram been done, 19% of the eligible patients and 22% of the randomized patients would have been lost to the study. Finally, of the 3,957 patients who were screened for CAPS with at least one 24-hour ambulatory electrocardiogram, 17.4% or 687 patients were eligible and 12.7%, 502 patients, were randomized. Patients who qualified on a second screening 24-hour ambulatory electrocardiogram were required to obtain a third 24-hour ambulatory electrocardiogram recording as a baseline for drug/dose finding.

Of all eligible patients, including those who were rescreened, 185 (27%) were not randomized. For 6% of these 185 patients, the protocol time window elapsed before the patient could be randomized. For 13%, the patient's private physician refused approval. The other reasons given were categorized as inconvenience of

the scheduled visits (too many visits, difficulty in traveling to the site), 16%; patient unwillingness to extend hospitalization to initiate the CAPS drug or to be rehospitalized to initiate the second drug, 11%; dislike of research trials in general, 16%; other physical or anxiety problems, 11%; concern over the listed adverse effects, 3%; denial of the seriousness of the illness, 3%; and no reason given, 21%.

For randomized patients, although the mean time from qualifying AMI to 24-hour electrocardiogram was 26 days over all sites, means at individual sites varied from 16 to 33 days. The mean time from first to second screening 24-hour electrocardiogram was 28 days and varied between sites from 21 to 36 days. The mean time from qualifying 24-hour electrocardiogram to randomization was 4.7 days over all sites, and varied from 3.0 to 6.1 days at individual sites. These recruitment times did not change over the course of the study.

Baseline Descriptions

Enrollment began July 25, 1983, and ended on August 21, 1985, during which time 502 patients were enrolled. The patients included 418 men with a mean age of 59 ± 9 and 84 women with mean age of 61 ± 9 years. Total enrollment by month showed a moderate learning curve and slight peaks in mid-winter. Twenty-nine percent of patients were randomized by the end of the second week after AMI, 15% in the third

Abbreviations as in Table II.

week, 7% in the fourth week and 49% 4 to 8 weeks after AMI.

Descriptive statistics of selected factors for patients grouped by initial drug assignment and for all patients are shown in Tables II, III and IV. Overall, the mean ejection fraction was 0.45 and 175 (35%) of the patients fell in the low (<0.40) ejection fraction stratum. Baseline rates of VPCs of <30/hour were seen in 171 (35%) patients and 180 (36%) had rates ≥100 VPCs/hour. At least 1 run of asymptomatic ventricular tachycardia (VT) of length 3 to 9 VPCs at a rate of ≥100 beats/min was observed in 172 (34%) of the baseline 24-hour electrocardiograms. The 27 (5.4%) patients with baseline VPCs/hour rates of <10 consist of 1 patient who qualified only on the basis of runs, of 21 patients who had <10 VPCs/hour on an initial screening 24-hour electrocardiogram and hence were required to have a baseline (third recording) obtained after having ≥10 VPCs/hour on a second screening electrocardiogram, and of 5 patients for whom the baseline was reestablished during the drug/dose finding phase. More women than men had a family history of angina (38 [51%] vs 147 [38%], p <0.03), sustained systemic hypertension (34 [41%] vs 125 [30%], p <0.05), diabetes mellitus (21 [25%] vs 60 [14%], p <0.015) and had never smoked cigarettes (26 [31%] vs 60 [14%], p <0.001).

Not all factors are uniformly distributed across initial treatment groups. Of note is the lower incidence of cardiac enlargement in 21 (23%) of patients assigned to encainide-imipramine/moricizine limb; this occurred in 35 (39%) of patients assigned to placebo. With the possible exception of calcium antagonists there were no significant differences in the distribution of drugs taken at baseline across drug groups. Overall 116 (23%) of the patients were taking digitalis, 161 (32%) were taking diuretics, 203 (41%) were taking β blockers and 76 (15%) were taking potassium supplements. Two hundred (40%) patients were taking calcium antagonists; 51% of the patients assigned to the flecainide-imipramine/moricizine limb (the highest) and 34% of the patients assigned to the encainide-imipramine/moricizine limb and to placebo (the lowest).

Twenty-four-hour ambulatory electrocardiogram: The qualifying (usually but not always the baseline used during the drug/dose finding phase) 24-hour ambulatory electrocardiogram was obtained an average of 27 ± 18 days post-AMI and was obtained in-hospital in 60% of the patients. The usable recording time averaged 23 ± 1.6 hours. The electrocardiographic measurements from the 24-hour electrocardiogram were RR 0.79 ± 0.18, PR 0.17 ± 0.03, QRS 0.08 ± 0.02 and QT 0.37 ± 0.05. The average number of VPCs per recording was 3,151 (median 1,167). There was an av-

† Based on the final baseline established for titration decisions.

AMI = acute myocardial infarction; CAPS = Cardiac Arrhythmia Pilot Study; CHF = congestive heart failure; EF = ejection fraction; PTCA = percutaneous transluminal coronary angioplasty; Runs = 3 to 9 consecutive ventricular premature depolarizations at ≥100 beats/min; VF = ventricular fibrillation; VPC = ventricular premature complexes; other abbreviations as in Table II.

erage of 13 runs of length 3 to 9 VPCs at a rate ≥100 beats/min among the 33% of recordings with at least 1 run. Of these, 51% had only 1 run. Because of concern about selection based on extreme observations, a third 24-hour electrocardiogram obtained between qualifying and beginning the drug/dose finding phase was required by protocol for the 111 patients who qualified at a second (and not at the initial) screening. Among the 96 patients for whom a third recording was done (the protocol was not adhered to in 15 instances), data from both 24-hour electrocardiograms were submitted for 87 patients. In these, the spontaneous decrease in VPCs/hour between the successful screening and the baseline recording averaged 8.3 ± 165.4 and the inter-

val between these 2 recordings averaged 4.6 ± 2.1 days. The baseline rate was <10 VPCs/hour for 21 of the 87 patients. The baseline ultimately used for evaluation during the drug/dose finding phase of the study was the VPC/hour rate obtained on the last 24-hour ambulatory recording taken while the patient was off antiarrhythmic therapy before the end of drug/dose finding. This was different from the qualifying or pretitration baseline recording for 60 patients for whom the mean qualifying rate was 122 ± 191 VPCs/hour while the baseline rate was 238 ± 249 VPCs/hour.

Radionuclide ventriculography: Baseline radionuclide ventriculography was performed in 86% of all randomized patients yielding a mean left ventricular ejection fraction of 0.44 ± 0.13 and a mean right ventricular ejection fraction of 0.37 ± 0.15. Of patients with a radionuclide ventriculogram, regional wall motion studies were conducted in 404/434 (93.1%). Left ventricular motion was quantified in 9 segments, 5 in the anterior or right anterior oblique view and 4 in the left anterior oblique view. Segments were classified as normal, moderately hypokinetic, severely hypokinetic, akinetic, dyskinetic, aneurysmal or unknown. Wall motion was normal in 37% of apical segments and in 52 to 79% of the other segments. Akinetic motion was seen in approximately 10% of segments, most often in the apical region (20%). The ejection fraction determination was made from angiography in the catheterization laboratory for 14% of patients. The mean left ventricular ejection fraction for these patients was 0.51 ± 0.13. For 2 patients, the ejection fraction was done less than 48 hours after the AMI (outside the protocol time window), and for another, the ejection fraction was visually estimated, though not measured, by angiography.

Physical examination: The mean recorded weight was 79.9 ± 15.9 kg for men and 71.4 ± 15.5 for women. Men averaged 174.7 ± 8.0 and women 161.6 ± 7.7 cm in height. Ninety-three percent of the baseline physical examinations were done within the time window (1 day before randomization, up to the day the drug was initiated), and a total of 98% were done more than 5 days post-AMI and before drug initiation. For these, the supine heart rate averaged 73.3 ± 14.1 beats/min and the blood pressure averaged 120 ± 18/75 ± 10 mm Hg. An S_4 sound was commonly found (38%), while carotid bruit (4%), rales (7%), heaves (7%), S_3 sounds (5%) and murmurs (14%) occurred less frequently. Edema of the lower extremities was found in 10% and peripheral pulses were absent or diminished in 25%.

Chest x-ray: The chest x-ray was obtained on average 26 days post-AMI and 4.4 days before randomization, with 7% not done within the required time (at least 48 hours after the AMI, and up to 3 days after randomization). Thirty-eight percent of the patients were taking β-blocking drugs at the time of the chest x-ray, cadiac enlargement was noted in 130 (28%) of the patients, the transverse cardiac diameter averaged 153 ± 20 mm and the cardiothoracic ratio averaged 0.49 ± 0.06.

Blood samples: Ninety-eight percent of the baseline blood samples and 92% of the urine samples were done within the protocol time window (from 1 week before, up to the day of drug initiation). For these patients baseline blood samples were collected on average 2.2 ± 1.5 days before randomization and urine samples on average 0.6 ± 1.5 days. Blood and urinalysis were performed at the on-site hospital laboratories, which were not standardized, but all were certified by professional societies. The percent of measurements declared abnormal (>2 standard deviations from laboratory standards) are as follows: hemoglobin 33%, hematocrit 45%, white count 15%, platelet count 16%, specific gravity 8%, pH 9%, protein (urinalysis) 9%, glucose (urinalysis) 6%, ketones (urinalysis) 3%, sodium 8%, potassium 9%, chloride 15%, bicarbonate 13%, glucose (blood chemistry) 36%, urea nitrogen 18%, bilirubin total 8%, bilirubin direct 26%, alkaline phosphatase 25%, total serum protein 12%, albumin 15%, serum glutamic oxaloacetic transaminase 12%, serum glutamic pyruvic transaminase 15%, creatinine 13% and calcium 15%.

Twelve-lead electrocardiogram: The 12-lead electrocardiogram for baseline was obtained an average of 27 ± 21 days post-AMI and 4 ± 7.9 days before randomization. For patients randomized more than 15 days after the qualifying AMI, another electrocardiogram was required at randomization, and 1% of these baseline electrocardiograms were not done. (All electrocardiograms documenting the qualifying AMI were done.) ST abnormalities were noted in 40% of the patients, with elevation (Minnesota codes 9-2-1, 9-2-2 or 9-2-3) present in 68% of these and depression (Minnesota codes 4-1, 4-2, 4-3 or 4-4) present in 54%. T-wave abnormalities were noted in 85% of the patients. Q waves diagnostic of an AMI were observed in 69% of the patients. The distribution of the location of the AMI were: anterior 45.6%, inferior 39.6% and other 14.7%.

Three extensive baseline data forms were collected, including a socio/demographic form, a history and clinical form (tabulated in Table II) and an adverse effects form.

Socio/demographic form: The patient population was predominantly white (79%) with 17% black, 3% Hispanic and 1% Asian. Most (74%) of the patients were married, with 9% divorced, 10% widowed, 3% separated and 4% single. The average number of people living in the patient's household was 3. Only 13% had fewer than 7 years of education, but 47% had not completed high school. The most common occupation listed was laborer (32%), with 15% described as clerical, 14% as professional, 5% as homemaker and 11% as self-employed. At the time of the AMI episode, 47% were working full-time and 8% part-time and 32% were retired. Only 17% of the patients had never smoked. Although 31% of the patients stated that they were present smokers, fully 60% stated that they had been smoking as recently as the week before admission for AMI. Of those who claimed to be former smokers, over 50% reported quitting since 1981. Change to a less strenuous lifestyle, with reduced ac-

tivity, before the AMI because of health was reported by 29% of patients.

Adverse symptoms: Data on adverse symptoms were obtained at baseline on 98% of patients. At least 1 adverse symptom was volunteered by 192 (39%) of the patients. The most common symptoms volunteered were unusual tiredness or fatigue during ordinary activities (8%), heart beating fast or skipping beats (6%), headache (5%), dizziness or light headedness (5%), restlessness, nervousness (4%), dizziness only upon standing (4%), insomnia or frequent awakening from sleep (3%) and constipation (3%). When symptoms were elicited by asking a response for each specific symptom on the list, the results were similar, although the incidence was higher. Besides the aforementioned symptoms, dry mouth and coldness in hands or feet were frequently (46%) elicited.

Other procedures: Many patients underwent exercise tolerance testing (n = 107), invasive electrophysiologic studies (n = 5), coronary angiography (n = 146), angioplasty (n = 33), thrombolysis (n = 79) coronary artery bypass surgery (n = 67) or some combination of these. The CAPS protocol also included a behavioral stress testing procedure, consisting of a Pac-Man game played under pressure to improve scores in patients with adequate vision and no dominant hand mobility problems. This procedure was performed in 340 (68%) of the patients. Of the 162 instances in which the procedure was not done, 81 were due to referral to a special protocol, 7 to morbidity and the remainder to refusals and scheduling problems. Blood pressures and mean heart rates were obtained during the baseline period and during a stress period, and then during a relaxation period, each approximately 10 minutes long. The mean heart rate increased 2.6 ± 7.0 from 73.8 at baseline to 76.4 during stress and then dropped back to 74.5 beats/min during relaxation. Systolic blood pressure changed 8.0 ± 11.5 from 117.5 to 125.5 and fell back to 117.7 mm Hg. Diastolic blood pressure increased 4.8 ± 10.0 from 75.9 to 80.7 and then returned to 76.9 mm Hg.

Psychologic measures were also obtained when there were no language or reading problems. Comparisons are made for the Bortner type A scale,[10] the Beck depression inventory,[11] the Marlowe-Crowne measure of social desirability[12] and the Spielberger State/Trait Anxiety and Anger Expression Scales.[13,14] These measures were obtained on 351 patients. The Bortner type A scale quantifies factors related to hard-driving traits, time-pressured qualities and competitiveness, but not factors related to anger expression. The results from the CAPS sample, 176 ± 40, were quite similar to the post-AMI English sample, 174 ± 42, enrolled in the United Kingdom Disease Prevention Project.[15] The overall mean was approximately one-half standard deviation below the 200 cutoff on the Bortner for a type A classification. The Beck depression inventory scores appeared to be quite low in the CAPS sample, 8.4 ± 6.5. Based on norms established with psychiatric patients, this suggests that only about 2 to 3% would be expected to exhibit clinical levels of depression. It appears more parsimonious to assume that actual rates of depression were higher, and that psychiatric norms cannot be applied to the CAPS sample.

TABLE V Bivariate Distribution of VPC Frequency and Left Ventricular Ejection Fraction (LVEF)

VPC frequency (in counts per hour)*	LVEF (%) <30	30 <40	40 <50	≥50	Total
<10	0%	1%	1%	3%	5%
10 <30	5%	6%	9%	10%	29%
30 <100	4%	6%	7%	12%	30%
≥100	5%	7%	10%	14%	36%
Total	15%	20%	27%	38%	

* Based on the final baseline established for titration decisions.
VPC = ventricular premature complex.

While there was little evidence of depression, the Marlowe-Crowne scale indicated significant evidence of defensiveness. The mean level for the Marlowe-Crowne scale obtained in the CAPS sample, 19.8 ± 6.0, is at the cutoff for a significant level of defensiveness,[16] similar to a mixed cardiac sample, 19.4 ± 5.7.[17] The trait anxiety, 38.9 ± 8.2, and state anxiety, 35.7 ± 10.9, scores were similar to those observed in another post-myocardial infarction sample.[18] The anger expression data from the CAPS sample, 19.6 ± 7.4, indicated that CAPS patients were not particularly expressive of their anger.

The baseline data shown demonstrate that the randomization process worked well. There was good comparability, for most variables, between treatment groups. Most baseline data were collected within the established time windows, and the various protocol-required measures and procedures were obtained in almost all patients.

Bivariate Relations

Ignoring obvious correlations between weight and height, supine systolic and diastolic blood pressures, heart rate and electrocardiogram measurements, correlations between baseline clinical factors tended to fall into the negligible range (−0.2 to 0.2), while pairwise correlations between the summary measures of behavioral tests at baseline appear to be quite high, especially between trait anxiety and state anxiety (0.63), Beck depression instruments and state anxiety (0.57), and Beck depression instruments and trait anxiety (0.62). Correlations between these behavioral scores and a few important clinical factors (age, ejection fraction, VPC rate, heart rate and blood pressure), as well as reactivity measurements obtained from the behavioral stress test, tended to be negligible with the strongest correlations (−0.04 to −0.17), indicating more psychosocial dysfunction with increasing age.

Because of the prominence of the ejection fraction as a predictor for death,[1,5] and because of the extreme importance of the outcome measure, VPCs per hour, for CAPS, we investigated the relation of these 2 variables to virtually every other variable collected at baseline. The correlation between ventricular premature depolarization frequency and left ventricular ejection fraction was −0.07. The bivariate distribution

is shown in Table V and confirms the lack of any correlation. A *t* test was used as a nominal instrument for measuring significant mean differences of either of these 2 variables on groups determined by baseline dichotomous variables in the first 251 cases. Significance was taken as the nominal 0.165 level. Those variables found to determine groups with significantly differing mean left ejection fraction or VPC frequency for the first 251 patients were submitted to analysis on the second 251 patients, and were considered "significant" if the p value was again <0.165 and the effect was in the same direction. Similarly, a test that the correlation was zero was used to find continuous variables "significantly" related to left ventricular ejection fraction or VPC frequency. The nominal level 0.165 was chosen because if a variable was "significant" in 502 cases at the 0.05 level and was evenly distributed in the first and second 251 cases, the observed level would be 0.165 in each half. On the other hand, if all the variables were independent of the variable of interest, only 1.4% would be expected to be "significant" by chance. Of 170 variables examined, 4 were nominally "significant" with regard to ectopy counts (log[VPC/hr + 1]). These are: atrial heart rate (positively correlated) (p <0.001); use of antiarrhythmics before AMI (positively correlated) (p <0.003); bradycardia <60 (negatively correlated) (p <0.0001) and right bundle branch block (negatively correlated) (p <0.01). Two of these variables were related to heart rate (atrial heart rate and bradycardia recorded on physical examination). The use of antiarrhythmics before the AMI might well be expected to relate to measured frequency after AMI.

Using the same 170 variables, the ejection fraction showed a significant relation to 32. Many of these variables demonstrate an association of higher ejection fraction with location and "size" of infarct, fewer drugs and fewer signs of congestive heart failure. When these 32 variables were submitted to a stepwise regression procedure (BMDP2R) with a selection level of p = 0.10, the factors associated with higher ejection fraction in order of selection were an inferior AMI location, lower atrial heart rate, no prior AMI, absence of Q-waves noted on baseline electrocardiogram, higher supine systolic blood pressure, no history of congestive heart failure before the AMI, absence of diuretic use at baseline, normal white count, creatine phosphokinase within the upper limit of normal, shorter QRS duration noted on baseline electrocardiogram, β blocker use at baseline and percutaneous transluminal coronary angioplasty for this myocardial infarction.

Discussion

CAPS was designed to test the feasibility of performing a large-scale study to evaluate the effect of antiarrhythmic drug therapy for ventricular arrhythmias after AMI. Many patients were screened to identify eligible candidates. Of patients who were age and AMI eligible and who had a screening 24-hour ambulatory electrocardiogram, only 22% had qualifying arrhythmias. Over 20 patients who were age and AMI eligible were identified for each patient randomized. Of 687 eligible patients, 502 (73%) signed informed consent.

This patient population had been truncated to eliminate patients with very low ejection fraction and patients who had few VPCs. One-third of all patients included had at least 1 run of asymptomatic VT. Baseline drug administration was similar in each group, but, by chance, slightly more patients in the flecainide-imipramine/moricizine limb were taking calcium antagonists.

No relation was noted between baseline VPC frequency and the baseline ejection fraction. The selection process eliminated patients with ejection fraction ≤20% and patients with VPC rates <10/hour, and might have obscured the weak association usually found between ejection fraction and VPC rates.[1,5] The frequency of VPCs correlated positively with heart rate and use of antiarrhythmics before AMI, and was correlated negatively with bradycardia and right bundle branch block. The significance tests relating ejection fraction to other variables should be viewed cautiously. Because so many variables were examined, it would be expected that some correlations could have been noted spuriously. However, because of the approach used, it is unlikely that more than 3 or 4 correlations are spurious, and it is likely that several marginally significant correlations were missed. It is reasonable that ejection fraction correlates with measures of myocardial damage and with drug use. The lack of significant associations with VPC frequency may be in part due to the selection process in CAPS and the naturally occurring large variation in these rates. It is also possible, as others have suggested, that ectopy is independent of the baseline variables that are generally collected.

Prevalence and Significance of Atrial Fibrillation in Coronary Artery Disease (CASS Registry)

AIRLIE CAMERON, MD, MILES J. SCHWARTZ, MD, RICHARD A. KRONMAL, PhD, and ANDRZEJ S. KOSINSKI, MSc

Estimates of the prevalence of atrial fibrillation (AF) in patients with coronary artery disease have varied from "frequent" to <2%. Data on 18,343 patients with angiographically demonstrated CAD in the Coronary Artery Surgery Study (CASS) registry were reviewed and AF was found to be present in 116 (0.6%) patients. The presence of AF was positively associated with the following clinical and angiographic variables: older age, sex (male), mitral regurgitation and functional impairment due to congestive heart failure. The number of diseased coronary arteries was negatively related to the presence of AF. Atrial fibrillation was an independent predictor of survival and its presence doubled the estimated risk over those patients without AF.

(Am J Cardiol 1988;61:714–717)

Standard reference sources indicate that atrial fibrillation (AF) commonly occurs in patients with arteriosclerotic coronary artery disease (CAD).[1,2] The Framingham study[3] concluded that CAD is a "significant" precursor of chronic AF in men. Clinical[4] and angiographic[5,6] assessments of patients with proven CAD reveal an incidence of ≤2%. The pathophysiologic correlates of AF in chronic CAD are unclear. In a study of 1,126 patients with angiographic CAD, Kramer et al[6] found that in the 10 patients with AF this arrhythmia was related to left ventricular dysfunction and mitral regurgitation. In an analysis of 841 patients of varied etiologies, Haddad et al[5] wrote that, "in patients with severe left ventricular failure with multiple narrowings and low ejection fraction (10 to 25%) no AF was present." The present study evaluates the prevalence and significance of AF in the setting of angiographically proven CAD using the registry data of the Coronary Artery Surgery Study (CASS) (see Appendix).

Methods

The CASS included a multicenter registry of all patients undergoing cardiac catheterization for suspected CAD.[7] From this registry, all patients with angiographic evidence of coronary artery stenosis ≥50% of luminal diameter were reviewed as to the presence of AF on the 12-lead baseline electrocardiogram. All electrocardiograms were read in a central electrocardiographic laboratory using criteria for interpretation derived from those developed by Blackburn et al.[8] The 116 patients with AF and CAD were compared with the 15,893 patients with sinus rhythm and CAD.

Definitions and calculation methods for all variables studied have been previously described in detail.[7] In addition to age and sex, other variables further described below were considered in the analysis. The presence of congestive heart failure and functional impairment were generally evaluated prior to cardiac catheterization. Congestive heart failure was considered present when the patient had clinical signs, symptoms or radiographic signs of congestion. The clinical symptoms and signs included orthopnea, paroxysmal nocturnal dyspnea, dyspnea on exertion, congestive hepatomegaly, ascites or peripheral edema. The radiographic signs included pleural fluid, pulmonary venous congestion and prominent pulmonary veins. Functional impairment due to congestive heart

failure was estimated as mild when symptoms occurred with heavy exercise, moderate when symptoms appeared with usual daily activities and severe when the patient was limited to bed-chair existence.

Cardiothoracic ratio was the ratio of the sum of the maximal half diameters of the heart from the midline and the maximal diameter of the chest at or above the upper level of the diaphragm. Left ventricular score was computed from wall motion evaluation of the left ventriculogram in the 30° right anterior oblique projection. As has been previously described,[7] a score of 5 indicated normal contractility whereas >10 was a sign of moderate impairment. The ejection fraction was calculated by the single-plane area-length method and the left ventricular end-diastolic pressure defined as the nadir following the atrial component of the left ventricular pressure pulse.

The number of arteries narrowed was defined as the number of major coronary arteries with lesions ≥70%. Two-vessel disease was diagnosed with ≥50% stenosis of the left main coronary artery. Mitral regurgitation was recorded as slight (minimal opacification), moderate (complete opacification over 3 to 4 cardiac cycles) and severe (complete opacification of the left atrium over 1 to 2 cardiac cycles). An aneurysm of the left ventricle was defined as a discrete area protruding from the expected outline of the ventricular chamber during systole. Patients with a history of previous treatment for hypertension were considered to have hypertension.

Follow-up was obtained with standardized questionnaries by mail and telephone for 8 years according to CASS protocol,[7] with 98% follow-up obtained.

The presence of AF was tabulated versus each of the aforementioned variables. Statistical testing of the independence of the arrhythmia status from a particular variable was performed via chi-square test. To determine the relation among all of the considered variables with AF status, a stepwise discriminant analysis was performed as an initial step to predict whether or not an individual will have AF on the basis of the various independent variables and this way to narrow down the number of variables of interest. Then a logistic regression, which serves a purpose similar to that of discriminant analysis but requires less restrictive assumptions, was performed on the smaller set of variables. The rationale for using discriminant analysis was to save computer time in screening the large number of variables considered.

The set of important predictive covariates was obtained along with their p values and estimated relative risks. All p values given are 2-sided. Relative risks for continuous variables are the risks associated with a 1-unit increase in a covariate value. Relative risks for categorical variables are the risks at particular levels of the covariate compared with the lowest level of that covariate.

A Cox regression analysis, useful in choosing important predictors of survival out of the set of variables, also was carried out. All variables were considered with the exception of ejection fraction and cardiothoracic ratio, for although both are statistically significantly predictors, they had many missing values and using them would considerably reduce the number of AF cases available for the analysis. Variables chosen as important predictors are reported together with p values and the instantaneous hazard ratios (referred to as relative risks). Interpretation of these relative risks is similar to that described for logistic regression. Survival curves were calculated by the lifetable method and compared by log-rank statistics.

Only p values <0.05 were considered statistically significant. All p values should be cautiously interpreted because of the large number of statistical tests carried out and the difficulty of verifying the assumptions underlying the multivariate procedures.

TABLE I Univariate Relation Between Age, Sex and Systemic Hypertension and the Presence of Atrial Fibrillation

	Sinus Rhythm (n = 15,893) No. (%)	AF (n = 116) No. (%)	p Value
Age 18–39	976 (6)	2 (2)

≥60	4,214 (27)	62 (54)	
Men	13,253 (83)	107 (92)	0.0157
Hypertension	5,360 (34)	39 (34)	NS

AF = atrial fibrillation; NS = not significant.

Results

Atrial fibrillation was present in 116 (0.6%) of the 18,343 patients with angiographically demonstrated CAD in the CASS registry. Sinus rhythm was present in 15,893 (87%) patients. Other arrhythmias were premature beats (7%), sinus bradycardia (4.1%), sinus tachycardia (1.5%), ventricular or supraventricular tachycardias (0.08%), atrial flutter (0.07%), pacemaker (0.03%), wandering atrial pacemaker (0.01%)and atrial-ventricular dissociation (0.01%). The 116 patients with AF did not have any associated arrhythmia. Of

AF = atrial fibrillation; 0 = none; + = slight; ++ = moderate; +++ = severe.

the 63 patients having repeat electrocardiograms during follow-up, 45 (71%) had sustained AF on 1 or more electrocardiograms, 3 had miscellaneous arrhythmias and 15 (24%) had reverted to sinus rhythm.

Atrial fibrillation in CAD was more common in patients older than 60 years of age ($p < 0.0001$) and in men ($p = 0.0157$) but was not influenced by history of hypertension (Table I). All parameters of ventricular function (Table II) showed a significant correlation of increasing impairment with a higher prevalence of AF. Neither the extent of CAD as measured by the number of segments diseased, nor the presence of a ventricular aneurysm affected the prevalence of AF (Table III); however, increasing severity of mitral regurgitation correlated with higher frequency of AF ($p < 0.0001$).

Using logistic regression analysis, the statistically significant independent predictors positively associated with atrial fibrillation were identified as age, sex, functional impairment and mitral regurgitation, all at $p < 0.0001$.

The relative risk associated with a 1-year increase in age was 1.07. Males were estimated to be at 5.4 times the risk of females. A comparison of patients with various degrees of functional impairment due to congestive heart failure with patients without congestive heart failure revealed a clear trend of greater relative risk with increasing impairment (relative risks of 2.48, 3.52, 8.15 and 6.03 for nonexistent, mild, moderate and severe impairment, respectively). Similarly, increasing severity of mitral regurgitation resulted in greater estimated relative risks when compared with patients without mitral regurgitation (relative risks of 1.91, 4.54 and 6.57 for slight, moderate and severe mitral regurgitation, respectively). The number of coronary arteries diseased was negatively associated with the presence of AF. The relative risk for patients with 1, 2, or 3 vessels was less than half (0.39, 0.28 and 0.27, respectively) that of patients with no arteries with >70% stenosis ("0-artery disease").

Atrial fibrillation, using Cox regression analysis, was an independent predictor of mortality with a relative risk of 1.982 (95% confidence interval 1.496, 2.626; $p < 0.0001$), as compared with sinus rhythm. Other predictors were high left ventricular score, functional impairment, moderate or severe mitral regurgitation, multiple CAD, history of hypertension and older age. The estimated probability of survival at 7 years (Figure 1) was 38% for patients with AF and 80% for patients in sinus rhythm ($p < 0.0001$).

Discussion

Observations as to the frequency of AF in CAD range from "common"[2] to 0.8% in 1,176 patients[6] or 0.2% in 496 patients.[5] The present study, carried out with a larger number of patients (18,343) and representing many hospitals and geographic areas, confirms a low overall frequency (0.6%) of AF in patients with angiographically proven CAD.

Previous studies[5,6] have disagreed as to the relation of AF to left ventricular dysfunction. The CASS data clearly established that AF is associated with the clinical features of congestive heart failure and the laboratory criteria reflective of left ventricular dysfunction or mitral regurgitation; however, it does not correlate with the extent of CAD as measured by the number of coronary artery segments with lesions of ≥50% stenosis. Atrial fibrillation is negatively associated with the number of major coronary arteries with ≥70% stenosis.

According to Ewy et al,[9] the causes of chronic AF include pathologic changes in the atrial wall, alter-

ations in the sinoauricular node and intranodal pathways, increasing age and left atrial pressure. In our study, the abnormal hemodynamics associated with left ventricular dysfunction and mitral regurgitation may have led to AF by increasing left atrial pressure and diameter. The increased incidence in males noted in our study and in previous reports[3,4] is not readily explained and may be related to some unknown variables such as alcohol consumption.[10]

Both paroxysmal and persistent AF are included in the present study. Because follow-up electrocardiograms were available in only 54% of patients presenting with AF, it was not possible to determine if the adverse effect of AF on survival was present in both the paroxysmal and persistent forms. Presumably, paroxysmal AF is a frequent percursor of persistent or sustained arrhythmia and would impart a similar adverse effect on survival. The prevalence of thromboembolic episodes was not investigated in this study but has been shown in other reports[11,12] to be greatly increased in patients with AF, particularly with associated mitral stenosis. The risk of systemic embolism in association with AF has been shown[12] to be almost as high in ischemic heart disease as with mitral valve disease. Undoubtedly, systemic embolism played a role in the impaired survival noted in this study of patients with AF.

The present study demonstrates that the presence of AF alone, without other stigmata of CAD, should prompt the physician to search for causes of AF other than angiographically demonstrated CAD.

Helicopter Transport of Patients During Acute Myocardial Infarction

RAYE L. BELLINGER, MD, ROBERT M. CALIFF, MD, DANIEL B. MARK, MD, MPH, RITA A. WEBER, RN, MS, PATRICIA COLLINS, RN, JANICE STONE, RN, HARRY R. PHILLIPS, III, MD, LAWRENCE GERMAN, MD, and RICHARD S. STACK, MD

Initial experience with a regional system of emergency helicopter transport of patients with acute myocardial infarction (AMI) referred for emergent cardiac catheterization and percutaneous transluminal coronary angioplasty (PTCA) is described. Two hundred fifty patients with AMI were transported from within a 150-mile radius to Duke University Medical Center over a 15-month period. All patients were within 12 hours of onset of symptoms. Thrombolytic therapy was administered to 240 (96%) patients (72% before or in-flight). The time to administration of thrombolytic therapy ranged from 30 to 120 minutes (median 180), while the time to arrival in the interventional catheterization laboratory ranged from 105 to 815 minutes (median 300). The flight time was 12 to 77 minutes (median 31). Most patients had 1- or 2-vessel coronary artery disease; the baseline ejection fraction ranged from 27 to 70% (median 42). Transient hypotension was the most common complication both pre-flight and in-flight. Third-degree atrioventricular block and nonsustained ventricular tachycardia were the next most common complications. Ventricular fibrillation or sustained ventricular tachycardia occurred before takeoff in 38 patients (15%). No patients had ventricular fibrillation, asystole or respiratory arrest during transport. Fluid boluses for hypotension were the most common intervention. Five patients required cardiopulmonary resuscitation in-flight; 3 before liftoff and 2 required a brief period of cardiopulmonary resuscitation during sustained ventricular tachycardia. Fourteen patients had pressor therapy, military antishock trousers or both to maintain adequate blood pressure. Neither cardioversion, defibrillation nor intubation were performed in-flight. Thus, in-flight complications are infrequent and can be managed en route to an intervention center. The overall benefit of regional helicopter transportation relative to its cost has yet to be determined.

Therapies designed to achieve early and sustained coronary reperfusion in patients with acute myocardial infarction (AMI) decrease in-hospital mortality[1] and improve left ventricular function[2,3] compared with standard therapy. Intravenous thrombolytic therapy alone has 2 major shortcomings. First, a significant number of patients fail to achieve reperfusion. Second, a significant atherosclerotic plaque often remains after successful thrombolytic therapy, increasing the risk of recurrent infarction[4] and periinfarction ischemia.[5] Percutaneous transluminal coronary angioplasty (PTCA) provides a reasonable adjunct to thrombolytic therapy because it often achieves reperfusion where thrombolysis fails[6] and it increases the luminal diameter narrowed by the residual atherosclerotic plaque.[7]

An interventional program including thrombolytic therapy, acute cardiac catheterization, PTCA and coronary artery bypass surgery is beyond the means of many hospitals. However, patients admitted to such institutions may benefit from a regional system that includes immediate thrombolysis followed by rapid transportation of patients with AMI to a nearby intervention center. While a helicopter is the most efficient means of transportation for distances up to 150 miles, concerns have arisen about the safety of such transportation for potentially unstable AMI patients. This study examines our initial experience with a regional system of helicopter transport of patients in the early stages of AMI with particular attention to the complications encountered.

Methods

The Duke LifeFlight Helicopter Service began transporting critically ill patients in March 1985. Many patients were transported for interventional cardiac catheterization during AMI. Because of established referral patterns with community hospitals and the limited range of the helicopters used, most flights stayed within a 150-mile radius of our medical center.

Patients were considered to have an AMI if they met the following criteria: (1) a compatible clinical history of chest pain or equivalent of <12 hours in duration; (2) at least 1 mm of ST elevation in at least 2 of 6 anterior leads (V_1 through V_6), 2 of 3 inferior leads (II,III, aVF) or both lateral leads (I, aVL); (3) no resolution of ST elevation with 0.4 mg sublingual nitroglycerin in 3 consecutive doses. Once patients fulfilled the criteria for AMI, thrombolytic therapy was usually administered after intravenous premedication with 50 mg diphenhydramine and 300 mg cimetidine. Patients who were at high risk of bleeding or had other known contraindications to thrombolytic therapy did not receive thrombolytic agents.

Streptokinase was the predominant thrombolytic agent used; 1.5 million units of streptokinase mixed in 250 cc of 5% dextrose and water was infused intravenously over a 30- to 45-minute period. During the course of this study, recombinant tissue-type plasminogen activator was made available to patients with the entry requirements of the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) trial. The study protocol and dosing regimen for the recombinant tissue-type plasminogen activator infusion have been described previously.[8]

Patients were designated as meeting the criteria for AMI by their referring physicians. The referring physicians then notified either the Duke cardiologist on-call or the Duke LifeFlight medical control officer on-call to arrange transfer of the patient. A helicopter and flight crew consisting of an experienced pilot and 2 flight nurses with previous critical care experience were dispatched to the referring hospital. If the weather conditions were adverse (20% of flight requests), alternative transport by ambulance was arranged or the patient was not transferred. At the discretion of the referring physician and the Duke accepting physician, thrombolytic therapy was started either at the community hospital, during air transport or at Duke University Medical Center. Vasoactive, antiarrhythmic and other specialized therapy was initiated by the referring physician as needed. After acceptance of the patient, the flight crew radioed the patient's status to the Duke medical control officer and, during the transport, notified the medical control officer of any changes in the patient's status so that existing therapy could be modified or new therapy initiated. Changes in patient status and interventions were documented by the flight team.

Upon arrival at Duke, all patients underwent diagnostic cardiac catheterization and, when clinically indicated, coronary angioplasty or coronary artery bypass grafting. Each patient's flight record and in-patient chart were reviewed to ascertain complications and interventions during transport and throughout the hospitalization.

TABLE I Patient Data: Quartiles

† Time from the onset of chest pain to the start of cardiac catheterization.

Results

From March 1, 1985, through June 30, 1986, 1,597 critically ill patients were transported from community hospitals to Duke University Medical Center. Within the group transported for cardiac reasons (n = 896), 250 patients met the study criteria for AMI. Most patients (96%) were given thrombolytic therapy: intravenous streptokinase was administered to 77%; intravenous recombinant tissue plasminogen activator was administered to 19%; and 4% (10/250) of patients did not receive thrombolytic therapy because of contraindications. Thrombolytic therapy was started at the referral hospital in 70% (168/240), in-flight in 5% (12/240) and at Duke University Medical Center in 25% (60/240) of patients.

Tables I and II summarize the clinical and transport-related variables. Thrombolytic therapy was started early in most patients (median of 3 hours from symptom onset) and cardiac catheterization was performed within 2 hours of thrombolytic therapy treatment in most patients.

All patients underwent emergency coronary arteriography and ventriculography upon arrival at Duke. Only 3 (1%) patients were found to have insignificant coronary artery disease (i.e., ≤50% diameter stenosis in all major coronary vessels). One hundred and seven (43%) patients had 1-vessel coronary artery disease, 93

TABLE III Complications During Helicopter Transport of Patients with Acute Myocardial Infarction

	Pre-Flight (n)	In-Flight (n)	Total (n)
Sinus bradycardia (HR <40 beats/min)	10	4	14
Atrial fibrillation/flutter	3	3	6
Ventricular fibrillation	19	0	19
Ventricular tachycardia sustained	19	3	22
Ventricular tachycardia nonsustained	6	7	13
Asystole	1	0	1
Third-degree AV block	19	8	27
Second-degree AV block type I	2	0	2
Second-degree AV block type II	3	0	3
Transient hypotension*	30	21	51
Sustained hypotension†	20	4	24
Respiratory arrest	9	0	9

* Defined as a systolic blood pressure of <90 mm Hg for <1 hour.
† Defined as a systolic blood pressure of <90 mm Hg for >1 hour.
AV = atrioventricular; HR = heart rate.

(37%) had 2-vessel disease and 48 (19%) had 3-vessel disease. The baseline ejection fraction was 42%. Five percent of patients had coexistent left main disease.

One hundred and eighty-eight (75%) patients underwent PTCA during their admission; 176 (94%) were performed emergently (i.e., at the time of the cardiac catheterization). Persistent reperfusion (i.e., sustained angiographic perfusion of the infarct-related artery) was obtained in 94% of the patients who underwent emergent coronary angioplasty. Forty-five (18%) patients underwent coronary artery bypass grafting during admission for either severe 3-vessel disease, coexistent left main disease or failed reperfusion by PTCA. Seventeen (7%) patients were reperfused with thrombolytic therapy alone and, because of no significant residual coronary stenosis in the infarct-related artery after thrombolysis, did not undergo either coronary angioplasty or coronary artery bypass grafting.

Table III summarizes the pre-flight and in-flight complications encountered during the transport of patients with AMI. Transient hypotension (systolic blood pressure of <90 mm Hg for <1 hour) was the most frequent complication both pre-flight and in-flight. Third-degree atrioventricular block was the second most frequent in-flight complication followed by nonsustained ventricular tachycardia. Sustained ventricular tachycardia was only encountered in 3 patients. No patient had ventricular fibrillation, asystole or respiratory arrest while in-flight; yet 19 patients had ventricular fibrillation and 19 patients had sustained ventricular tachycardia before air transport.

Table IV lists therapeutic interventions made by the LifeFlight medical crew both pre-flight and in-flight for these patients. Fluid boluses for transient and sustained hypotension were the most frequent therapy during air transport. Fourteen patients required either pressor therapy, use of military antishock trousers or both to maintain adequate blood pressure. Thirty-four patients required cardiopulmonary resuscitation pre-flight. Five patients received cardiopulmonary resuscitation during air transport: 3 had been receiving cardiopulmonary resuscitation pre-flight with continuation during transport, and 2 patients with sustained ventricular tachycardia required cardiopulmonary resuscitation for a short time before spontaneously converting to sinus rhythm. Cardioversion, defibrillation or intubation was not necessary during any of the air transports.

The majority of patients received lidocaine before transport as prophylactic antiarrhythmic therapy. All patients who received antiarrhythmic therapy while in-flight did so because of ventricular or supraventricular arrhythmias that were felt to be life-threatening. Hemodynamically unstable bradyarrhythmias in the form of severe sinus bradycardia (heart rate <40 beats/min) and third-degree atrioventricular block were generally treated initially with atropine. In 3 patients, an external pacemaker had been placed pre-flight and was used in-flight. Fifteen patients with temporary transvenous pacemakers placed pre-flight were transported without incident.

Emergency landing: On July 21, 1986, while transporting a patient from a referring hospital to Duke, the helicopter experienced a power loss at an altitude of 2,500 feet. The aircraft was transporting a 62-year-old man with an anterior AMI. He had been given 1.5 million units of streptokinase just before takeoff. The pilot successfully landed the aircraft in an open field. The pilot, crew and patient suffered only minor injuries, but the aircraft was damaged beyond repair. The patient was subsequently transported to Duke University Medical Center by a second helicopter and arrived at Duke approximately 90 minutes after the emergency landing.

Discussion

The most important finding of our study is the relatively small number of complications encountered by our patients while they were being transported from

their community hospitals. The low complication rate is especially remarkable in view of the large number of complications they experienced before transfer. Patients who suffered complications before transport may, in fact, have benefitted more from helicopter transfer than other patients because of the greater risk that a long ground trip to a tertiary center poses to an unstable patient.

The rarity of both ventricular tachycardia and fibrillation during flight may have resulted from the frequent use of antidysrhythmic prophylaxis before takeoff. Nonsustained ventricular tachycardia was treated with a bolus infusion of either lidocaine or procainamide; patients who did not respond were given bretylium. All 3 patients developing sustained ventricular tachycardia in-flight spontaneously converted to sinus rhythm prior to direct current countershock. Two of the 3 patients received brief cardiopulmonary resuscitation by 1 crewmember while the other crewmember was preparing to administer a direct current countershock. All 3 patients had received lidocaine therapy before liftoff.

Patients who developed severe bradyarrhythmias (severe sinus bradycardia or high grade second- or third-degree atrioventricular block) were first treated with atropine. If a transcutaneous external pacemaker was available, the patient was paced externally as needed; in the absence of an external pacemaker, or if the patient did not respond to atropine, isoproterenol was infused. None of the 3 patients developing atrial fibrillation or flutter required therapy during transport.

The helicopter transport system used in this study has certain advantages over conventional ambulance transport. The care given in the helicopter by 2 highly-trained critical care nurses in constant radio communication with a physician at the tertiary center is likely to be more effective than care rendered in an ambulance. Even when a physician accompanies a patient during ground transport, the environment lacks the physical stability possible within a helicopter, which allows for careful monitoring and control of blood pressure, cardiac rhythm and therapeutic infusions. When specific interventions, such as volume, antidysrhythmic and inotropic infusions are required, the medical flight team can maintain precise control with physician guidance by radio communication.

While the total amount of time from referral to arrival at the tertiary center may not be less with helicopter transport, the amount of time the patient spends travelling between hospitals is markedly diminished. The patient remains under the careful management of the referring physician until the arrival of the helicopter, minimizing the time in a less controlled environment. This aspect of helicopter transport also preserves local emergency medical transport resources, making it unnecessary for a physician or nurse from the community hospital to accompany the patient to the tertiary hospital, as is frequently the case with ambulance transport. The loss of medical personnel and equipment, especially in smaller communities, impairs the ability of the local medical services to respond to other emergencies. Helicopter transport with constant radio communication also makes it possible for the tertiary center to prepare for the patient being transported, based on information passed between helicopter and hospital about the status of the patient. Many of the potential advantages of this system pertain more to the personnel and equipment for communication than to the specific mode of transport. A similar system could be developed for specialized ambulance and fixed-wing transport.

TABLE IV Interventions During Helicopter Transport of Patients with Acute Myocardial Infarction

	Pre-Flight (n)	In-Flight (n)	Total (n)
CPR	34	5	39
Cardioversion/defibrillation	24	0	24
Intubation	12	0	12
Fluid bolus	29	24	53
MAST	0	7	7
External pacer	3	3	6
Transvenous pacer	15	0	15
Atropine	13	7	20
Isoproterenol	3	2	5
Lidocaine	196	10	206
Procainamide	6	0	6
Bretylium	7	2	9
Dopamine	30	5	35
Dobutamine	6	0	6
Levophed	0	2	2

CPR = cardiopulmonary resuscitation; MAST = military antishock trousers.

Aircraft safety is an important and controversial issue, which has major ramifications for the transport of critically ill patients. From 1980 to 1986, there have been 66 aeromedical helicopter crashes; 21 people have died and 16 have been injured. At present, there are approximately 171 aeromedical helicopter services operating throughout the U.S. For 1986, the accident rate for medical helicopters was 17.7/100,000 patient transports.[9] Documented causes of these crashes include catastrophic mechanical failures and pilot error during operation in marginal weather conditions. Recently, the American Society of Hospital-Based Air Medical Services has published guidelines concerning pilot and crew standards, aircraft operating and equipment and maintenance standards in order to improve safety during aeromedical transports.[10] Details of our safety standards have been published elsewhere.[11]

Intravenous thrombolytic therapy is the most common technique used in clinical practice today for rapid reperfusion of infarct-related vessels. It is especially suited to community hospitals, which may not have the resources to support a full-time interventional cardiac catheterization facility capable of acute coronary angioplasty and emergency coronary bypass surgery. Intravenous thrombolytic therapy has a reperfusion rate of 30 to 70% in well-controlled trials. For the 30 to 70% of patients who do not respond to thrombolytic therapy in a community hospital without interventional facili-

ties, transportation of the patient to a specialized interventional center will improve the chances of infarct-vessel patency.

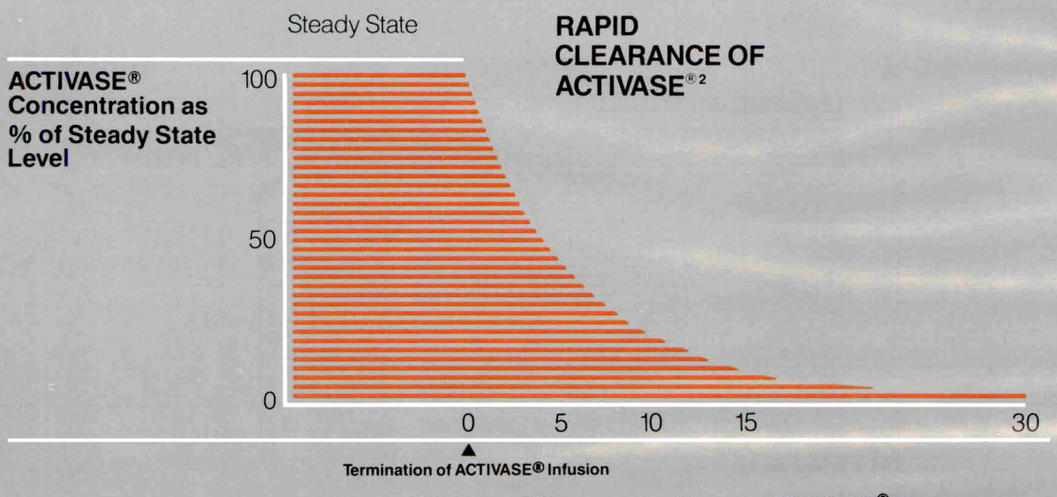
FIBRINOLYTIC SAFETY

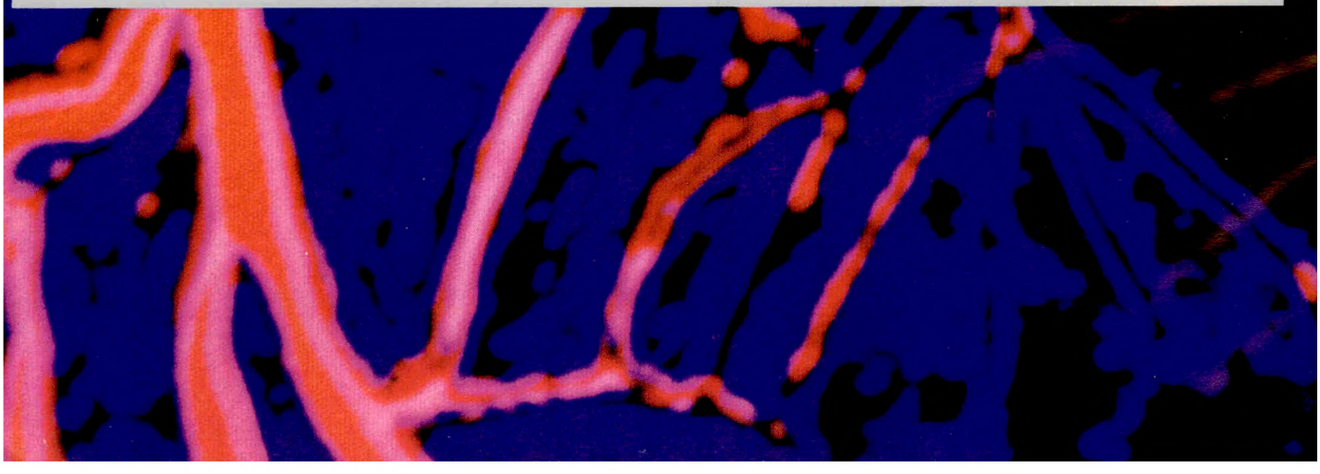
EXCELLENT SAFETY PROFILE IN ACUTE MI:

▲ FIVE-MINUTE HALF-LIFE AND FIBRIN SPECIFICITY Lower the Risk of Serious Bleeding in Emergency Procedures Such as Hemodynamic Monitoring, Angioplasty and Bypass Surgery (CABG).



▲ ACTIVASE® Is Identical to Human Tissue Plasminogen Activator (t-PA). No Serious or Life-Threatening Reactions Have Been Reported.

2. Data on file, Genentech, Inc.



In Acute Myocardial Infarction,

TIME IS MUSCLE

Bleeding is the Most Common Complication of Thrombolytic Therapy

INCIDENCE OF BLEEDING COMPLICATIONS FOLLOWING ACTIVASE® IN 848 PATIENTS:

Bleeding site	Clinically significant events %
–Arterial catheterization site	20
–Gastrointestinal (GI)	5
–Venipuncture	4
–Hematuria	4
–Occult GI	1
–Microscopic hematuria	1
–Ecchymosis	1
–Retroperitoneal	< 1
–Intracranial	0.4

Careful Patient Selection Can Optimize the Benefit-to-Risk Ratio. Consider These Factors in Evaluating an Individual for ACTIVASE® Therapy:

CONTRAINDICATIONS

–Active internal bleeding
–History of cerebrovascular accident
–Recent (within two months) intracranial or intraspinal surgery or trauma (see WARNINGS)
–Intracranial neoplasm, arteriovenous malformation, or aneurysm
–Known bleeding diathesis
–Severe uncontrolled hypertension

Alteplase, recombinant

I.V. fibrinolytic therapy for acute myocardial infarction

NEW

ACTIVASE®
Alteplase, recombinant

In Acute Myocardial Infarction,
TIME IS MUSCLE

Rationale for ACTIVASE® Therapy

Acute MI is an evolving process caused by an occlusive coronary thrombus

I.V. administration of ACTIVASE®:

- *Opens coronary arteries rapidly, effectively, and keeps them open*
- *Improves left ventricular function, and reduces incidence of congestive heart failure*
- *Prompt intervention possible shortly after ACTIVASE® therapy due to excellent safety profile—compatible with angioplasty, bypass surgery and hemodynamic monitoring*

ACTIVASE® is a potent agent, and the benefit-to-risk ratio should be carefully considered in every patient

ACTIVASE® Dosage Schedule

Lytic dose	Bolus Hr 1	6-10mg 50-54mg
Maintenance Dose	Hr 2 Hr 3	20mg 20mg
TOTAL Recommended Dose		100mg

ACTIVASE®
Alteplase, recombinant

I.V. fibrinolytic therapy for acute myocardial infarction

ACTIVASE®
Alteplase, recombinant

DESCRIPTION: ACTIVASE®, Alteplase, is a tissue plasminogen activator produced by recombinant DNA technology. It is a sterile, purified glycoprotein of 527 amino acids. It is synthesized using the complementary DNA (cDNA) for natural human tissue-type plasminogen activator obtained from a human melanoma cell line. The manufacturing process involves the secretion of the enzyme, alteplase, into the culture medium by an established mammalian cell line (Chinese Hamster Ovary cells) into which the cDNA for alteplase has been genetically inserted.

ACTIVASE®, a sterile, white to off-white, lyophilized powder, is intended for intravenous administration after reconstitution with Sterile Water for Injection, USP. The quantitative composition of the lyophilized product is:

50 mg (29 million IU) Vial	20 mg (11.6 million IU) Vial
Alteplase 50 mg (29 million IU)	Alteplase 20 mg (11.6 million IU)
L-Arginine 1.7 g	L-Arginine 0.7 g
Phosphoric Acid 0.5 g	Phosphoric Acid 0.2 g
Polysorbate 80, less than 4 mg	Polysorbate 80, less than 1.6 mg

Phosphoric acid and/or sodium hydroxide may be used prior to lyophilization for pH adjustment.

Biological potency is determined by an *in vitro* clot lysis assay and is expressed in International Units as tested against the WHO standard. The specific activity of ACTIVASE® is 580,000 IU/mg.

CLINICAL PHARMACOLOGY: ACTIVASE® is an enzyme (serine protease) which has the property of fibrin-enhanced conversion of plasminogen to plasmin. It produces limited conversion of plasminogen in the absence of fibrin. When introduced into the systemic circulation at pharmacologic concentration, ACTIVASE® binds to fibrin in a thrombus and converts the entrapped plasminogen to plasmin. This initiates local fibrinolysis with limited systemic proteolysis. Following administration of 100 mg ACTIVASE®, there is a decrease (16-36%) in circulating fibrinogen.[1,2,3] In a controlled trial, 8 of 73 patients (11%) receiving ACTIVASE® (1.25 mg/kg body weight over 3 hours) experienced a decrease in fibrinogen to below 100 mg/dL.[2]

ACTIVASE® is cleared rapidly from circulating plasma at a rate of 550-680 mL/min. ACTIVASE® is cleared primarily by the liver. More than 50% of ACTIVASE® present in plasma is cleared within 5 minutes after the infusion has been terminated, and approximately 80% is cleared within 10 minutes.

Coronary occlusion due to a thrombus is present in the infarct-related coronary artery in approximately 80% of patients experiencing a transmural myocardial infarction evaluated within four hours of onset of symptoms.[4,5]

In patients studied in a controlled trial with coronary angiography at 90 and 120 minutes following infusion of ACTIVASE®, infarct artery patency was observed in 71% and 85% of patients (n=85), respectively.[2,3] In a second study, where patients received coronary angiography prior to and following infusion of ACTIVASE® within six hours of the onset of symptoms, reperfusion of the obstructed vessel occurred within 90 minutes after the commencement of therapy in 71% of 83 patients.[1]

In a double blind, randomized trial (138 patients) comparing ACTIVASE® to placebo, patients infused with ACTIVASE® within 4 hours of onset of symptoms experienced improved left ventricular function at day 10 compared to the placebo group, when ejection fraction was measured by gated blood pool scan (53.2% versus 46.4%, p=0.018). Relative to baseline (day 1) values, the net changes in ejection fraction were +3.6% and -4.7% for the treated and placebo group, respectively (p=0.0001). Also documented was a reduced incidence of clinical congestive heart failure in the treated group (14%) compared to the placebo group (33%) (p=0.009).[3]

In a second double blind, randomized trial (136 patients) comparing ACTIVASE®, Alteplase, to placebo, patients infused with ACTIVASE® within 2.5 hours of onset of symptoms experienced improved left ventricular function at a mean of 21 days compared to the placebo group, when ejection fraction was measured by gated blood pool scan (54% versus 48%, p=0.008) and by contrast ventriculogram (62% versus 54%, p=0.002). Although the contribution of ACTIVASE® alone is unclear, the incidence of nonischemic cardiac complications when taken as a group (i.e., congestive heart failure, pericarditis, atrial fibrillation, conduction disturbance) was reduced compared to those patients treated with placebo (p<0.01).[3]

INDICATIONS AND USAGE: ACTIVASE® is indicated for use in the management of acute myocardial infarction (AMI) in adults for the lysis of thrombi obstructing coronary arteries, the improvement of ventricular function and reduction of the incidence of congestive heart failure. Treatment should be initiated as soon as possible after the onset of AMI symptoms (see CLINICAL PHARMACOLOGY).

CONTRAINDICATIONS: Because thrombolytic therapy increases the risk of bleeding, ACTIVASE® is contraindicated in the following situations: • Active internal bleeding • History of cerebrovascular accident • Recent (within two months) intracranial or intraspinal surgery or trauma (see WARNINGS) • Intracranial neoplasm, arteriovenous malformation, or aneurysm • Known bleeding diathesis • Severe uncontrolled hypertension.

WARNINGS: Bleeding The most common complication encountered during ACTIVASE® therapy is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding involving the gastrointestinal tract, genitourinary tract, retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., venous cutdowns, arterial punctures, sites of recent surgical intervention).

The concomitant use of heparin anticoagulation may contribute to the bleeding. Some of the hemorrhagic episodes occurred one or more days after the effects of ACTIVASE® had dissipated, but while heparin therapy was continuing.

As fibrin is lysed during ACTIVASE® therapy, bleeding from recent puncture sites may occur. Therefore, thrombolytic therapy requires careful attention to all potential bleeding sites (including catheter insertion sites, arterial and venous puncture sites, cutdown sites and needle puncture sites).

Intramuscular injections and nonessential handling of the patient should be avoided during treatment with ACTIVASE®. Venipunctures should be performed carefully and only as required.

Should an arterial puncture be necessary during an infusion of ACTIVASE®, it is preferable to use an upper extremity vessel that is accessible to manual compression. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

Should serious bleeding (not controllable by local pressure) occur, the infusion of ACTIVASE®, Alteplase, and any concomitant heparin should be terminated immediately.

Each patient being considered for therapy with ACTIVASE® should be carefully evaluated and anticipated benefits weighed against potential risks associated with therapy.

In the following conditions, the risks of ACTIVASE® therapy may be increased and should be weighed against the anticipated benefits: • Recent (within 10 days) major surgery, e.g., coronary artery bypass graft, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels • Cerebrovascular disease • Recent gastrointestinal or genitourinary bleeding (within 10 days) • Recent trauma (within 10 days) • Hypertension: systolic BP ≥ 180 mm Hg and/or diastolic BP ≥ 110 mm Hg • High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation • Acute pericarditis • Subacute bacterial endocarditis • Hemostatic defects including those secondary to severe hepatic or renal disease • Significant liver dysfunction • Pregnancy • Diabetic hemorrhagic retinopathy, or other hemorrhagic ophthalmic conditions • Septic thrombophlebitis or occluded AV cannula at seriously infected site • Advanced age, i.e., over 75 years old • Patients currently receiving oral anticoagulants, e.g., warfarin sodium • Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Arrhythmias Coronary thrombolysis may result in arrhythmias associated with reperfusion. These arrhythmias (such as sinus bradycardia, accelerated idioventricular rhythm, ventricular premature depolarizations, ventricular tachycardia) are not different from those often seen in the ordinary course of acute myocardial infarction and may be managed with standard antiarrhythmic measures. It is recommended that antiarrhythmic therapy for bradycardia and/or ventricular irritability be available when infusions of ACTIVASE® are administered.

PRECAUTIONS: General Standard management of myocardial infarction should be implemented concomitantly with ACTIVASE® treatment. Noncompressible arterial puncture must be avoided (i.e., internal jugular and subclavian punctures should be avoided to minimize bleeding from noncompressible sites). Arterial and venous punctures should be minimized. In the event of serious bleeding, ACTIVASE® and heparin should be discontinued immediately. Heparin effects can be reversed by protamine.

Readministration There is no experience with readministration of ACTIVASE®. If an anaphylactoid reaction occurs, the infusion should be discontinued immediately and appropriate therapy initiated.

Although sustained antibody formation in patients receiving one dose of ACTIVASE® has not been documented, readministration should be undertaken with caution. Detectable levels of antibody (a single point measurement) were reported in one patient but subsequent antibody test results were negative.

Laboratory Tests During ACTIVASE® therapy, if coagulation tests and/or measures of fibrinolytic activity are performed, the results may be unreliable unless specific precautions are taken to prevent *in vitro* artifacts. ACTIVASE® is an enzyme that when present in blood in pharmacologic concentrations remains active under *in vitro* conditions. This can lead to degradation of fibrinogen in blood samples removed for analysis. Collection of blood samples in the presence of aprotinin (150-200 units/mL) can to some extent mitigate this phenomenon.

Drug Interactions The interaction of ACTIVASE® with other cardioactive drugs has not been studied. In

addition to bleeding associated with heparin and vitamin K antagonists, drugs that alter platelet function (such as acetylsalicylic acid, dipyridamole) may increase the risk of bleeding if administered prior to, during or after ACTIVASE®, Alteplase, therapy.

Use of Anticoagulants Heparin has been administered concomitantly with and following infusions of ACTIVASE® to reduce the risk of rethrombosis. Because either heparin or ACTIVASE® alone may cause bleeding complications, careful monitoring for bleeding is advised, especially at arterial puncture sites.

Pregnancy (Category C) Animal reproduction studies have not been conducted with ACTIVASE®. It is also not known whether ACTIVASE® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. ACTIVASE® should be given to a pregnant woman only if clearly needed.

Pediatric Use Safety and effectiveness of ACTIVASE® in children has not been established.

Carcinogenesis, Mutagenesis, Impairment of Fertility Long-term studies in animals have not been performed to evaluate the carcinogenic potential or the effect on fertility. Short-term studies, which evaluated tumorigenicity of ACTIVASE® and effect on tumor metastases in rodents, were negative.

Studies to determine mutagenicity (Ames test) and chromosomal aberration assays in human lymphocytes were negative at all concentrations tested. Cytotoxicity, as reflected by a decrease in mitotic index, was evidenced only after prolonged exposure and only at the highest concentrations tested.

Nursing Mothers It is not known whether ACTIVASE® is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when ACTIVASE® is administered to a nursing woman.

ADVERSE REACTIONS: Bleeding The most frequent adverse reaction associated with ACTIVASE® is bleeding. The type of bleeding associated with thrombolytic therapy can be divided into two broad categories: • Internal bleeding, involving the gastrointestinal tract, genitourinary tract, retroperitoneal or intracranial sites • Superficial or surface bleeding, observed mainly at invaded or disturbed sites (e.g., venous cutdowns, arterial punctures, sites of recent surgical intervention).

The following incidence of significant internal bleeding (estimated as > 250 cc blood loss) has been reported in studies in over 800 patients treated at all doses:

	Total Dose ≤ 100 mg	Total Dose > 100 mg
gastrointestinal	5%	5%
genitourinary	4%	4%
ecchymosis	1%	< 1%
retroperitoneal	< 1%	< 1%
epistaxis	< 1%	< 1%
gingival	< 1%	< 1%

The incidence of intracranial bleeding (ICB) in patients treated with ACTIVASE® is as follows:

Dose	Number of Patients	%
100 mg	3272	0.4
150 mg	1779	1.3
1-1.4 mg/kg	237	0.4

These data indicate that a dose of 150 mg of ACTIVASE® should not be used because it has been associated with an increase in intracranial bleeding.

Although fatalities due to intracranial bleeding have been observed during and after ACTIVASE® therapy, an analysis of data from three controlled clinical trials in acute myocardial infarction revealed no evidence of increased overall in-hospital mortality. While not statistically significant, in-hospital mortality in patients treated with ACTIVASE®, Alteplase, was lower (4.7%, 11/232) compared to patients not receiving ACTIVASE® (6.8%, 11/162).[3]

Should serious bleeding in a critical location (intracranial, gastrointestinal, retroperitoneal, pericardial) occur, ACTIVASE® therapy should be discontinued immediately, along with any concomitant therapy with heparin.

Fibrin which is part of the hemostatic plug formed at needle puncture sites will be lysed during ACTIVASE® therapy. Therefore, ACTIVASE® therapy requires careful attention to potential bleeding sites, e.g., catheter insertion sites, arterial puncture sites.

Allergic Reactions No serious or life-threatening allergic reactions have been reported. Other mild hypersensitivity reactions such as urticaria have been observed occasionally.

Other Adverse Reactions Other adverse reactions have been reported, principally nausea and/or vomiting, hypotension, and fever. These reactions are frequent sequelae of myocardial infarction and may or may not be attributable to ACTIVASE® therapy.

DOSAGE AND ADMINISTRATION: Administer ACTIVASE® as soon as possible after the onset of symptoms.

Lysis of coronary artery thrombi has been documented in 71% of patients treated with ACTIVASE® within 6 hours of onset of symptoms.[1] Improvement of ventricular function and reduction of the incidence of congestive heart failure have been documented in patients treated within 4 hours of the onset of symptoms.[2]

ACTIVASE® is intended for administration by intravenous infusion only.

The recommended dose is 100 mg administered as 60 mg (34.8 million IU) in the first hour (of which 6 to 10 mg is administered as a bolus over the first 1-2 minutes), 20 mg (11.6 million IU) over the second hour, and 20 mg (11.6 million IU) over the third hour. For smaller patients (less than 65 kg), a dose of 1.25 mg/kg administered over 3 hours, as described above, may be used.[6]

A DOSE OF 150 MG OF ACTIVASE®, ALTEPLASE, SHOULD NOT BE USED BECAUSE IT HAS BEEN ASSOCIATED WITH AN INCREASE IN INTRACRANIAL BLEEDING.

Although the use of anticoagulants and antiplatelet drugs during and following administration of ACTIVASE® has not been shown to be of unequivocal benefit, heparin has been administered concomitantly for 48 hours or longer in more than 90% of patients. Aspirin and/or dipyridamole have been given either during and/or following heparin treatment.

Reconstitution and Dilution DO NOT USE IF VACUUM IS NOT PRESENT.

ACTIVASE® should be reconstituted by aseptically adding the appropriate volume of the accompanying Sterile Water for Injection, USP to the vial. It is important that ACTIVASE® be reconstituted only with Sterile Water for Injection, USP, without preservatives. Do not use Bacteriostatic Water for Injection, USP. The reconstituted preparation results in a colorless to pale yellow transparent solution containing ACTIVASE® 1.0 mg/mL at approximately pH 7.3. The osmolality of this solution is approximately 215 mOsm/kg.

Reconstitution should be carried out using a large bore needle (e.g., 18 gauge), directing the stream of Sterile Water for Injection, USP into the lyophilized cake. Slight foaming upon reconstitution is not unusual; standing undisturbed for several minutes is usually sufficient to allow dissipation of any large bubbles.

Because ACTIVASE® contains no antibacterial preservatives, it should be reconstituted immediately before use. The solution may be used for direct intravenous administration within 8 hours following reconstitution when stored between 2-30°C. Before further dilution or administration the product should be visually inspected for particulate matter and discoloration prior to administration whenever solution and container permit.

ACTIVASE®, Alteplase, may be administered as reconstituted at 1.0 mg/mL. As an alternative, the reconstituted solution may be diluted further immediately before administration in an equal volume of 0.9% Sodium Chloride Injection, USP or 5% Dextrose Injection, USP to yield a concentration of 0.5 mg/mL. Either polyvinyl chloride bags or glass bottles are acceptable. ACTIVASE® is stable for up to 8 hours in these solutions at room temperature. Exposure to light has no effect on the stability of these solutions. Excessive agitation during dilution should be avoided; mixing should be accomplished with gentle swirling and/or slow inversion. Do not use other infusion solutions, e.g., Sterile Water for Injection, USP or preservative-containing solutions for further dilution.

No other medication should be added to infusion solutions containing ACTIVASE®. Any unused infusion solution should be discarded.

HOW SUPPLIED: ACTIVASE® is supplied as a sterile, lyophilized powder in 20 mg and 50 mg vials containing vacuum.

Each 20 mg ACTIVASE® vial (11.6 million IU) is packaged with diluent for reconstitution. (20 mL Sterile Water for Injection, USP): NDC 50242-044-12.

Each 50 mg ACTIVASE® vial (29.0 million IU) is packaged with diluent for reconstitution. (50 mL Sterile Water for Injection, USP): NDC 50242-044-13.

Storage Store lyophilized ACTIVASE® at controlled room temperature not to exceed 30°C (86°F), or under refrigeration (2-8°C/36-46°F). Protect the lyophilized material during extended storage from excessive exposure to light.

Do not use beyond the expiration date stamped on the vial.

Comparison of Two Dose Regimens of Intravenous Tissue Plasminogen Activator for Acute Myocardial Infarction

ERIC J. TOPOL, MD, BARRY S. GEORGE, MD, DEAN J. KEREIAKES, MD, RICHARD J. CANDELA, MD, CHARLES W. ABBOTTSMITH, MD, DAVID C. STUMP, MD, JANE M. BOSWICK, MPH, RICHARD S. STACK, MD, ROBERT M. CALIFF, MD, and the TAMI Study Group*

Two dosing schedules of intravenous tissue plasminogen activator (t-PA) for acute myocardial infarction were compared in a multicenter trial. At 2.95 ± 1.1 hours from onset of chest pain, 386 patients received 150 mg of intravenous t-PA. For the first 178 patients (group A), 60 mg were given in the first-hour dose and the remaining 90 mg were infused over 7 hours. In the subsequent 208 patients (group B), the first-hour dose was 1.0 mg/kg and the remaining 150 mg were given over 5 hours. At initial angiography 94 ± 30 minutes into therapy, the infarct vessel patency was 64% in group A versus 75% in group B ($p = 0.02$). By final angiography with up to 4 selective contrast injections, patency was 68% versus 77%, respectively ($p = 0.06$). Repeat angiography at 7 to 10 days demonstrated reocclusion in 17% of group A and 13% of group B patients ($p = 0.35$). There was no difference in fibrinogen nadir or mean hematocrit drop between the 2 groups: 120 mg/dl and 11 points, respectively, in group A compared with 120 mg/dl and 10 points in group B. However, bleeding was reduced in group B patients as evident by a decrease in requirement for ≥2 units of packed red blood cell transfusion (group A 36%, group B 27%, $p = 0.05$) and lower incidence of gastrointestinal bleeding (group A 12%, group B 4%, $p = 0.002$). To further study the importance of weight adjustment, patients were divided into 2 groups according to weight (≤90 kg versus >90 kg). According to the results, lighter weight patients had greater transfusion requirements (35% versus 20%, $p = 0.006$) and more frequent major bleeding episodes (16% versus 7%, $p = 0.025$). Thus, a higher, weight-adjusted first-hour dose of intravenous t-PA, with a shorter duration of maintenance infusion, is associated with: (1) improved infarct vessel patency; (2) more rapid recanalization; and (3) less bleeding complications without more fibrinogenolysis.

(Am J Cardiol 1988;61:723–728)

Since the clinical introduction of recombinant tissue-type plasminogen activator (t-PA) for myocardial infarction in 1984, there has been considerable growth in our understanding of its pharmacology and a significant change in production methods. Although very low doses of intravenous t-PA were initially used for a brief duration (1 to 3 hours),[1-4] more recent trials have employed a larger first-hour dose and a prolonged maintenance infusion.[5,6] The initial studies used a predominant 2-chain form of t-PA which was not suitable for large-scale production. The single-chain form of t-PA subsequently introduced has a clearance 40% more rapid than the original preparation and thereby has required a new pharmacologic evaluation for optimal dosing.[5] Although high doses of this form of intravenous t-PA were demonstrated to promote rapid recanalization,[7] they were associated with an increased rate of serious hemorrhagic episodes which led to a recommendation for a decreased dose.[8,9] Thus, controversy exists as to the optimal dosing of this fibrinolytic enzyme for achieving maximal coronary thrombolytic

TABLE I Comparison of the Two Dose Regimens

	Group A (n = 178)	Group B (n = 208)
Total dose (mg)	150	150
First-hour dose (10% as bolus)	60 mg	1.0 mg/kg
Maintenance infusion		
Amount (mg)	90	150 − first-hour dose
Duration (hr)	7	5

TABLE II Baseline Characteristics*

	Group A (n = 178)	Group B (n = 206)†
Age (yrs)	56 ± 10	56 ± 11
Men (%)	81	76
Weight (kg)	80 ± 16	83 ± 14
Infarct-related artery (%)		
Left main	1	0
LAD	42	39
LC	14	12
Right	43	49
Time CP → t-PA (hrs)	2.9 ± 1.1	3.0 ± 1.1
No. of narrowed coronary arteries (%)‡		
1	54	52
2	28	28
3	17	18
4	1	2
Systolic blood pressure (mm Hg)	134 ± 25	136 ± 26
Heart rate (beats/min)	82 ± 18	79 ± 19

* There were no significant differences ($p < 0.05$) between groups for the variables listed.

† Although 208 patients were treated with this dosing regimen, 2 did not undergo acute catheterization.

‡ Number of major epicardial vessels with ≥50% stenosis.

CP = chest pain; LAD = left anterior descending; LC = left circumflex.

efficacy with the least possible rate of bleeding complications. The present study was undertaken to determine which of 2 t-PA dosing regimens employed in a multicenter trial was superior in terms of frequency and speed of coronary artery recanalization, effects on hemostasis and the coagulation system, and the importance of weight adjustment.

Methods

The Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) study design has been previously described in detail.[10] To summarize, selection criteria were: (1) patients with ≤4 hours of chest discomfort or severe symptoms with a duration of 4 to 6 hours, and ongoing pain; and (2) at least 1 mm of electrocardiographic ST-segment elevation in 2 contiguous leads. Patients were excluded for age >75, recent (<6 months) trauma, surgery or stroke, prolonged cardiopulmonary resuscitation, prior coronary artery bypass grafting, cardiogenic shock and previous transmural infarction in the same area. All patients provided informed consent and the protocol was approved by the institutional review board at the respective clinical site.

In the trial, the predominantly single-chain form of t-PA was used.[5] The first 178 patients received an intravenous t-PA dose based on schedule A: 60 mg in the first hour given as a 6-mg bolus and 54-mg drip, and then 20 mg for each of 2 hours, followed by 10 mg/hr for 5 hours with a total dose of 150 mg. In the subsequent 208 patients (schedule B), the same total dose of 150 mg was administered using weight adjustment and a briefer maintenance infusion as follows: 1 mg/kg for the first hour with 10% as a bolus and a maximum dose of 90 mg, and the remainder of 150 mg over the next 5 hours. The patient's report provided the information on body weight required for dosing. The dose regimens are summarized in Table I.

After initiation of t-PA, the patients were transferred to the cardiac catheterization laboratory of the respective clinical site for acute angiography. Nonionic contrast dye was used. The first contrast injection of the infarct vessel was performed after 60 minutes of therapy and images obtained no later than 90 minutes. An exception to the latter occurred when difficulties arose in obtaining arterial access or interhospital transport was delayed. The final determination of infarct vessel patency was made at 90 minutes, after up to 4 injections of the infarct-related artery.

The perfusion status was classified according to the TIMI (Thrombolysis in Myocardial Infarction Study Group) grading system.[2] For the purpose of this study, TIMI 0 and 1 were considered occluded and TIMI 2 or 3 patent. The angiograms were subsequently reviewed at the core angiographic laboratory for verification of the final TIMI grade determination.

On the basis of the 90-minute infarct vessel angiogram, patients were triaged to 3 different groups as follows: (1) persistent occlusion—coronary angioplasty was considered at the discretion of the investigator; (2) patent, ≥50% residual stenosis, suitable for angioplasty—patients were randomized to undergo the procedure immediately or at 7 days; (3) patent, with coronary anatomy unsuitable for angioplasty. Emergency coronary artery bypass surgery was defined as a direct transfer from the cardiac catheterization laboratory during the acute study to the operating room. The procedure was performed for failed percutaneous transluminal coronary angioplasty or high-risk coronary anatomy. In the first 50 patients from the aforementioned groups 1 and 3, only the first 3 hours of t-PA (100 mg) were infused (all in group A patients). Angioplasty's complete success was defined as <50% residual stenosis and partial success as ≥50% residual stenosis after balloon dilatation.

Concomitant medical therapy consisted of heparin (5,000 U at access, 5,000 U at the time of angioplasty if performed acutely, and 500 to 1,000 U/hr for ≥3 days by continuous infusion adjusted to 2.5 to 3 times the partial thromboplastin time), aspirin (325 mg/day), dipyridamole (75 mg, 3 times daily) and diltiazem (30 to 60 mg, 4 times daily).

At 7 to 10 days, patients underwent repeat cardiac catheterization to determine infarct vessel patency and left ventriculography. Besides the paired studies, patients returned to the catheterization laboratory be-

fore 7 days had elapsed if recurrent ischemia occurred, as defined by ≥20 minutes of chest discomfort associated with electrocardiographic changes. After urgent angiography in these patients, who by now had reached a clinical endpoint, either coronary angioplasty or bypass surgery was performed and followed by a repeat (third) cardiac catheterization, whenever possible, before hospital discharge. Reocclusion was defined by angiographic documentation of flow pattern as TIMI grade 0 or 1 and flow pattern diagnosed subsequent to established perfusion as TIMI 2 or 3.[2]

Bleeding complications were characterized according to: (1) site; (2) need for transfusion of ≥2 units of packed red blood cells for augmentation of hematocrit >30; and (3) baseline and nadir hematocrit values. Gastrointestinal bleeding referred to either guaiac-positive results or frank blood in emesis or stool. Intracranial and retroperitoneal hemorrhage was diagnosed using computed axial tomographic scanning. Assessment of coagulation proteins included assay of the serum fibrinogen by the Clauss and sodium sulfite precipitation methods[11,12] and the fibrinogen degradation product titer[13] by tanned red cell agglutination method at baseline, 3, 8 and 12 hours after t-PA.

Statistical analysis: Values are expressed as mean ± 1 standard deviation unless otherwise specified. Comparison of group A versus group B patients was made using chi-square analysis for dichotomous variables and an unpaired *t* test or Wilcoxon log-rank test, as specified, for continuous variables. The comparison between the 2 dose regimens was performed with and without those 50 patients in group A who received 100 mg instead of 150 mg of t-PA. For analysis of the importance of weight (≤90 or >90 kg), chi-square analysis was used for dichotomous variables, a Wilcoxon rank-sum test for continuous variables and a logistic regression model for testing the relation between the 2 weight groups for multiple variables.

Results

Study population: The relevant demographic characteristics for the 2 patient groups are summarized in Table II. Patients receiving the 2 different dose regimens were similar with regard to the baseline hemodynamic, angiographic and demographic features.

Patency of the infarct vessel: Table III lists the results for acute and follow-up (before discharge) infarct vessel perfusion status. A significantly higher patency was demonstrated for group B patients at the initial angiogram. As demonstrated in Figure 1, nearly all patients in group B who demonstrated infarct vessel recanalization were already patent at the initial angiogram. The residual stenosis of the infarct vessel was significantly decreased in group B patients compared with group A (Figure 2). The results for initial angiographic patency excluding the 50 patients in group A who did not receive the full 150 mg t-PA dose were: group A, 68% patent; group B, 75% patent; p = 0.16.

Acute coronary angioplasty was performed in 89 patients in group A and 93 patients in group B with complete or partial success in 73% versus 83%, respectively (p = 0.09). Emergency bypass surgery was necessary in 8% of group A patients compared to 4% in group B (p = 0.09). During hospitalization, a total of 39 (22%) bypass surgery procedures were performed in group A compared with 44 (21%) in group B (p = 0.19). Intraaortic balloon counterpulsation was used in 11% of group A versus 6% of group B patients (p = 0.09).

Bleeding complications and coagulation system effects: The transfusion requirement, admission and nadir hematocrits, and incidence of bleeding by site appear in Table IV. As shown, the frequency of gastrointestinal bleeding was significantly higher in group A patients. Only 2 patients (both in group B) developed intracranial hemorrhage. Both patients were female with a history of longstanding hypertension, age 68 and 73, respectively.

In Figure 3, the serum fibrinogen values are plotted for the 2 dosage regimens. There was no difference in the nadir fibrinogen level (120 mg/dl for both groups). The median peak FDP titer was 1:16 in group A versus 1:32 for group B.

Influence of body weight: Patients were divided into 2 groups as shown in Table V. The baseline weight was not recorded in 5 patients enrolled in the trial. As expected, there was a significantly lower proportion of males in the ≤90-kg weight column. There were no differences (p <0.05) in patency of the infarct vessel, infarct location, presence of multivessel disease, group A or B dosing or bypass surgery. Lighter weight patients underwent acute coronary angioplasty less fre-

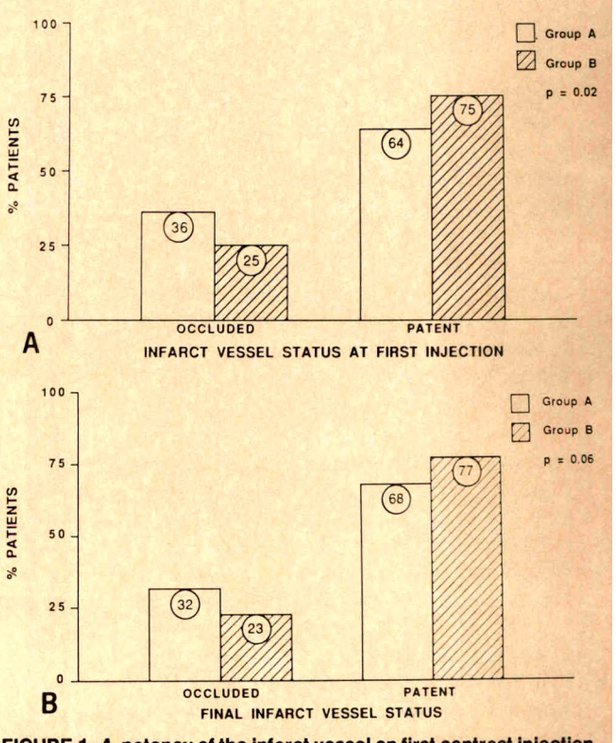

FIGURE 1. *A*, patency of the infarct vessel on first contrast injection. Group B patients demonstrated a significantly higher patency rate. *B*, patency of the infarct vessel after up to 4 injections at 90 minutes of tissue plasminogen activator (t-PA) therapy. A trend of higher patency was observed for group B patients.

TABLE III Patency of the Infarct Vessel

	Group A (n = 178)	Group B (n = 206)	p Value

TIMI 2 or 3 = Thrombolysis in Myocardial Infarction Study Group's grade 2 or 3 (perfusion status patent).

quently (45 versus 58%, respectively, p = 0.023) and had a higher success rate for angioplasty (84 versus 68%, p = 0.06).

Despite less invasive procedures performed in the lighter weight patient group (equivalent to a 21% bypass surgery rate during hospitalization, less acute angioplasty), their transfusion requirement was higher, with major bleeding episodes more frequent as confirmed by a significantly lower nadir hematocrit (Table V). In addition, these patients had a lower nadir plasma fibrinogen and a decreased likelihood of reocclusion.

Discussion

In the current study, 2 different t-PA dose regimens with the same 150 mg cumulative dose were compared. The second regimen, which provided for a weight-adjusted first-hour dose and a lesser duration of maintenance infusion, was found to be superior with respect to frequency and rapidity of infarct vessel patency, decreased transfusion requirement and overall bleeding complications, without more extensive fibrinogenopenia.

Comparison with previous studies: There have been 3 previous trials using the single-chain preparation of t-PA. In the randomized trial of Topol et al,[5] 0.75 mg/kg of t-PA was given over the first hour and 0.25 mg/kg per hour over the subsequent 2 hours. Infarct vessel patency at 90 minutes was 69% and increased to 79% at 120 minutes. Using criteria for bleeding complications similar to those adopted in the current study, 29% received transfusion, gastrointestinal bleeding occurred in 1.1%, genitourinary bleeding in 5% and the fibrinogen nadir was 62% of baseline. Reocclusion was not systematically determined but the angiographically confirmed incidence was 20%. As recently reported by Mueller et al,[7] the open-label Thrombolysis in Myocardial Infarction (TIMI) multicenter trial was divided into 5 separate groups (A through E). In the E phase, 167 patients received a dose of 90 mg over the first hour and 60 mg over the subsequent 4 hours. A high rate of infarct vessel patency resulted (85% at 120 min), albeit accompanied by a 1.6% incidence of intracranial hemorrhage. This resulted in a recommendation for a lower dose: 60 mg in the first hour and a cumulative dose of 100 mg.[8]

The dose of 150 mg used in the TAMI trial achieved a high proportion of infarct vessel patency without inducing an unacceptable rate of serious bleeding episodes. Although the overall transfusion rate and periaccess bleeding incidence was somewhat higher compared to other trials, all TAMI patients underwent emergent angiography per protocol, with a significant proportion (21%) undergoing coronary artery bypass surgery. Nearly all of these patients received transfusion.

First-hour dose: The dose of t-PA in the first hour appears to be a critical determinant of the time of recanalization. As previously demonstrated by TIMI with baseline angiography, increasing the dose from 50 to 90 mg did not yield significantly higher patency at 90 minutes of therapy, but the speed of achieving reperfusion was markedly enhanced.[7] In the current trial, the higher first-hour dose used in group B was associated with more rapid recanalization and a trend

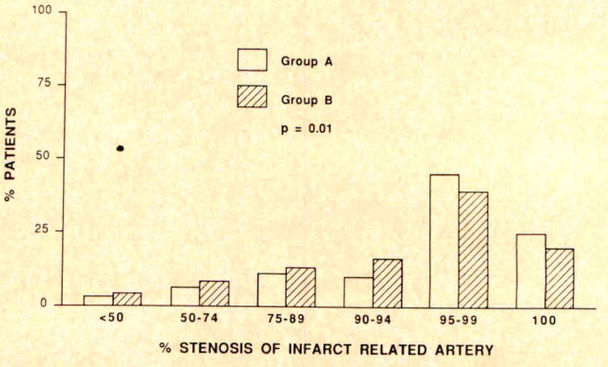

FIGURE 2. Infarct-related artery percent diameter stenosis for group A versus group B patients at the final angiogram obtained during the acute study. A comparison of group A with group B patients shows an overall higher grade residual stenosis for group A.

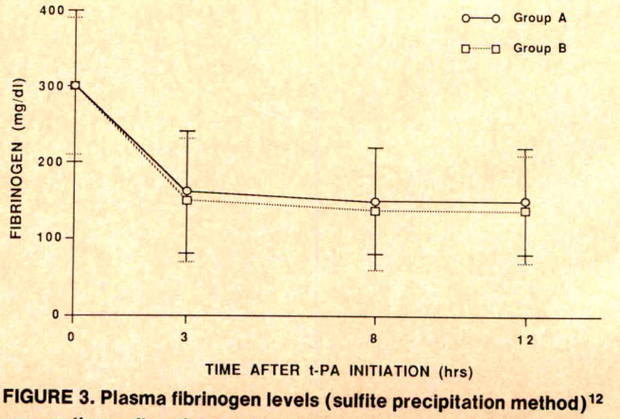

FIGURE 3. Plasma fibrinogen levels (sulfite precipitation method)[12] versus time after tissue plasminogen activator (t-PA) therapy. There were no significant differences between the 2 dose groups for nadir fibrinogen values.

toward a higher proportion of infarct vessel patency at the final angiogram.

Weight adjustment: The results of this study further confirm the importance of a weight-adjusted dose of t-PA. In previous studies by Topol et al[14] and Gold and co-workers,[6,15] the utility of a weight-adjusted dose and its increased safety have been demonstrated. Even though a higher dose was employed in TAMI's group B patients, an overall decreased bleeding complication rate resulted which likely reflects weight adjustment. Patients weighing <90 kg had a definite increased risk of bleeding complications compared with heavier patients. In contrast, with a higher weight-adjusted first-hour dose of t-PA, there was an increase in rate and proportion of infarct vessel patency. Thus, in order to avoid bleeding episodes and a high transfusion requirement, patients weighing <60 kg should probably receive a lower than 60 mg first-hour dose of t-PA. Group B data suggest that patients weighing up to 90 kg derive benefit from the higher dose in terms of coronary recanalization. Because doses >90 mg were not given in the first hour, the relative effects of thrombolysis versus hemorrhage remain speculative in patients >90 kg.

Maintenance infusion: As demonstrated by Gold et al,[6] the purpose of the maintenance infusion is to increase the extent of coronary thrombolysis and limit rethrombosis. The ideal length and dose requirement of such a prolonged infusion have not yet been determined. In 1 recent study, too long an infusion has been reported to yield a high rate of periaccess bleeding that may be unacceptable,[16] whereas in a recent multicenter trial with a predominant 2-chain form of t-PA, up to a 24-hr low-dose infusion has been tested with apparent low reocclusion and bleeding rate complication.[17]

In the current trial, a possible explanation for the increased bleeding observed in patients from group A is the lack of weight adjustment and the duration of maintenance infusion for 7 rather than 5 hours (group B). The additional 2 hours of maintenance infusion may be significant, as reflected by the 3-fold increase in gastrointestinal bleeding in group A, most of which was initially manifest during the infusion. The increased bleeding with longer maintenance infusions may reflect sustained fibrinolytic action of t-PA. Although the half-life of this t-PA preparation is <3 minutes,[5] the beta phase half-life is more than 20 minutes[18] and this ongoing fibrinolysis proceeds despite physiologic plasma levels of t-PA.[19] It would therefore be anticipated that in group A patients there was a considerably longer pharmacologic fibrinolytic effect. Because reocclusion was actually not increased in group B patients, our data suggest that a shorter maintenance infusion of 5 hours may be preferable to 7 hours in achieving the purpose of limiting rethrombosis without promoting bleeding.

Effects of dose on angioplasty success rate: A trend toward a higher success rate in acute coronary angioplasty was observed among group B patients, along with a decrease in the need for emergency bypass surgery. Although this observation may theoretically be attributed to enhanced coronary thrombolysis (with facilitation of the dilatation procedure), it also may be related to a learning curve phenomenon during the TAMI trial. This point brings up the chief limitation of the current study: although a relatively large sample size at each of the 2 dose schedules was studied, this was a consecutive series and not a randomized comparison. Selection of patients for randomization to angioplasty was determined by the investigators. During the course of the trial, a trend toward decreased randomization to angioplasty and less need for emergency bypass surgery was noted, so that it remains unclear whether the dose change actually served as a pivotal factor for angioplasty success.[20]

TABLE IV Bleeding Complications

	Group A (n = 178)	Group B (n = 206)
Transfusion >2 U PRBC	64 (36%)	56 (27%)*

Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size. VI: Identification of Screening Criteria For Non-Acute Myocardial Infarcts

WILLIAM D. ANDERSON, BA, NANCY B. WAGNER, BA, KERRY L. LEE, PhD, RICHARD D. WHITE, MD, JAMES YUSCHAK, MD, VICTOR S. BEHAR, MD, RONALD H. SELVESTER, MD, RAYMOND E. IDEKER, MD, PhD, and GALEN S. WAGNER, MD

Each of the 54 criteria in the Selvester 32-point QRS scoring system for estimation of myocardial infarct (MI) size has attained ≥95% specificity in normal subjects. This study was performed to identify a subset of those criteria with cumulative specificity ≥95% and maximal sensitivity for use in screening for the presence of non-acute MI. Coronary angiography and left ventriculography were used to identify 500 normal subjects, 60 patients with isolated anterior MI and 62 patients with isolated inferior MI. Patients with the QRS confounding factors of ventricular hypertrophy, fascicular block or bundle branch block on their electrocardiogram were not included. Using stepwise logistic regression analysis, the screening criteria identified were: (1) Q ≥30 ms in aVF, (2) R ≤10 ms and ≤0.1 mV in V_2 and (3) R ≥40 ms in V_1. Cumulatively, these 3 screening criteria achieved 84% and 77% sensitivities for inferior and anterior MI groups, respectively. Thus, a set of 3 criteria from the Selvester QRS scoring system is capable of identifying single non-acute anterior or inferior MI in 80% of patients, and falsely indicating presence of MI in only 5% of normal subjects.

(Am J Cardiol 1988;61:729–733)

For more than half a century, the 12-lead electrocardiogram has been the standard for determining both the presence and location of a myocardial infarct (MI). However, the commonly used electrocardiographic criteria for MI diagnosis have proven to be relatively insensitive. Previous studies from this institution have compared the sensitivities of standard electrocardiographic and vectorcardiographic criteria.[1,2] From the electrocardiogram, sensitivities ranging from 28% to 44% for inferior MI criteria and from 43% to 60% for anterior MI criteria were identified. In contrast, vectorcardiographic criteria attained sensitivities of 82% and 95% for inferior and anterior MI locations respectively, suggesting there is additional MI diagnostic capability in the QRS complex beyond that attained by established electrocardiographic criteria.

Selvester et al[3–5] designed computer simulations of the human heart activation sequence to identify the changes in the QRS complex occurring with various sized infarcts in the distributions of the 3 primary coronary arteries. This information was used to develop a 54 criteria/32 point QRS scoring system based on the electrocardiogram for estimating MI size, with each point representing approximately 3% of the left ventricle.[6] The present study utilizes the Selvester scoring system to: (1) identify a subset of criteria that retain high cumulative specificity in normal subjects and achieve maximal sensitivity in patients with single non-acute anterior or inferior MI, and (2) compare the

performance of the resultant "screening" criteria to established vectorcardiographic criteria.

Methods

Patient selection: *Normal population:* The previously reported normal population consists of 500 subjects with 50 men and 50 women in each of the 5 decades between ages 20 and 69.[6] These subjects were either healthy volunteers younger than 40 years of age or patients with chest pain who underwent cardiac catheterization and were shown to have neither significant coronary arterial stenosis nor left ventricular wall motion abnormalities. Patients were also required to have either left ventricular ejection fraction >50% or left ventricular end-diastolic pressure ≤12 mm Hg. Patients whose electrocardiograms showed evidence of left or right bundle branch block, left or right ventricular hypertrophy or left anterior or posterior fascicular block were excluded.

Myocardial infarction populations: The Duke University Medical Center computerized data bank[7] was searched to identify patients with a single non-acute anterior or inferior MI, and available vectorcardiograms and electrocardiograms. There were 60 patients with an "anterior MI"[2] defined by the simultaneous presence of a ≥75% diameter stenosis of the left anterior descending coronary artery and akinesia or dyskinesia of the anterior wall on the right anterior oblique ventriculogram. There were 62 patients with an "inferior MI"[1] defined by the presence of ≥75% diameter stenosis of the right coronary artery in conjunction with akinesia or dyskinesia of the inferior wall. The validity of these criteria for identifying MI has been previously established by comparison with postmortem hearts.[8] Patients were excluded if catheterization showed evidence of valvular or congenital heart disease or the pulmonary artery mean pressure was ≥25 mm Hg.

Both the Frank lead vectorcardiograms and the standard electrocardiogram of all MI patients had been obtained within 3 days of catheterization. Patients were excluded for electrocardiographic evidence of right ventricular hypertrophy, left anterior or posterior fascicular block or left or right bundle branch block. They were also excluded for either electrocardiographic or vectorcardiographic evidence of left ventricular hypertrophy.[1,2]

Electrocardiographic and vectorcardiographic evaluations: All electrocardiograms were evaluated using the complete Selvester QRS scoring system. This system and its method of application have been described in detail elsewhere.[6] Measurements of amplitude are reported in mV (1 mm = 0.1 mV) and duration is reported in ms (1 mm = 40 ms). The vectorcardiograms were evaluated using the criteria previously described by Starr et al.[1,2] Each set of vectorcardiographic criteria has been reported to achieve ≥95% specificity in a group of normal subjects with characteristics similar to the normal population described in the present study.

Data analysis: A stepwise logistic regression analysis was used to identify a subset from the 54 criteria that would have maximal ability to discriminate between the patients with either anterior or inferior MI and the normal subjects. The first step selected the single criterion that attained the highest sensitivity. Further steps identified additional criteria that added the greatest increments of sensitivity while retaining the cumulative specificity of the screening group at a level of ≥95%. If 2 or more criteria indicative of MI in the same location were equally sensitive, both their individual and combined effects on the performance of the screening group were considered.

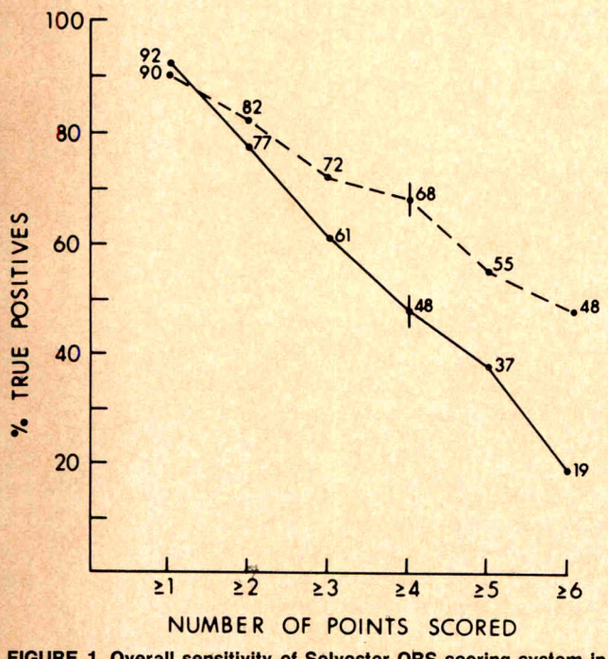

FIGURE 1. Overall sensitivity of Selvester QRS scoring system in inferior (n = 62) and anterior (n = 60) myocardial infarct (MI) populations. Specificity level ≥95% was maintained by requiring ≥4 points. At this level, 68% of anterior MI group (*dashed line*) and 48% of inferior MI group (*continuous line*) were identified.

Results

When ≥1 point was required for MI detection using the complete scoring system, sensitivities of 92% and 90% were achieved in the inferior and anterior MI populations, respectively (Figure 1). However, this system has been previously reported to require ≥4 points to achieve ≥95% specificity.[6] This ≥4 point level attained sensitivities of only 48% in the inferior MI population and 68% in the anterior MI population.

Table I lists the performances of the most sensitive individual criteria. A Q wave ≥30 ms in lead aVF was the single most sensitive criterion, identifying 45% of the combined MI populations. Nine other criteria identified between 25% and 33% of the combined populations.

Table II lists the results of the stepwise logistic regression analysis. When the R-wave duration or amplitude criteria in lead V_2 were added to the Q-wave criterion in lead aVF, sensitivities of 75% were

achieved for each. The cumulative specificities decreased to 96% with each criterion individually but only to 97% when both the R-wave duration and amplitude criteria were considered together. In step III, the criterion of R wave ≥40 ms in lead V_1 added the greatest further increase in sensitivity. The specificity decreased to <95% when the 2 R-wave criteria in lead V_2 were considered separately. Only when these were combined (R wave in V_2 ≤10 ms and ≤0.1 mV) was the cumulative specificity of the screening set maintained at the required specificity standard.

The performances of each of the screening criteria considered independently for the 2 MI locations are listed in Table III. In 49 of the 55 times the Q wave ≥30 ms in lead aVF was satisfied (89%), the MI was inferior. This criterion was 79% sensitive in screening for inferior MI, identifying 49 of the 62 patients. In 41 of these 49 patients (84%), the Q wave ≥30 ms in aVF was the only screening criterion satisfied.

The combined R-wave duration and amplitude criteria in lead V_2 were associated only with the anterior MI location. These criteria achieved individual sensitivities of 67% and 65% in the anterior MI population, respectively, and when combined attained a cumulative sensitivity of 65%.

The R wave ≥40 ms criterion in lead V_1, which is usually associated with posterolateral MI location,[10] was met by both patients with inferior (n = 11) and anterior (n = 5) MI locations.

In Figure 2, the sensitivity of the screening criteria group (≥1 point) is compared to the sensitivities of the entire Selvester scoring system (≥4 points) and the vectorcardiographic criteria. In the inferior MI population, the sensitivity of the screening criteria equals that of the vectorcardiographic criteria (84%) and is superior to that of the complete scoring system. For the anterior MI group the screening criteria achieve a sensitivity superior to the sensitivities of both the vectorcardiographic criteria (77% vs 72%) and the complete scoring system (77% vs 68%).

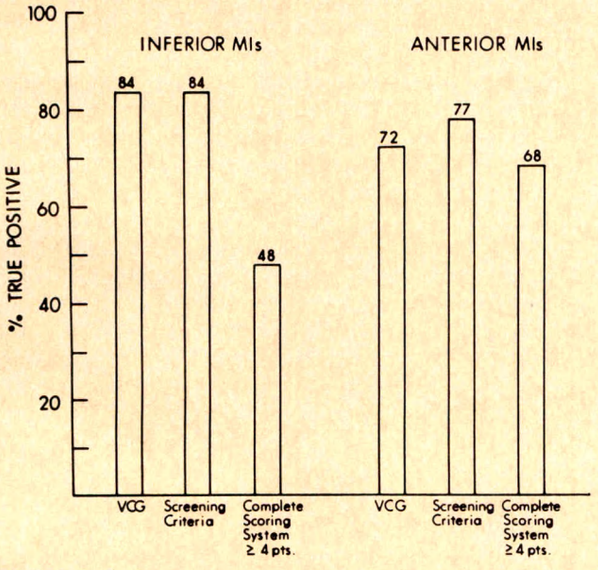

FIGURE 2. Performance of screening criteria versus established vectorcardiographic (VCG) criteria and entire Selvester QRS scoring system (≥4 points). VCG and screening criteria identified 84% of inferior MI group compared to 48% detected by the complete scoring system. In the anterior myocardial infarction (MI) population, the screening criteria (77%) were superior to both the VCG criteria (72%) and the entire Selvester QRS scoring system (68%).

TABLE I Sensitivities of Individual Criteria

Lead	Criterion	Sensitivity (%)
aVF	Q ≥30 ms	45

* Both criteria must be satisfied.

Discussion

Effective electrocardiographic criteria for the identification of non-acute MI should be easy to apply and should achieve both high specificity and sensitivity. The need for improved electrocardiographic criteria clearly exists, as traditional criteria have been shown to be insensitive. Hurd et al[10] demonstrated sensitiv-

TABLE III Performance of Screening Criteria

Lead	Criterion	Inferior MI (n = 62) Criterion Met No. (%)	Inferior MI (n = 62) Only Criterion Met (n)	Anterior MI (n = 60) Criterion Met No. (%)	Anterior MI (n = 60) Only Criterion Met (n)

MI = myocardial infarct; ( ) = % of either inferior or anterior MI population.

ities from 4% to 34% for 3 different sets of criteria for the identification of inferior MI, a marked contrast with the 82% sensitivity achieved by the vectorcardiographic criteria of Starr et al.[1] A similar disparity has been reported between traditional electrocardiographic criteria and the vectorcardiographic criteria of Starr et al[2] for anterior MI. Warner et al[11,12] have reported high sensitivities using new electrocardiographic criteria in both inferior and anterior MI populations. However, the Warner criteria for inferior MI diagnosis require an electrocardiogram of exceptional quality and may, therefore, be difficult to apply routinely. The Warner criterion for anterior MI detection is similar (R duration <20 ms in lead V_2) to the R duration criterion identified in the present study. The quality of the electrocardiograms and the limitations of manual measurement techniques preclude comparison with the Warner anterior MI criteria.

The need for improved diagnostic criteria from the electrocardiogram is not met by use of the complete Selvester QRS scoring system. The high point score (≥4 points) required to meet specificity standards renders the system too insensitive for the identification of MI. The 3 proposed screening criteria achieve both a specificity of 95% and high sensitivity. Their application effectively distinguishes between patients with or without MI, indicating the group for whom all of the criteria of the complete Selvester QRS scoring system can be appropriately applied for estimating MI size.

The selection of MI populations defined by clinical parameters from cardiac catheterization rather than from direct anatomic observations may have diminished the sensitivities of both the electrocardiographic and vectorcardiographic criteria in this study. A ventriculographic/anatomic correlation study by Ideker et al[8] showed that while hypokinesia was frequently not associated with any fibrosis, there was always some fibrosis in those ventricular walls that had demonstrated either akinesia or dyskinesia. However, it is still possible that some of the patients in the MI groups had no infarcted myocardium. When the Selvester scoring system is used to identify MI with the minimal point requirement ≥1, sensitivities of 92% and 90% are obtained in the inferior and anterior MI populations, respectively. Thus approximately 10% of both MI populations fail to satisfy any QRS scoring criterion, suggesting the absence of any infarction. Postmortem anatomic studies will be required to determine the true sensitivity of the screening criteria identified in the present study.

Because patients with confounding electrocardiographic abnormalities were excluded, the screening criteria can be applied with confidence only to electrocardiograms without evidence of ventricular hypertrophy, fascicular block or bundle branch block. Further studies are necessary to evaluate the performance of the screening criteria in patients with such abnormalities. However, diminished R waves in lead V_2 are common in left ventricular hypertrophy and left bundle branch block, and increased R waves in lead V_1 are common in right ventricular hypertrophy and right bundle branch block. New sets of screening criteria will therefore be necessary in the presence of these factors.[13]

Only anterior and inferior MI locations were included in this study because they occur most commonly and can be reliably detected on the right anterior oblique view of the left ventriculogram. Future studies will be required to develop screening criteria for MI in the posterolateral myocardium, commonly in the distribution of the left circumflex coronary artery. However, the criterion of R ≥40 ms in V_1 identified in this study may be quite useful.

The screening criteria proposed in this study compare favorably with the previously developed vectorcardiographic criteria of Starr et al.[1,2] In the inferior MI population the screening criteria equalled the sensitivity of the vectorcardiogram (84%), and in the anterior MI population it was exceeded (77% vs 72%). These results are particularly significant when the clinical prevalence of the standard 12-lead electrocardiogram is considered.

Development and Validation of an Automated Method of the Selvester QRS Scoring System for Myocardial Infarct Size

JAMES E. POPE, MD, NANCY B. WAGNER, BA, DAVID DUBOW, BS,
JOHN H. EDMONDS, MD, GALEN S. WAGNER, MD,
and W. KENNETH HAISTY, Jr., MD

The Selvester QRS score for estimation of myocardial infarct (MI) size from the standard 12-lead electrocardiogram (ECG) has not yet achieved wide recognition as a valuable tool in the routine assessment of the MI patient, primarily because of the practical limitations inherent to manual application. This study examined the ECGs of 438 patients (105 normal subjects, 161 with "possible" MI and 172 with "definite" MI based on data from cardiac catheterization) to develop software for an automated method of the Selvester system in attempts to overcome the manual constraints. After a comprehensive validation process involving extensive interactions between the manual scorer and the software developer, an automated method of the Selvester system was generated that had a high correlation with manual application (r = 0.94) and was superior regarding time, training, reader bias, reproducibility and precision of measurement. These results indicate that an automated version of the Selvester QRS scoring system would resolve many of the limitations of manual application and would provide a reliable, technically accurate estimate of MI size that could be incorporated into ECG diagnostic programs and used in standard digital ECG machines.
(Am J Cardiol 1988;61:734–738)

The Selvester QRS scoring system[1] is an established method for estimating the size of a single myocardial infarction (MI) in the distribution of the 3 major coronary arteries based on quantitative QRS changes from the standard 12-lead electrocardiogram (ECG). This system has been tested for intra- and interobserver variability,[2] validated through comprehensive anatomic correlations[3–5] and refined to yield a complete 54-criteria/32-point QRS scoring system[6] with 98% specificity at a threshold of ≥4 points in an extensive normal population equally distributed by age and sex (Figure 1).

Although the Selvester system has been evaluated in a variety of studies,[7–14] and the method for its manual application described in detail,[15] it has not yet experienced general clinical acceptance. The system is limited by the tediousness of performing precise manual measurements, the training necessary to perform these measurements correctly, the reproducibility of results, the time necessary to score individual ECGs and the bias of the reader. A digital computer for ECG analysis programmed to apply the Selvester criteria would likely resolve these limitatioins. Once validated, and the strengths and weaknesses understood, an automated scoring method could be incorporated into ECG diagnostic programs and used in standard digital ECG machines. This study was performed to develop and validate software for an automated method of Selvester QRS scoring.

Methods

Patient population: Consecutive patients who had elective cardiac catheterization for the evaluation of chest pain at North Carolina Baptist Hospital of the

Wake Forest University Medical Center between November 1981 and June 1983 were considered for this study. Patients were excluded for prior cardiac surgery, evidence of valvular heart disease and historical or wall motion study evidence of prior MI. Patients were also excluded for ECG evidence of right or left bundle branch block, left anterior or posterior fascicular block, left or right ventricular hypertrophy, paced rhythm or ventricular preexcitation. Ninety-eight percent of the ECGs were recorded within 2 days before cardiac catheterization.

Of the 438 patients who formed the final study group, the mean age was 53 years, and 71% were men. Data from cardiac catheterization revealed 105 patients with no obstructive coronary artery disease or left ventricular wall motion abnormalities. There were 161 patients with "possible" evidence of a single MI suggested by a localized area of hypokinesis, and 172 with "definite" evidence of a single MI as supported by localized akinesis or dyskinesis. Patients classified as a "possible MI" or "definite MI" were also required to have an obstructive coronary lesion in the vessel supplying the region of the wall motion abnormality.

Every alternating fourth or fifth ECG (n = 93) was duplicated from the study group and randomly distributed among the population. These were subsequently matched to their originals, thus forming a set of 186 ECGs, and used for determination of blinded intraobserver agreement in the manual scoring method.

Study design: *Manual application:* Manual QRS scoring was performed on 3-channel ECGs (at a paper speed of 25 mm/s and standard gain) obtained by a Marquette recorder by an investigator at Duke University Medical Center experienced in the application of the system. The method for manual application has been described previously in detail.[6,15] All criteria satisfied and a final score for each ECG were entered into a microcomputer for subsequent comparison with automated scoring.

The duplicate ECGs and their paired originals were examined independently for determination of the intraobserver agreement of the manual scorer. The percentage of cases in which the manual scorer agreed with the observation from the paired ECG was assessed for each criterion. The level of intraobserver agreement attained in this analysis and the results of automation were compared to evaluate the efficacy of each method.

Development of automated application: The development of software for automated QRS scoring first required establishing precise definitions of the Selvester criteria to be incorporated into the program logic. This required repetitive interactions between the developer of the automated method and the manual scorer. These definitions were programmed in the C-language to generate the software capable of applying the Selvester criteria using a standard IBM/XT microcomputer. The automated QRS score was derived from the median beat complex[16] in each lead as constructed from a 10-second recording.

From the 438 ECGs scored by both manual and automated methods 100 were randomly selected as a learning subset to identify program errors in the software. This was facilitated by the creation of an "error identification" program that elucidated the precise nature of each disagreement (Figure 2). With this process, human errors could be easily identified and those automated versus manual results that remained dis-

FIGURE 1. The Selvester QRS scoring system, consisting of 54 criteria for a total of 32 points. Each point represents approximately 3% infarction of the left ventricle. Note that there are 12 unique criteria, with the remaining 42 contained in bracketed groups arranged by decreasing weights. Reproduced with permission from Hindman et al, Am J Cardiol.[6]

cordant were considered to be due to inadequate criteria definitions or faulty program logic. The program was then revised accordingly and retested in the same learning set. This developmental process was repeated until all errors of the automated method that could have been caused by inadequacy of definition or logic had been eliminated. Errors persisting beyond this point were attributed to the limitations intrinsic to automation. The resultant software was considered to be "automated Selvester QRS scoring" and was used in all the subsequent analyses.

Validation of automated Selvester QRS scoring: As outlined by Hindman et al,[6] precise application of the Selvester QRS scoring system requires defining the aspects of the waveforms rigorously, weighting the criteria to award additional points when there are increasing magnitudes of the same waveform abnormality, and selecting appropriate criteria within a group. It is important to note that because there are only 12 unique criteria, and the remaining 42 are contained within groups (Figure 1), it was possible for the automated and manual methods to achieve the same score through selection of different criteria (Figure 2). Thus, it was essential that the ECGs be compared by each individual criterion as well as by total score. This extensive validation procedure was necessary to identify the errors intrinsic to automation and to categorize the errors of manual application.

FIGURE 2. Error identification between manual and automated scoring was facilitated by an automated comparison of criteria selected by each method. Criteria listed were determined to be present by the respective methods. Criteria marked --*- indicate 1 point awarded. Refer to Figure 1 for determination of the weighting of criteria contained within groups. It is important to note that a score of 8 was achieved by both the computer and the manual scorer through selection of different criteria, thus emphasizing the need to evaluate the electrocardiograms criterion by criterion.

Results

The distributions of automated and manual scores are shown in Figure 3. Manual scores ranged from 0 to 15, with a mean of 2.85 ± 3.17 points. The automated

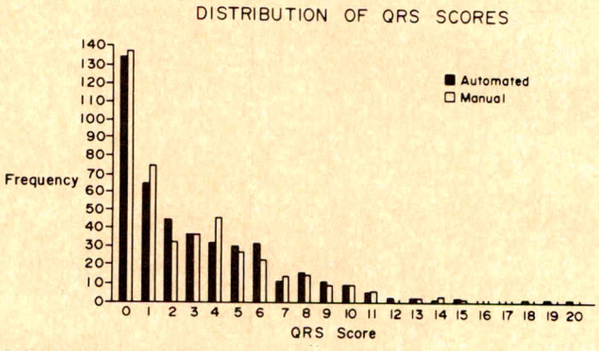

FIGURE 3. Comparison between the distributions of automated and manual QRS points for the 438 electrocardiograms. Automated scores ranged from 0 to 20. Manual scores ranged from 0 to 15.

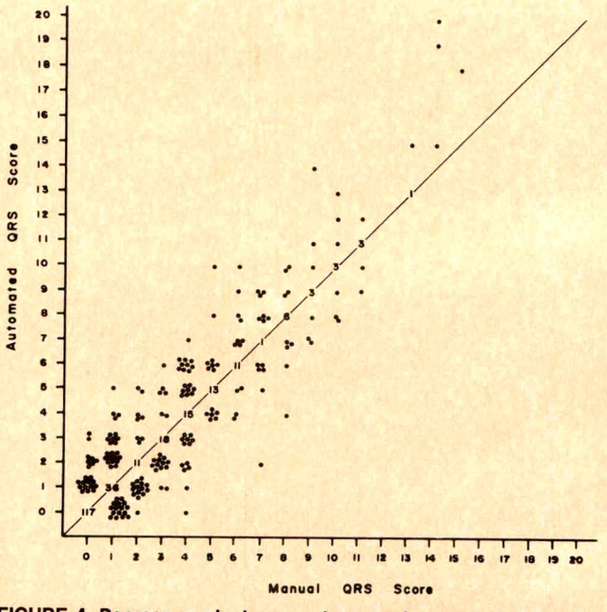

FIGURE 4. Pearson product-moment regression analysis between automated and manual Selvester QRS scores yielded a correlation coefficient of 0.94. The line of identity with the corresponding identical score matches (in numerals) are shown.

scores ranged from 0 to 20, with a mean of 3.05 ± 3.46 points. The 2 methods were significantly different from each other, with p = 0.0003 by the signal rank test. The average difference between methods was −0.2032 ± 1.2167 points, with a median of 0 (range −6 to 5 points). While Pearson product-moment regression analysis revealed a correlation coefficient of 0.94, only 54% (n = 238) of the ECGs matched overall scores identically (Figure 4). The average difference in score for the remaining 200 ECGs was −0.445 ± 1.7728 points, with a median of −1 (range −6 to 5 points).

Errors intrinsic to automation included failure to recognize minute R and S waves <20 mV and failure to detect downstroke R-wave notching. Errors in manual application were due to data recording and arithmetic, mismeasurement of waveforms, failure to accurately assess the isoelectric periods, criteria oversights and beat-to-beat variations of the waveforms.

Intraobserver agreement for the paired sets of duplicate ECGs revealed that the manual scorer matched criteria selection identically in only 60 of the 93 sets (65%). There were other instances in which the total score matched but the criteria selection did not, as illustrated by the example in Figure 2. Each of the 54 criteria when examined independently had agreement levels ranging from 96% to 100%.

The time required to score the 438 ECGs of the primary data set plus the 93 duplicate ECGs (total 531) by the automated method using an IBM/XT microcomputer was 1% of the time required for manual scoring of the same ECGs (20 minutes vs 36 hours, respectively).

Discussion

With the advent of interventional techniques aimed at limiting acute MI size, such as thrombolytic therapy and coronary angioplasty, the availability of indexes that can estimate the amount of myocardium in jeopardy, the extent of final MI and the prognosis have great importance. The standard 12-lead ECG is being examined for an increased role in this clinical setting because it is readily available and can be performed quickly at low cost.[7–14] The present study offers enhancement of an existing method for estimation of MI size, the Selvester QRS scoring system. While the practical limitations inherent to manual application of this method—such as time, training, variability and bias—have made it difficult for the Selvester system to gain wide recognition, an automated version would likely augment its usefulness in the routine assessment of the MI patient. Indeed, the relatively low level of intraobserver agreement of even the expert manual scorer (65%) supports the need for automation to provide a reliable, expeditious method that can quickly and reproducibly estimate MI size in an individual patient or in large research populations.

Although there are problems with manual application, conversion to an automated system also has limitations. Other attempts to automate the Selvester system have had suboptimal results, limited primarily by the lack of sufficient on-going intensive interactions between the manual scorer and the software developer to establish criteria definitions.[17,18] Because precise definitions of criteria include literal applications as well as the nuances of manual interpretation, the translation process from human to computer is extremely difficult. Although the algorithms may appear well described, intricate waveforms occur that make application of certain criteria ambiguous. While a trained observer can intelligently modify his or her approach in these cases, a computer is limited unless this logic has been fully considered and incorporated into the program. Because it is not possible to consider all intricacies of a waveform there will always be instances where the observer's knowledge about electrocardiography will result in an educated opinion for the correct application of a particular criterion. However, this same knowledge of ECG interpretation leads to bias in the scoring process. Although computerization of complex, but systematic, logic can assist clinical decision-making, it must also be recognized that as the number and complexity of the programmed criteria increase, the clinicans using the system will tend to have less knowledge of the criteria incorporated into the program logic. This may lead to overreliance or false confidence in computer results when complex scoring systems are used.

Significance of Q-Wave Regression After Transmural Acute Myocardial Infarction

SANTIAGO COLL, MD, AMADEO BETRIU, MD, TOMÁS DE FLORES, MD, EULALIA ROIG, MD, GINÉS SANZ, MD, LUIS MONT, MD, JORGE MAGRIÑÁ, MD, ANTONIO SERRA, MD, and FRANCISCO NAVARRO LÓPEZ, MD

A total of 313 consecutive patients was studied to assess the prevalence and prognostic implications of Q-wave loss after transmural acute myocardial infarction. Heart catheterization, including single-plane left ventriculography and selective coronary arteriography, was performed before hospital discharge. After a mean follow-up of 65 (1 to 100) months, 34 patients (11%) lost their Q waves. The time interval from the acute event to the first electrocardiogram showing Q-wave disappearance was 14 (1 to 32) months. Peak creatine kinase value was significantly higher in patients who retained their Q waves than in those who lost them (1,121 ± 813 vs 779 ± 464 IU, respectively, $p < 0.05$). Severity of coronary artery disease, as judged by the number of diseased arteries and the number of arteries with total or subtotal occlusion, was similar in both groups. However, patients showing Q-wave regression had lower left ventricular end-diastolic pressure, higher ejection fraction and fewer abnormally contracting segments than their counterparts (12 ± 6 vs 15 ± 7 mm Hg, $p < 0.05$; 53 ± 11 vs 44 ± 14%, $p < 0.001$; 1 ± 1 vs 2 ± 1 segments, $p < 0.001$, respectively). In addition, no patient with normalized electrocardiogram presented with left ventricular aneurysm. Although differences in mortality, nonfatal reinfarction and new onset of angina between the 2 groups were not significant, congestive heart failure was prevalent among patients with permanent Q waves (23 vs 6%, $p < 0.05$). Our findings suggest that Q-wave loss after AMI may be related to a smaller infarct size.

(Am J Cardiol 1988;61:739–742)

It has recently been recognized that loss of Q waves after transmural acute myocardial infarction [AMI] is not as unusual as previously suspected.[1-3] However, conflicting results have been published with regard to the prevalence and prognostic implications of Q-wave regression following AMI. Discrepancies among series are to be expected because available studies deal with selected groups of patients and lack angiographic data. The present investigation assesses the natural history of patients with transmural AMI in whom serial electrocardiograms showed disappearance of diagnostic Q waves.

Methods

Patients: From January 1975 to January 1980, 376 men with AMI aged ≤60 years were admitted to our institution. A detailed description of the University of Barcelona's Myocardial Infarction Project has been published elsewhere.[4] Of 357 survivors, 44 were excluded from the study due to either coexisting noncardiac life-threatening conditions (5 patients), refusal to undergo coronary angiography (24) or to the presence of non-Q-wave AMIs (15). Thirty four of the remaining 313 patients showed regression of Q waves on serial electrocardiograms and formed the basis of this study.

Criteria for infarction: Myocardial infarction was diagnosed when evolving Q-wave abnormalities with ST-segment and T-wave changes were associated with either ischemic chest pain lasting >20 minutes or serial elevation of serum enzymes. Previous infarction was diagnosed when either prior hospital admission for documented AMI or electrocardiographic Q-wave abnormalities diagnostic of an old infarction was present.

Transmural myocardial infarction was coded according to location as anterior, inferior or combined. Criteria for infarction was based on major (Minnesota Code 1,1), moderate (1,2) or minor (1,3) electrocardiographic findings, as determined by the duration and depth of Q waves and the leads in which they appear.[5]

Catheterization and angiographic procedures: Heart catheterization was performed within 1 month of the acute event. Left ventriculograpjy was carried out in the 30° right anterior oblique projection. Coronary arteriograms were obtained in multiple projections. Left ventricular volumes and ejection fraction were determined using the area-length method.[6] To assess regional wall motion, 5 areas of interest were considered: anterobasal, anterolateral, apical, diaphragmatic and posterobasal.[7] The systolic change for each region was measured as the segmental ejection fraction. Lesions of <50% reduction in diameter were considered to be nonobstructive. Total coronary occlusion was defined as the absence of forward flow of contrast material in the involved artery. Each patient was classified as having 1-, 2- or 3-vessel disease. Obstructions of diagonal and marginal branches were considered lesions of the left anterior descending or circumflex artery, respectively. Collaterals were judged to be well developed when the diameter of the receiving artery measured >1 mm and the sending vessel showed no obstructive lesions.

Follow-up: Patients were seen monthly during the first 3 months and every 3 months thereafter. Clinical status, results of physical examination and a 12-lead electrocardiogram were recorded at each visit. Mean follow-up was 65 months (1 to 100).

Statistical analysis: Differences between patients who retained their Q waves and those who lost them were analyzed using the Statistical Package for Social Sciences,[8] applying the Student *t* test, Fischer exact test or the chi-square test, when appropriate. Survival analysis was done by constructing Kaplan-Meier actuarial curves for the 2 groups.[9] Statistical differences were assessed by the log-rank test.[10] A p value <0.05 was considered significant.

TABLE I Clinical and Angiographic Data

	Q Wave Lost	Q Wave Retained	p Value
No.	34	279	
Mean age (yr)	48 ± 8	51 ± 7	
Previous AMI (%)	1 (3)	30 (10)	NS
Previous angina (%)	14 (41)	136 (48)	NS
Systemic hypertension (%)	12 (35)	107 (38)	NS
Diabetes mellitus (%)	7 (20)	55 (19)	NS
Dyslipemia (%)	19 (56)	97 (34)	NS
Cigarette smoking (%)	32 (94)	17 (92)	NS
Creatine kinase	779 ± 464	1,121 ± 813	<0.02
LVEDP (mm Hg)	12 ± 6	15 ± 7	<0.03
Ejection fraction (%)	53 ± 11	44 ± 14	<0.0003
Affected areas	1 ± 1	2 ± 1	<0.00001
LV aneurysm (%)	0	42 (15)	<0.02
Coronary arteries narrowed >50% in diameter			
0 (%)	3 (9)	16 (6)	NS
1 (%)	15 (44)	93 (33)	NS
2 (%)	8 (23.5)	94 (33)	NS
3 (%)	8 (23.5)	79 (28)	NS
Coronary collaterals (%)	2 (6)	38 (13)	NS

AMI = acute myocardial infarction; LV = left ventricular; LVEDP = left ventricular end-diastolic pressure; NS = not significant.

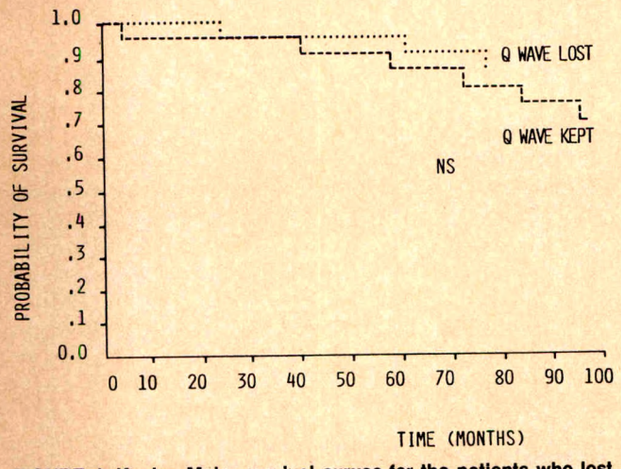

FIGURE 1. Kaplan-Meier survival curves for the patients who lost their Q waves and those who kept them. No differences were found when both populations were compared (85% and 75% survival at 7.5 years, respectively).

Results

Prevalence: Loss of Q waves was documented in 34 patients (11%). The time interval from the AMI to the first electrocardiogram showing Q-wave disappearance was 14 ± 10 months (mean ± standard deviation, range 1 to 32). Loss occurred in 53% of patients with anterior and 44% of patients with inferior AMI. Q loss occurred 3% of the time when the infarction involved both anterior and inferior walls.

Clinical and angiographic findings: Baseline clinical data and catheterization findings are listed in Table I. Patients who lost Q waves had a lower peak creatine kinase level (779 ± 464 vs 1,121 ± 813 IU, p <0.05) than their counterparts. Age, previous history of coronary artery disease, hypertension, dyslipemia, cigarette smoking and diabetes mellitus were not different in the 2 groups. Left ventricular end-diastolic pressure was lower (12 ± 6 vs 15 ± 7 mm Hg, p <0.05) and ejection fraction higher (53 ± 11 vs 44 ± 14%, p <0.001) in patients who lost their Q waves. Regional wall motion analysis showed that this group of patients had fewer abnormally contracting segments (1 ± 1 vs 2 ± 1 segments, p <0.0001) and higher prevalence of normal left ventricular angiograms (35 vs 12%, p <0.001) than those who retained Q waves. In addition, no patient with a normalized electrocardiogram had left ventricular aneurysm (p <0.05). The number of diseased arteries and the number of arteries showing total or subtotal (>90%) lesions was comparable in both groups of

patients. Similarly, no differences were found between the 2 groups with regard to the presence of well developed collaterals.

Follow-up: Fifty-two patients, 4 who lost and 48 who kept their Q waves, died during the follow-up period. Figure 1 shows the Kaplan-Meier actuarial curves for the 2 groups. No differences were found when both populations were compared (75 and 85% survival rates at 7.5 years, respectively). Prevalence of nonfatal reinfarction (3 vs 34 patients) and new onset angina (18 vs 150) was similar in both groups. Congestive heart failure, however, was more frequently found among patients with permanent Q waves (2 vs 63, $p < 0.05$).

Discussion

Prevalence: Retrospective studies[1,2] have found the prevalence of Q-wave regression after AMI to vary between 7 and 15%. To our knowledge, the present investigation represents the first attempt to assess the prevalence of Q-wave loss in a series of unselected consecutive patients surviving an AMI. Thus, the finding that 34 of 313 AMI survivors (11%) lost their Q waves after a mean time interval of 14 ± 10 months is relevant because the study population included 91% of potential candidates and follow-up was complete in all but 13 patients. Although we analyzed a limited age group of men, this series included 70% of all patients with AMI admitted in our unit. Thus, our results are not likely to be biased by selection criteria. In the Aspirin Myocardial Infarction Study[3] (AMIS), 14% of the patients lost Q waves that were present on the qualifying electrocardiogram. Differences between that trial and our own series are minor and might be related to patient selection criteria, as participants in the AMIS trial were older than our cohort and entered the study at variable time intervals after the acute event. In addition, unstable patients and early deaths (within 2 months after myocardial infarction) were excluded from the AMIS protocol.

Clinical and angiographic findings: Previous reports of patients who lost Q waves after AMI do not include angiographic data.[1,3] The present study showed the prevalence of total or subtotal occlusion of the involved artery to be comparable in patients who lost their Q waves and those who retained them. Nevertheless, the latter group had a better left ventricular function, as substantiated by a higher ejection fraction, fewer abnormally contracting segments and lower left ventricular end-diastolic pressure. These data, plus the finding of a lower peak creatine kinase value, strongly suggest a smaller infarct size in patients with lost Q waves. Of interest in that regard is the recent documentation of a negative relation between infarct size (as assessed by an electrocardiographic score) and left ventricular ejection fraction.[11,12]

Q-wave regression mechanism: A review of clinical and angiographic data was of little help in identifying the exact mechanism of Q-wave regression in our series. It is known that a new ventricular conduction disturbance may alter activation pathways and mask prior Q waves. Similarly, a second myocardial infarction involving the contralateral ventricular wall may cause an apparent regrowth of R waves over the area of previous infarct.[13] In our case, however, these 2 mechanisms are unlikely as demonstrated by serial electrocardiogram readings of individual patients and, in the case of reinfarction, by lack of clinical manifestations. The disappearance of Q waves has been documented after successful myocardial revascularization[14]; similarly, increased local flow by late coronary artery recanalization[15-17] might well explain the Q-wave loss in our series. However, this hypothesis cannot be proven because repeat angiography was not performed. Alternatively, regression of Q wave may result from progressive reduction of scar tissue to a critical-size area.[18]

Prognostic implications: After reviewing serial electrocardiograms from 251 men, Kaplan and Berkson[2] failed to find any difference in survival between patients whose Q waves disappeared (21%) and those whose Q waves persisted (30%). Kalbfleisch et al[1] analyzed a series of 775 patients with myocardial infarction, 52 of whom (7%) showed complete disappearance of diagnostic Q waves. The mortality rate of this subset was comparable to that of the entire group (21 vs 23%). Data from the Coronary Drug Project[19] conflicted with these observations because infarct survivors with Q patterns on the baseline electrocardiogram had a >3-fold mortality of those with no residual recordable Q waves after infarction (13 vs 4%, $p < 0.01$). The reason for the discrepancy between the Coronary Drug Project and earlier series may be that the latter study specifically referred to loss of Q waves whereas the former referred only to the fact that there was no Q wave present at baseline. In the AMIS cohort,[3] the mortality associated with the absence or loss of Q waves did not differ from that in patients who had a single infarct and persistent Q waves. However, patients with extensive areas of infarction, as indicated by multiple infarct sites or major coding criteria, had a significantly higher total mortality than patients who lost Q waves. In keeping with these findings we showed by actuarial analysis that the mortality rate after Q-wave regression was comparable to that of patients with permanent Q waves.

The lack of significant differences in the rates of reinfarction and angina between patients who lost their Q waves and those who kept them probably is related to the extent and severity of coronary artery lesions found to be comparable in both groups. The prevalence of congestive heart failure among patients with permanent Q waves is in agreement with the higher left ventricular end-diastolic pressure and rate of left ventricular aneurysms in this group.

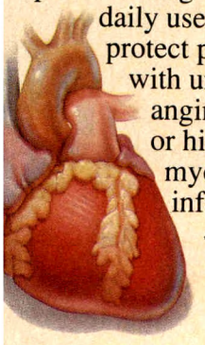
Ecotrin® Recommended by cardiologists over Bayer® aspirin.

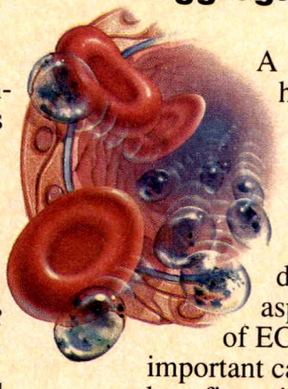
Aspirin therapy recommended by cardiologists.

ECOTRIN *is* aspirin–and it's the brand recommended by cardiologists more often than Bayer* aspirin for long-term daily use, to protect patients with unstable angina, TIA, or history of myocardial infarction.[1]



*Bayer® is a registered trademark of the Bayer Company.

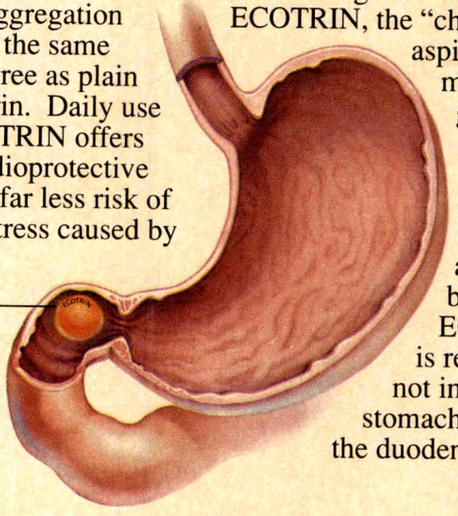
Effectively inhibits platelet aggregation.



A recent study[2] has shown that ECOTRIN inhibits platelet aggregation to the same degree as plain aspirin. Daily use of ECOTRIN offers important cardioprotective benefits–with far less risk of the gastric distress caused by plain aspirin.

Enteric-coated to spare the stomach.

More than 1,000 endoscopies have proved ECOTRIN superior to plain, buffered, and highly buffered aspirin in protecting the stomach in a regimen of 4 g a day.[3] ECOTRIN, the "chronic-use" aspirin, minimizes the gastric damage often associated with other forms of aspirin because ECOTRIN is released not in the stomach but in the duodenum.



ECOTRIN is released not in the stomach but in the duodenum.

Targeted-Release
Ecotrin®
Safety-Coated Aspirin 325 mg and 500 mg Tablets

The cardioprotective stomach-sparing aspirin.

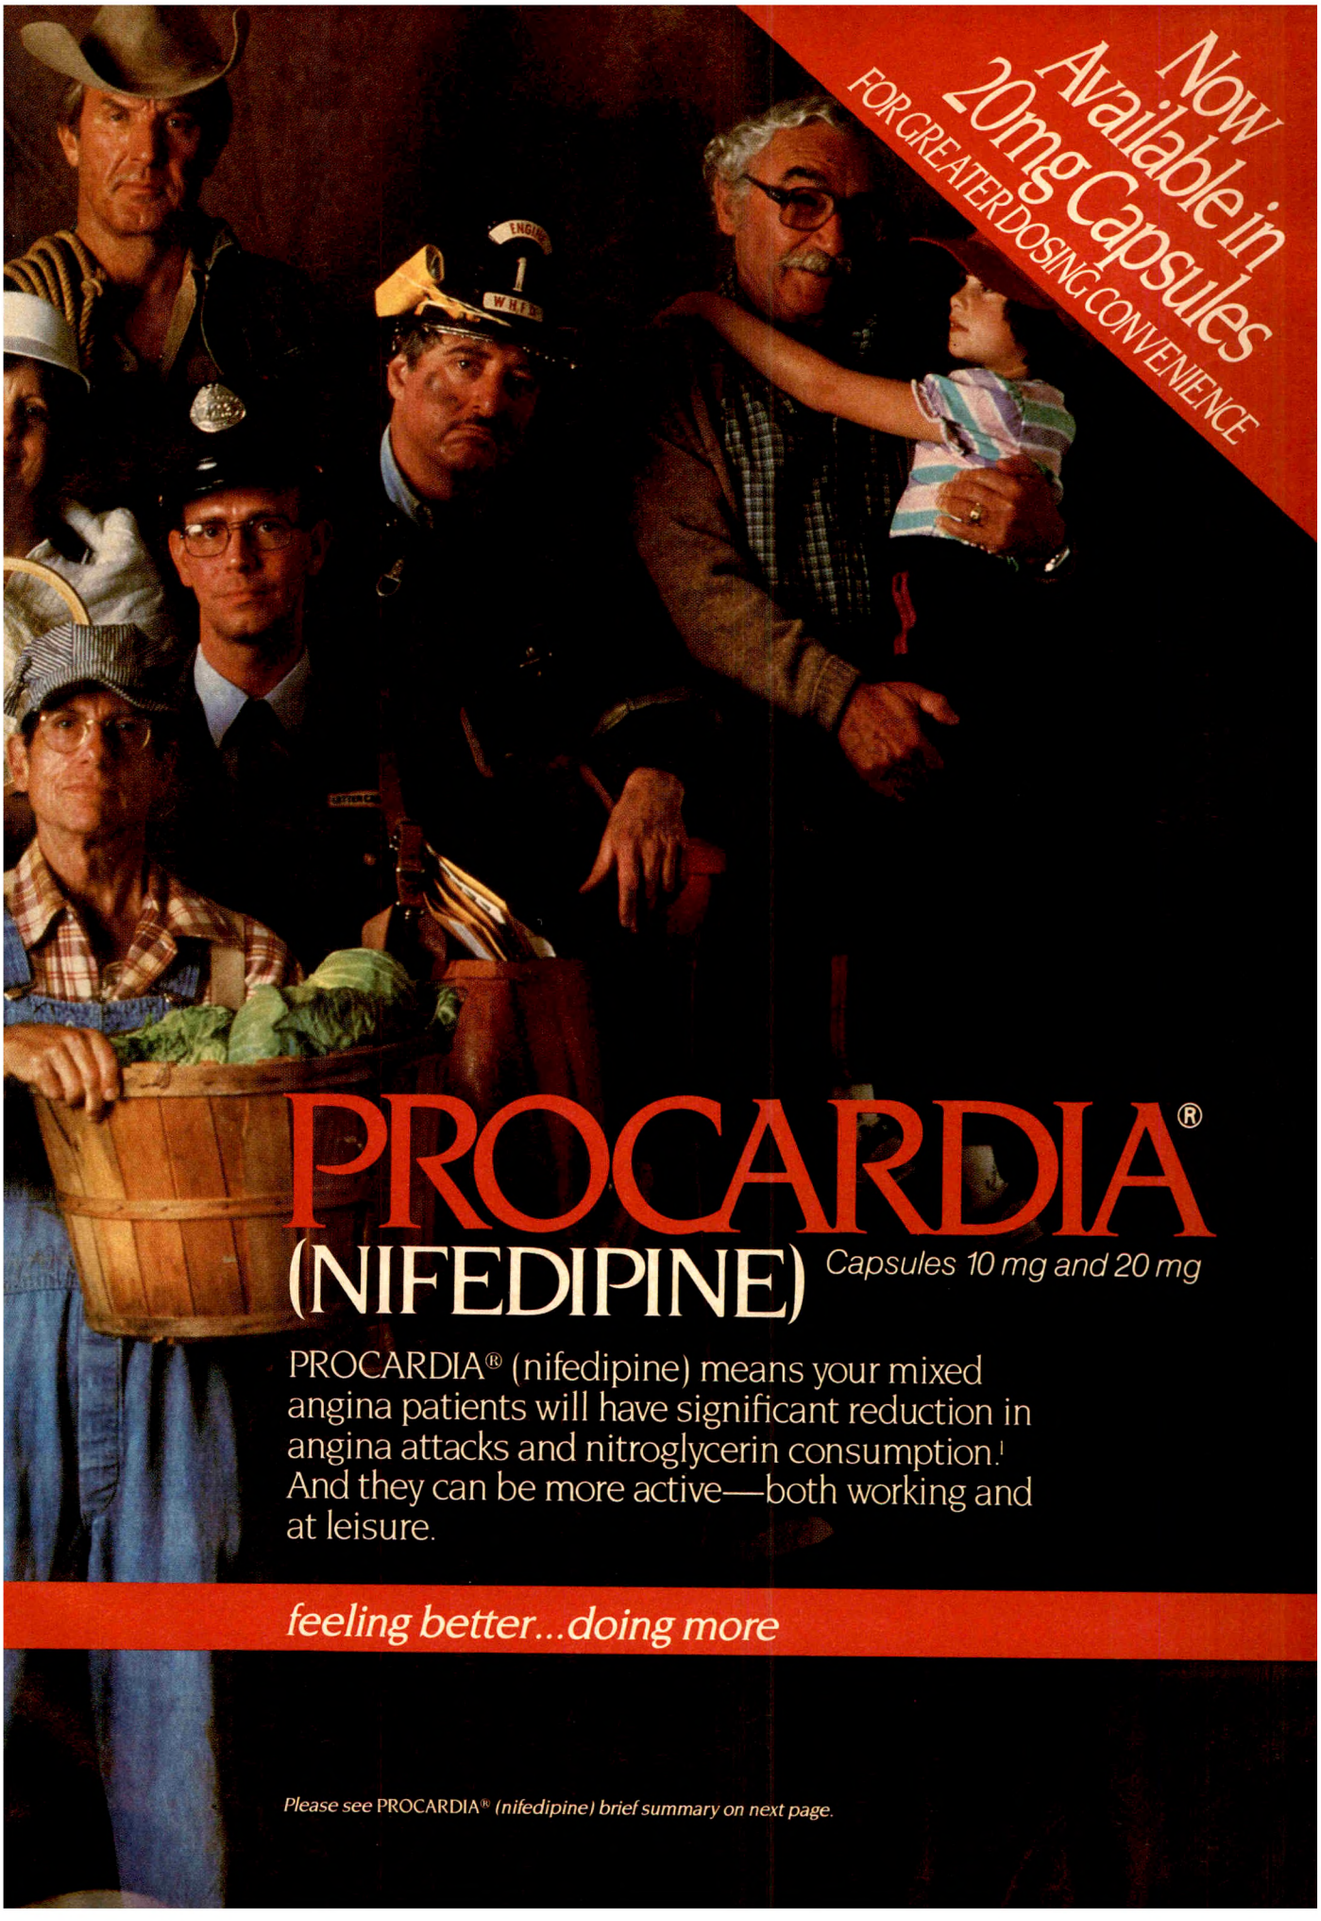
AN IMPROVED QUALITY OF LIFE
© 1986, Pfizer Inc.



Now Available in 20mg Capsules
FOR GREATER DOSING CONVENIENCE
PROCARDIA®
(NIFEDIPINE)
Capsules 10 mg and 20 mg
PROCARDIA® (nifedipine) means your mixed angina patients will have significant reduction in angina attacks and nitroglycerin consumption.[1] And they can be more active—both working and at leisure.
feeling better...doing more
Please see PROCARDIA® (nifedipine) brief summary on next page.

feeling better...doing more

PROCARDIA®
(NIFEDIPINE)

Capsules 10 mg and 20 mg

–Effective dosage range is 30-120 mg/day

For most patients, start with 10 mg *t.i.d.*, and titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking other drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

–Offers a favorable safety profile

Most frequently reported side effects associated with PROCARDIA therapy, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients; transient hypotension in about 5%; palpitation in about 2%; syncope in about 0.5%.

1. Stone PH, Muller JE, Turi ZG, et al: Efficacy of nifedipine therapy in patients with refractory angina pectoris: Significance of the presence of coronary vasospasm. *Am Heart J* 1983; 106:644-652.

Brief Summary For Oral U
PROCARDIA® (nifedipine) Capsules

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the manag ment of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest a companied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the pr ence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, p vided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentati suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain l a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible w intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the mana ment of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who rem symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmatio sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-block agents may be beneficial in patients with chronic stable angina, but available information is not sufficien predict with confidence the effects of concurrent treatment, especially in patients with compromised left v tricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care m be taken to monitor blood pressure closely since severe hypotension can occur from the combined effect the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDI modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These sponses have usually occurred during initial titration or at the time of subsequent upward dosage adjustm and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiv PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using h dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combinatio PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low dose fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCAR treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician shoul aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 ho should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina and/or Myocardial Infarction: Rarely, patients, particularly those who have severe structive coronary artery disease, have developed well documented increased frequency, duration and/or verity of angina or acute myocardial infarction on starting PROCARDIA or at the time of dosage increase. mechanism of this effect is not established.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal drome with increased angina, probably related to increased sensitivity to catecholamines. Initiatio PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provol reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blo withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stop them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resista careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is sugges Close observation is especially recommended for patients already taking medications that are known to l blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This ed occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose an is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema fron effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as line phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA therapy i certain in most cases, but probable in some. These laboratory abnormalities have rarely been associated clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of all hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platele gregation and increase in bleeding time in some PROCARDIA (nifedipine) patients. No clinical significanc these findings has been demonstrated. Positive direct Coombs test with/without hemolytic anemia has reported.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been repo in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncerta most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See INDICATIONS AND WARNINGS.) Experien over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports sugge that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerb of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no trolled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal unteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thi patients with coronary artery disease. In an uncontrolled study of over two hundred patients with conge heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin l be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or u digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking marin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasm els (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and ipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is ini in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to ra two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused red fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity st were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryoto rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, perip edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hyp sion in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recu reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, rhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteri sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperp depression, paranoid syndrome, transient blindness at the peak of plasma level, erythromelalgia, and ar with ANA (+). Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural h of the disease in these patients. It remains possible, however, that some or many of these events were related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulm edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0. patients.

HOW SUPPLIED: PROCARDIA soft gelatin capsules are supplied in:
Bottles of 100: 10 mg (NDC 0069-2600-66) orange #260; 20 mg (NDC 0069-2610-66) orange and light #261. Bottles of 300: 10 mg (NDC 0069-2600-72) orange #260; 20 mg (NDC 0069-2610-72) orange an brown #261. Unit dose packages of 100: 10 mg (NDC 0069-2600-41) orange #260; 20 mg (NDC 0069- 41) orange and light brown #261.

The capsules should be protected from light and moisture and stored at controlled room temperature 77°F (15° to 25°C) in the manufacturer's original container.

FOR MANY HYPERTENSIVE PATIENTS

Start with Once-a-Day

VASOTEC®

(ENALAPRIL MALEATE | MSD)

Certain CNS effects, such as impairment of memory, nightmares, or depression, have not been characteristic of VASOTEC.

Little or No Interference with Physical or Mental Activity

Certain subjective symptoms such as malaise and drowsiness, which may interfere with physical or mental activity, have not been characteristic of VASOTEC—a fact that may be related to the specificity of action of VASOTEC on the renin-angiotensin-aldosterone system.

VASOTEC is contraindicated in patients who are hypersensitive to this product.

Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with angiotensin-converting-enzyme (ACE) inhibitors, including VASOTEC (0.2% of patients treated with VASOTEC in clinical trials). In such cases, VASOTEC should be promptly discontinued and the patient carefully observed until the swelling disappears. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered.**

Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. In using VASOTEC, consideration should be given to the fact that another ACE inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease, and the available data are insufficient to show that VASOTEC does not have a similar risk.

For a Brief Summary of Prescribing Information, please see the last page of this advertisement.

MERCK SHARP & DOHME

It May Change the Way Your Patients Feel on Antihypertensive Therapy

VASOTEC®

(ENALAPRIL MALEATE | MSD)

Contraindications: VASOTEC® (Enalapril Maleate, MSD) is contraindicated in patients who are hypersensitive to this product.

Warnings: *Angioedema:* Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with ACE inhibitors, including VASOTEC. In such cases, VASOTEC should be promptly discontinued and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips, the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL), should be promptly administered.** (See ADVERSE REACTIONS.)

Hypotension: Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons such as those treated vigorously with diuretics or patients on dialysis. (See PRECAUTIONS, *Drug Interactions* and ADVERSE REACTIONS.) In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia, and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of enalapril and/or diuretic is increased. Similar considerations may apply to patients with ischemic heart or cerebrovascular disease, in whom an excessive fall in blood pressure could result in a myocardial infarction or cerebrovascular accident.

If hypotension occurs, the patient should be placed in supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses, which usually can be given without difficulty once the blood pressure has increased after volume expansion.

Neutropenia/Agranulocytosis: Another ACE inhibitor has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease. Available data from clinical trials of enalapril are insufficient to show that enalapril does not cause agranulocytosis at similar rates. Foreign marketing experience has revealed several cases of neutropenia or agranulocytosis in which a causal relationship to enalapril cannot be excluded. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered.

Precautions: *General: Impaired Renal Function:* As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors, including VASOTEC, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine were observed in 20% of patients. These increases were almost always reversible upon discontinuation of enalapril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent preexisting renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when VASOTEC has been given concomitantly with a diuretic. This is more likely to occur in patients with preexisting renal impairment. Dosage reduction of VASOTEC and/or discontinuation of the diuretic may be required.

Evaluation of the hypertensive patient should always include assessment of renal function. (See DOSAGE AND ADMINISTRATION in complete Prescribing Information.)

Hyperkalemia: Elevated serum potassium (greater than 5.7 mEq/L) was observed in approximately 1% of hypertensive patients in clinical trials. In most cases these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in 0.28% of hypertensive patients. Risk factors for the development of hyperkalemia may include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements, and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with VASOTEC. (See *Drug Interactions.*)

Surgery/Anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, enalapril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Information for Patients:

Angioedema: Angioedema, including laryngeal edema, may occur especially following the first dose of enalapril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to take no more drug until they have consulted with the prescribing physician.

Hypotension: Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, the patients should be told to discontinue the drug until they have consulted with the prescribing physician.

All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with the physician.

Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.

Neutropenia: Patients should be told to report promptly any indication of infection (e.g., sore throat, fever) which may be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with enalapril is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions:

Hypotension: Patients on Diuretic Therapy: Patients on diuretics and especially those in whom diuretic therapy was recently instituted may occasionally experience an excessive reduction of blood pressure after initiation of therapy with enalapril. The possibility of hypotensive effects with enalapril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with enalapril. If it is necessary to continue the diuretic, provide medical supervision for at least one hour after the initial dose. (See WARNINGS and DOSAGE AND ADMINISTRATION in complete Prescribing Information.)

Agents Causing Renin Release: The antihypertensive effect of VASOTEC is augmented by antihypertensive agents that cause renin release (e.g., diuretics).

Other Cardiovascular Agents: VASOTEC has been used concomitantly with beta-adrenergic-blocking agents, methyldopa, nitrates, calcium-blocking agents, hydralazine, and prazosin without evidence of clinically significant adverse interactions.

Agents Increasing Serum Potassium: VASOTEC® (Enalapril Maleate, MSD) may attenuate potassium loss caused by thiazide-type diuretics. Potassium-sparing diuretics (e.g., spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated because of demonstrated hypokalemia, they should be used with caution and with frequent monitoring of serum potassium.

Pregnancy—Category C: There was no fetotoxicity or teratogenicity in rats treated with up to 200 mg/kg/day of enalapril (333 times the maximum human dose). Fetotoxicity, expressed as a decrease in average fetal weight, occurred in rats given 1200 mg/kg/day of enalapril but did not occur when these animals were supplemented with saline. Enalapril was not teratogenic in rabbits. However, maternal and fetal toxicity occurred in some rabbits at doses of 1 mg/kg/day or more. Saline supplementation prevented the maternal and fetal toxicity seen at doses of 3 and 10 mg/kg/day, but not at 30 mg/kg/day (50 times the maximum human dose).

There are no adequate and well-controlled studies in pregnant women. VASOTEC should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is secreted in human milk. Because many drugs are secreted in human milk, caution should be exercised when VASOTEC is given to a nursing mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Adverse Reactions: VASOTEC has been evaluated for safety in more than 10,000 patients, including over 1000 patients treated for one year or more. VASOTEC has been found to be generally well tolerated in controlled clinical trials involving 2677 patients.

The most frequent clinical adverse experiences in controlled trials were: headache (4.8%), dizziness (4.6%), and fatigue (2.8%). For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6.0% of patients. In clinical trials, the overall frequency of adverse experiences was not related to total daily dosage within the range of 10 to 40 mg. The overall percentage of patients treated with VASOTEC reporting adverse experiences was comparable to placebo.

Other adverse experiences occurring in greater than 1% of patients treated with VASOTEC in controlled clinical trials were: diarrhea (1.6%), rash (1.5%), hypotension (1.4%), cough (1.3%), nausea (1.3%), and orthostatic effects (1.3%).

Clinical adverse experiences occurring since the drug was marketed or in 0.5 to 1.0% of patients in the controlled trials are listed below and, within each category, are in order of decreasing severity.

Cardiovascular: Myocardial infarction or cerebrovascular accident, possibly secondary to excessive hypotension in high risk patients (see WARNINGS, *Hypotension*); syncope; orthostatic hypotension; palpitations; chest pain.

Gastrointestinal System: Ileus, pancreatitis, hepatitis or cholestatic jaundice, abdominal pain, vomiting, dyspepsia, constipation.

Nervous System/Psychiatric: Depression, confusion, somnolence, insomnia, nervousness, paresthesia.

Renal: Renal failure, oliguria, renal dysfunction. (See PRECAUTIONS and DOSAGE AND ADMINISTRATION.)

Respiratory: Bronchospasm, dyspnea, rhinorrhea.

Other: Muscle cramps, hyperhidrosis, impotence, pruritus, asthenia, photosensitivity, alopecia, flushing, taste alteration, tinnitus, glossitis.

A symptom complex has been reported which may include fever, myalgia, and arthralgia; an elevated erythrocyte sedimentation rate may be present. Rash or other dermatologic manifestations may occur. These symptoms have disappeared after discontinuation of therapy.

Angioedema: Angioedema has been reported in patients receiving VASOTEC (0.2%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with VASOTEC should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.)

Hypotension: Combining the results of clinical trials in patients with hypertension or congestive heart failure, hypotension (including postural hypotension and other orthostatic effects) was reported in 2.3% of patients following the initial dose of enalapril or during extended therapy. In the hypertensive patients, hypotension occurred in 0.9% and syncope occurred in 0.5% of patients. Hypotension or syncope was a cause for discontinuation of therapy in 0.1% of hypertensive patients. (See WARNINGS.)

Clinical Laboratory Test Findings:

Serum Electrolytes: Hyperkalemia (see PRECAUTIONS), hyponatremia.

Creatinine, Blood Urea Nitrogen: In controlled clinical trials, minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 0.2% of patients with essential hypertension treated with VASOTEC alone. Increases are more likely to occur in patients receiving concomitant diuretics or in patients with renal artery stenosis. (See PRECAUTIONS.)

Hemoglobin and Hematocrit: Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.3 g% and 1.0 vol%, respectively) occur frequently in hypertensive patients treated with VASOTEC but are rarely of clinical importance unless another cause of anemia coexists. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia.

Other (Causal Relationship Unknown): In marketing experience, rare cases of neutropenia, thrombocytopenia, and bone marrow depression have been reported.

Liver Function Tests: Elevations of liver enzymes and/or serum bilirubin have occurred.

Dosage and Administration: In patients who are currently being treated with a diuretic, symptomatic hypotension occasionally may occur following the initial dose of VASOTEC. The diuretic should, if possible, be discontinued for two to three days before beginning therapy with VASOTEC to reduce the likelihood of hypotension. (See WARNINGS.) If the patient's blood pressure is not controlled with VASOTEC alone, diuretic therapy may be resumed.

If the diuretic cannot be discontinued, an initial dose of 2.5 mg (break the 5-mg tablet) should be used under medical supervision for at least one hour to determine whether excess hypotension will occur. (See WARNINGS and PRECAUTIONS, *Drug Interactions.)*

The recommended initial dose in patients not on diuretics is 5 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 10 to 40 mg per day administered in a single dose or in two divided doses. In some patients treated once daily, the antihypertensive effect may diminish toward the end of the dosing interval. In such patients, an increase in dosage or twice-daily administration should be considered. If blood pressure is not controlled with VASOTEC alone, a diuretic may be added.

Concomitant administration of VASOTEC with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium (see PRECAUTIONS).

Dosage Adjustment in Renal Impairment: The usual dose of enalapril is recommended for patients with a creatinine clearance >30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance ≤30 mL/min (serum creatinine ≥3 mg/dL), the first dose is 2.5 mg once daily. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily. For dialysis patients, the initial dose and the dose on dialysis days is 2.5 mg/day. Dosage on nondialysis days should be adjusted depending on blood pressure response.

Limitations in the Interpretation of Rest-Exercise Ejection Fraction Changes After Early Thrombolytic Therapy During Acute Myocardial Infarction

FLORENCE H. SHEEHAN, MD, DETLEF G. MATHEY, MD, JOACHIM SCHOFER, MD, SUZANNE MITTEN, and EDWARD L. BOLSON, MS

The effect of exercise on left ventricular wall motion in the infarct and noninfarct regions, and their contribution to the global ejection fraction response to exercise was evaluated in 24 patients studied at least 2 weeks following thrombolytic therapy for acute myocardial infarction. To achieve this goal, a nonstandard protocol was used: contrast ventriculography was performed at rest and immediately following 3 minutes of supine bicycle exercise at 50 watts. Wall motion in the infarct and noninfarct regions was measured using the centerline method. The global ejection fraction response to exercise correlated poorly with the exercise response of motion in the infarct region ($r = 0.38$). In 15 of the 24 patients, the function of the infarct and noninfarct regions changed in opposing directions, and in only 8 (53%) of these did the global ejection fraction response follow the exercise response of motion in the infarct region. The motion of the noninfarct region was the predominant influence on the ejection fraction response in the other 7 patients. Subgroup analysis revealed that the global ejection fraction response was more dependent on the response of motion in the anterior wall ($r = 0.71$, $p < 0.001$) than in the inferior wall ($r = 0.16$), regardless of infarct location. The regional wall motion response to exercise also better distinguished reperfused from nonreperfused patients than did the ejection fraction response. These results indicate that the global ejection fraction response to exercise may be an unreliable indicator of the functional status of the infarct region. The efficacy of thrombolytic therapy for acute myocardial infarction in salvaging myocardium is more accurately evaluated from the rest-exercise change in regional wall motion.

(Am J Cardiol 1988;61:743–748)

Studies of the prognostic value of measuring the rest-exercise ejection fraction response in patients who have suffered a recent myocardial infarction have had contradictory results. Some studies have reported a higher predictive accuracy with the exercise response than with the resting ejection fraction,[1–3] whereas others reported that the resting ejection fraction better predicted survival.[4] One reason may be that the global ejection fraction is an insensitive parameter of function in the infarct region in the presence of compensatory hyperkinesis of the noninfarct region.[5] Such hyperkinesis is primarily associated with acute infarction, but may occur later.[5,6] As a result, the severity of residual regional dysfunction and ischemia in the infarct site may be underestimated if the global ejection fraction response is maintained normal by enhanced contraction in noninfarct regions. The present study was performed to measure the change in regional wall motion with exercise in both the infarct and noninfarct regions in post-thrombolysis patients and to correlate these with the global ejection fraction response to exercise.

Methods

Patients: The study comprised 28 patients, admitted at University Hospital Eppendorf ≤3 hours after onset of acute myocardial infarction, who received intracoronary streptokinase as previously described.[5] They

were recalled 10 days to 2.6 years later for repeat cardiac catheterization and exercise contrast angiography. Twenty-eight (34%) of 83 patients treated consented to testing. Using the Judkins procedure, coronary arteriography was performed, followed by ventriculography in the 30° right anterior oblique projection. After a 15-minute wait to allow dissipation of the effect of contrast on ventricular function,[7] the patient was exercised at 50 watts for 3 minutes on a supine bicycle. Ventriculography was then repeated. None experienced complications from the exercise. Both the rest and the exercise ventriculograms were analyzable in 24 patients, whose data constitute the subject of the present report.

Ventriculographic analysis: The cine films were analyzed at the University of Washington. Chamber volume was determined using the area length method[8] and global ejection fraction was then calculated. Hypokinesis in the infarct site and hyperkinesis in the opposite wall were measured using the centerline method (Figure 1), as previously described.[9]

Statistical analysis: Patient groups were compared using the unpaired *t* test for continuous variables and chi-square analysis for dichotomous variables. Change between rest and exercise was evaluated using the paired *t* test. Regional and global function were correlated via multiple linear regression analysis. Discriminant analysis was used to determine which parameter of left ventricular function best distinguished reperfused from nonreperfused patients.[10]

Results

Patients: Participants in the rest-exercise study were similar to those who declined (Table I), except

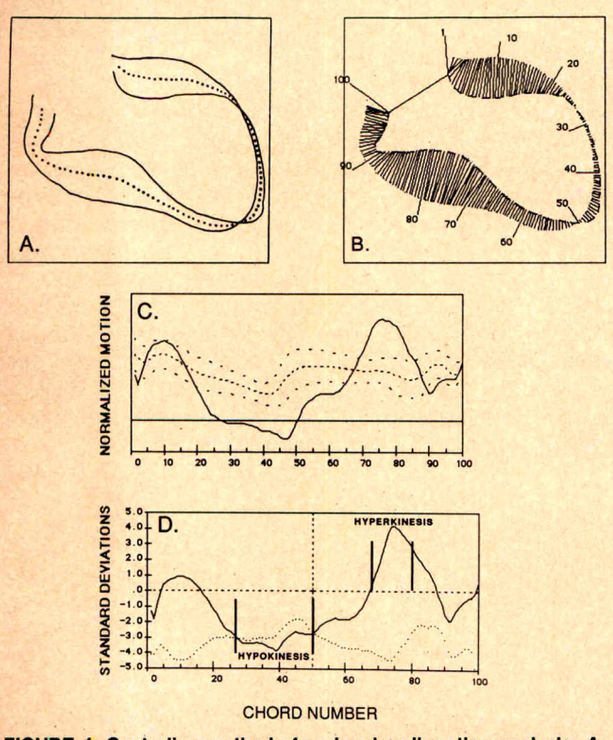

FIGURE 1. Centerline method of regional wall motion analysis. *A*, end-diastolic and end-systolic left ventricular endocardial contours and centerline constructed by the computer midway between the 2 contours. *B*, motion is measured along 100 chords constructed perpendicular to the centerline. *C*, motion at each chord is normalized by the end-diastolic perimeter to yield a shortening fraction. Motion along each chord is plotted for the patient (*solid line*). The mean motion in the normal ventriculogram group (*dashed line*) and 1 standard deviation above and below the mean (*dotted lines*) are shown for comparison. *D*, standardized motion. The wall motion of the patient is now plotted in units of standard deviations from the normal mean (*dotted line*). The normal ventriculogram group mean is represented by the horizontal zero-line. Vertical lines delimit the most hyperkinetic and most hypokinetic parts of the anterior and inferior regions.

Heart rate (beats/min)	82 ± 15	103 ± 16	<0.001	−9 to +49

NS = not significant ($p \geq 0.05$); SD = standard deviations from the mean of the normal reference group.

that all study patients had total occlusion of the infarct artery before thrombolytic therapy. Eighteen patients were considered fully reperfused because the full length of the infarct artery was reperfused after streptokinase therapy, and either (1) the infarct artery was patent at follow-up and there was no clinical evidence for reinfarction during the follow-up period, or (2) the patient underwent bypass surgery and either the native infarct artery or its graft was patent at follow-up. The other 6 patients either failed to reperfuse acutely or reperfused but suffered subsequent rethrombosis.

Exercise responses: With exercise, there was a significant increase in end-diastolic volume, stroke volume, heart rate and cardiac output. Increases in global ejection fraction and in regional wall motion, which are normalized for heart size, were more modest (Table II).

The global ejection fraction response to exercise correlated poorly with the exercise-induced change in wall motion in both the infarct site ($r = 0.38$, Figure 2) and the noninfarct region ($r = 0.47$). In 15 (63%) of the 24 patients, there was discord between the exercise response of the infarct and noninfarct regions, i.e., motion increased in 1 region but decreased in the other. In only 8 (53%) of these 15 did the ejection fraction response follow the infarct region's wall motion change. The ejection fraction response was determined mainly by the change in anterior wall motion ($r = 0.71$, $p < 0.001$, Figure 3) and was little influenced by the inferior wall ($r = 0.16$, Table III). Similar results were obtained in the patients recalled late (>6 months) after infarction ($n = 9$) as in patients entered into the study early (<6 weeks) after infarction ($n = 12$).

The left anterior descending artery perfuses twice as much myocardium as the right coronary artery[11] and, therefore, anterior wall motion would be expected to influence the ejection fraction more. To investigate the poor correlation between anterior wall motion and ejection fraction in patients with anterior infarction, we assessed the relation between motion in the infarct and noninfarct regions. There was an inverse correlation between the motion of the infarct and the noninfarct regions ($r = -0.57$, $n = 13$, $p < 0.05$), indicating discordance between the exercise responses of the 2 walls of the ventricle. This was not due simply to an exercise-induced change in the translational motion of the heart within the chest, because changes in the angle between the end-diastolic and end-systolic long axes were small and insignificant with exercise, and did not correlate with changes in regional wall motion. When partial correlation analysis was used to determine the relation between each wall and the ejection fraction while adjusting for the influence of the other wall, the ejection fraction correlated more highly with the function of the anterior wall than with the inferior wall, as indicated by the partial correlation coefficients (Table III). In patients with inferior wall infarc-

TABLE III Correlation Between Global and Regional Function Response to Exercise

Regional Wall Motion Response to Exercise	Correlation with EF Response (r)	(Partial r*)	(n)	p Value

tion, the motion of the anterior and inferior walls was unrelated.

Correlation between exercise response and perfusion status: In reperfused patients, exercise led to an increase in ejection fraction but not in wall motion in the infarct region. Nonreperfused patients had a significant worsening of motion in the infarct region but no change in global function. Both groups had small increases in the motion of the noninfarct region with exercise. Discriminant analysis revealed that reperfused and nonreperfused patients were better distinguished by measurements of wall motion during exercise than by the ejection fraction response to exercise (Table IV).

In reperfused patients who had improvement of wall motion in the infarct site after exercise, the residual stenosis in the infarct artery was slightly milder than that in reperfused patients without a positive exercise response, both immediately after thrombolysis (77 ± 24 [n = 12] vs 83 ± 13% [n = 6], difference not significant) and at follow-up (58 ± 35 vs 60 ± 38%, difference not significant). Thus, the failure to increase function with exercise probably reflected a lack of salvage rather than continuing ischemia. In the noninfarct region, motion was more likely to increase after exercise in patients with 1-vessel than those with multivessel disease (71% of 14 vs 30% of 10, difference not significant).

Discussion

This study examined the effect of exercise on left ventricular function in patients receiving thrombolytic therapy for acute myocardial infarction. The data indicate that the regional exercise response in the infarct site reflects the reperfusion status of the infarct artery more accurately than the global ejection fraction response.

These results agree with data from previous studies demonstrating the relative insensitivity of the *resting* global ejection fraction in reflecting the function of the infarct region.[5,12,13] As seen in these rest studies, the exercise response in the noninfarct region may significantly affect global function. As a result, the ejection fraction response to exercise may underestimate the severity of an ischemic response in the infarct site, i.e., worsening of regional hypokinesis, if the noninfarct region responds normally, with an increase in motion. The ejection fraction may also overestimate the functional response of the infarct region if motion in the noninfarct region responds concordantly. It is, there-

fore, not surprising that the regional response to exercise more accurately reflects the reperfusion status of the infarct artery than does the global ejection fraction response.

In the present study, discordance between regional and global function was observed at a low level of exercise. Similar discordance has been reported by others at all levels of exercise using noninvasive imaging techniques. Schneider et al[14] reported that discordance between the ejection fraction and the wall motion score, a visual estimate of the extent of regional hypokinesis, occurred as often at 25 to 50 watts as at higher levels of exercise. Others have also found discordance between regional and global left ventricular functional responses to maximal, symptom-limited exercise.[15-18] Applegate et al[19] found the regional response to be more predictive of morbid events after infarction than did the change in ejection fraction. The present study complements these by measuring the magnitude of hyperkinesis in the noninfarct region and its response to exercise, and by quantitatively demonstrating its influence on the exercise ejection fraction.

A limitation of our study is the long follow-up time from infarction to exercise study in some patients. However, all of the patients were clinically stable in the interim and results were similar in the subgroups studied <6 weeks and >6 months after infarction. Others have reported that the ejection fraction exercise response is stable 3 to 8 weeks after infarction[20] 1 to 4 months after infarction[2] and between 2 weeks and 6 to 14 months after infarction.[4]

To avoid motion artifact, ventriculography was performed immediately after rather than during exercise. Although this may affect measurement of the functional response to exercise, reports on the duration of transient wall motion abnormalities vary from <3 to >30 minutes after cessation of exercise,[21,22] with dependence on the extent of coronary artery diease[23] and on the severity of left ventricular dysfunction.[24] Furthermore, the left ventricular functional response measured at peak exercise is predicted by changes seen immediately afterwards using 2-dimensional echocardiography in postinfarct patients.[19] Because all of our patients had a myocardial infarction and many had multivessel disease, the duration of the abnormalities would probably have been long enough to be captured in the ventriculograms.

We measured left ventricular function from single-plane ventriculograms because these provide more accurate volume determination than biplane studies.[25] For comparison, wall motion was also calculated in this view, which is more sensitive in detecting hypokinesis due to coronary artery stenosis or myocardial infarction.[26,27]

Clinical implications: It is not the intent of this study to advocate exercise contrast ventriculography. Instead, our data indicate that the global ejection fraction response to exercise is significantly influenced by motion in both the infarct and noninfarct regions, and that the response to exercise in the noninfarct region may oppose and dominate that of the infarct region. This imprecision of the global ejection fraction may explain its insensitivity compared with the regional response in predicting recurrent ischemic events after myocardial infarction.[3] However, an evaluation of the prognostic value of measuring the regional as compared with the global exercise response is beyond the scope of the present analysis and will require further study. We conclude that measurement of the ejection fraction response to exercise in patients studied after myocardial infarction estimates the net function of all regions of the left ventricle. However, to evaluate salvage of myocardium following thrombolytic therapy from the rest-exercise response, regional wall motion in the infarct site should be measured.

Use of Initial ST-Segment Deviation for Prediction of Final Electrocardiographic Size of Acute Myocardial Infarcts

HARRY R. ALDRICH, MD, NANCY B. WAGNER, BA, JANE BOSWICK, BS, ANNE T. CORSA, MD, MICHAEL G. JONES, BA, PEER GRANDE, MD, KERRY L. LEE, PhD, and GALEN S. WAGNER, MD

The decision to administer thrombolytic therapy for limitation of acute myocardial infarction (AMI) size must occur when only the history, physical examination and 12-lead electrocardiogram of a patient are available. A method that could quickly assess the amount of jeopardized myocardium would greatly aid the physician. This study developed formulas from 68 anterior and 80 inferior AMI patients using the extent of initial ST-segment deviation (STΔ) to predict the final AMI size estimated by the Selvester QRS score in a population not receiving reperfusion therapy. Inclusion required: initial anterior or inferior AMI; admission electrocardiograpm $\leq$8 hours after the onset of symptoms with evidence of epicardial injury; elevated creatine kinase-MB; a predischarge electrocardiogram taken $\geq$72 hours after admission; and no AMI extension before the predischarge electrocardiogram. The extent of epicardial injury was quantified by counting the number of leads with $\geq$0.1 mm STΔ, by the sum (Σ) of STΔ in all leads and by the ΣSTΔ in the lead groups associated with each AMI location. These results were compared to the AMI size estimated from the predischarge electrocardiogram. Univariable and multivariable analyses generated these formulas for AMI size:

anterior = 3[1.5(number leads ST$\uparrow$) − 0.4];
inferior = 3[0.6(ΣST$\uparrow$ II, III, aVF) + 2.0].

Thus, formulas based on quantitative measurements of STΔ on the admission electrocardiogram are predictive of final QRS-estimated AMI size, and may be useful in determining the efficacy of acute reperfusion therapy.

(Am J Cardiol 1988;61:749–753)

Information on the standard 12-lead electrocardiogram during the course of acute coronary occlusion has been useful in a variety of clinical settings. The admission electrocardiogram has been valuable in acute myocardial infarction (AMI) diagnosis and as a predictor of in-hospital complications.[1,2] The extent of epicardial injury (STΔ), reflected by either ST elevation (ST$\uparrow$) or depression (ST$\downarrow$), has been shown to estimate the amount of myocardium in jeopardy and the subsequent prognosis.[3–8] With the current use of emergent reperfusion therapies to limit AMI size, careful examination of the presenting electrocardiogram becomes increasingly important. Quantitative methods that could quickly estimate the amount of myocardium in jeopardy, and thereby identify the patients most likely to benefit from reperfusion therapy, would be of great clinical value.

Comparison between the estimated sizes of initially jeopardized myocardium and the resultant AMI size in the absence of reperfusion therapies could form a basis for determining the effectiveness of such interventions. Since many techniques for quantifying AMI size are expensive and difficult to perform, the inexpensive, clinically versatile electrocardiogram provides an attractive alternative.[9,10] One such method, the Selvester QRS scoring system,[11] awards points for abnormal characteristics of the QRS complex to provide a quantitative estimate of the size of single AMIs. The efficacy of this system has been evaluated extensively in postmortem correlations,[12–14] normal subjects[15,16] and many clinical studies.[17–19]

TABLE I ST-Segment Criteria from the Admission Electrocardiogram*

Inclusion (All)	AMI Location
ST↑ ≥1 mm in ≥1 lead Max ST↑ ≥ max ST↓ or Max ST↓ in V_1 through V_3 ST↑ in V_2>V_1	Anterior max = ST↑ V_1 through V_3 Inferior max = ST↑ in II, III, AVF or ST↓ in V_1 through V_3

*Measured at J point all leads but aVR.
AMI = acute myocardial infarction; ↓ = depression; ↑ = elevation; max = maximum.

TABLE II Correlation of ST Deviation with AMI Size

AMI Location	ST Parameters	r
Anterior	Number of leads with ST↑	0.72
	ΣST↑ all leads	0.52
	ΣST↑ V_1 through V_3	0.38
	ΣST↑ V_1 through V_6	0.48
	ΣST↑ V_1 through V_3, I, aVL	0.46
Inferior	Number of leads with STΔ	0.50
	ΣST↑ all leads	0.61
	ΣST↑ all leads + ΣST↓ V_1 through V_3	0.60
	ΣST↑ II, III, aVF	0.61
	ΣST↑ II, III, aVF + ΣST↓ V_1 through V_3	0.59

Δ = change; Σ = sum; other abbreviations as in Table I.

The purposes of this study were to use the admission and discharge electrocardiograms to (1) determine the relations between the extent of initial STΔ and final AMI size by QRS score in anterior and inferior locations, and (2) develop formulas for each location to predict the final electrocardiographic estimation of AMI size from the initial STΔ.

Methods

Patient population: Between January 1965 and December 1981, consecutive patients admitted to Duke University Medical Center with a first AMI who did not receive thrombolytic therapy were screened.[20] Patients with the following characteristics were included: no clinical or electrocardiographic evidence of a previous AMI; admission heart rate ≤110 beats/min[21]; total creatine kinase ≥130 U/liter with presence of creatine kinase-MB; an "admission electrocardiogram" ≤8 hours after the acute onset of symptoms with evidence of epicardial injury (Table I); a "predischarge electrocardiogram" ≥72 hours after admission showing no AMI extension; and no complete left or right bundle branch block, anterior or posterior fascicular block, left or right ventricular hypertrophy or ventricular pacing on either electrocardiogram.[22]

Quantitative electrocardiographic analysis: The admission electrocardiogram was used to determine the extent of epicardial injury (STΔ) and to divide the patients into anterior or inferior AMI location based on the lead with the maximal deviation (Table I). Those who had concurrent elevation in leads I, aVL, V_5 or V_6 were classified as anterior or inferior according to the location of their primary change. Using the TP segment as the isoelectric line, ST↑ was measured manually to the nearest 0.5 mm (0.1 mV = 1 mm) in each lead except aVR at these intervals: J point, J + 40 ms and J + 80 ms. ST↓ was measured in the same way in leads V_1 through V_3, where it could have been caused by epicardial injury. The number of leads with ≥1 mm STΔ present, the sum (Σ) of the STΔ in all leads and the ΣSTΔ in the lead groups according to AMI location were determined (Table II).

Final AMI size was estimated from the Selvester QRS score on the predischarge electrocardiogram. This scoring system and its method of application have been described in detail elsewhere.[16,23] It was designed to contain a maximum of 32 points from consideration of 54 criteria, with each point representing approximately 3% infarction of the left ventricle.[11]

Data analysis: Quantification of epicardial injury was performed at each of the 3 intervals along the ST segment and compared with final AMI size. Although the correlations were similar for each of the intervals, the J point relation was slightly better. Thus, all subsequent analyses consider only measurements performed at the J point. All patients were analyzed according to the number of leads with ST↑, and by the 4 lead combinations associated with each of the MI locations (Table II). Pearson correlation coefficients, denoted by "r," were used to evaluate the relations among the ST parameters and the final AMI size.

Multivariable analyses using linear regression models were used to generate formulas from these ST determinations to predict the final AMI size for each location. The square of the multiple correlation coefficient, R^2, was used to describe the percent of variability of the AMI size accounted for by the ST-segment parameters in the regression models. Multivariable regression was also used to assess the degree to which duration of chest pain before the admission electrocardiogram might influence the formulas for predicting AMI size. The median absolute differences between the actual AMI size and that predicted from the formulas were determined for both locations according to the duration of chest pain.

Results

Of the 148 patients included in the study, 68 had an anterior AMI (48 men, 20 women; mean age 57, range 35 to 85) and 80 had an inferior AMI (62 men, 18 women; mean age 58, range 35 to 83) as defined by the criteria in Table I.

While the distributions of the number of leads with STΔ were similar for both AMI locations (Figure 1A), the ΣSTΔ varied significantly. As seen in Figure 1B, the ΣST in the anterior AMI patients ranged from 1 to 44 mm, with a median value of 9 mm. In contrast, in the inferior AMI patients the ΣST ranged from 1 to 28 mm, with a median value of 6.5 mm ($p = 0.04$). While the distributions of AMI size (Figure 2) were similar, the anterior group tended to have larger AMIs than the inferior group (respective median values 21% vs 15%, $p = 0.03$).

The relation of the ST parameters with AMI size are shown in Table II. For anterior AMI, the number of leads with ST↑ provided a stronger correlation than did ΣST↑ in any of the lead combinations. Conversely, the ΣST in the various lead combinations achieved stronger correlations than did the number of leads in the inferior AMI group. Although the ΣST↑ in all leads and the ΣST↑ in II, III and aVF both attained correlation coefficients of 0.61, the latter was considered to be preferable as it required quantification from only 3 versus 11 leads.

The formula for prediction of anterior AMI size that resulted from multivariable regression analyses was determined to be:

Anterior AMI = 3 [1.5 (number leads ST↑) − 0.4].

After consideration of the number of leads with ST↑, no other parameter added significantly to the predictive ability of this model. The Pearson correlation coefficient was r = 0.72. The square of this quantity (R^2) accounted for 52% of variability of the AMI size by the ST deviation factors in the regression models. The mean square error was 8.05.

For inferior AMI size prediction, multivariable regression analyses determined that:

Inferior AMI = 3 [0.6 (ST↓ II, III, aVF) + 2.0].

The Pearson correlation coefficient was r = 0.61. The R^2 accounted for 37% of variability of the AMI size by the ST-deviation factors in the regression models. The mean square error was 8.63. In these patients, consideration of the ΣST↓ in leads V_1 through V_3 further increased the variability in the final AMI size, which could be accounted for by ΣSTΔ from 37% to 39% but this was not a significant improvement. No other variables contributed additional significant information.

The duration of chest pain was assessed to determine its influence on the formulas. In Table III, the median absolute difference between the predicted AMI from the model and the observed AMI are stratified according to the duration of chest pain. The similarities in the median absolute difference for each time period illustrate that the formula is not influenced by the duration of chest pain within the first 8 hours of symptoms.

Discussion

Attempts to correlate initial epicardial injury with various electrocardiographic and enzymatic measures of AMI size have achieved differing results,[7-10,24] perhaps due in part to the limitations of both methods. The present study also has several inherent methodologic limitations. While STΔ at the J point was used for all analyses it had only a slightly (although not significantly) stronger correlation with AMI size than measurements performed at either J + 40 ms or J + 80 ms. Further, the amount of myocardial necrosis that had transpired before or after the admission electrocardiogram could not be considered since the Selvester score has not been validated for use in the presence of epicardial injury. Such quantification would likely be important in patients with "rapidly developing" AMI who have a quickly occurring increase and decrease in their ST segments, with concurrent QRS evolution.[25,26]

Although the duration of chest pain did not appear to affect the accuracy of the formulas (Table III), it is difficult to determine the exact time of onset of symptoms in patients with either intermittent pain or "silent" ischemic episodes. Other factors that may have

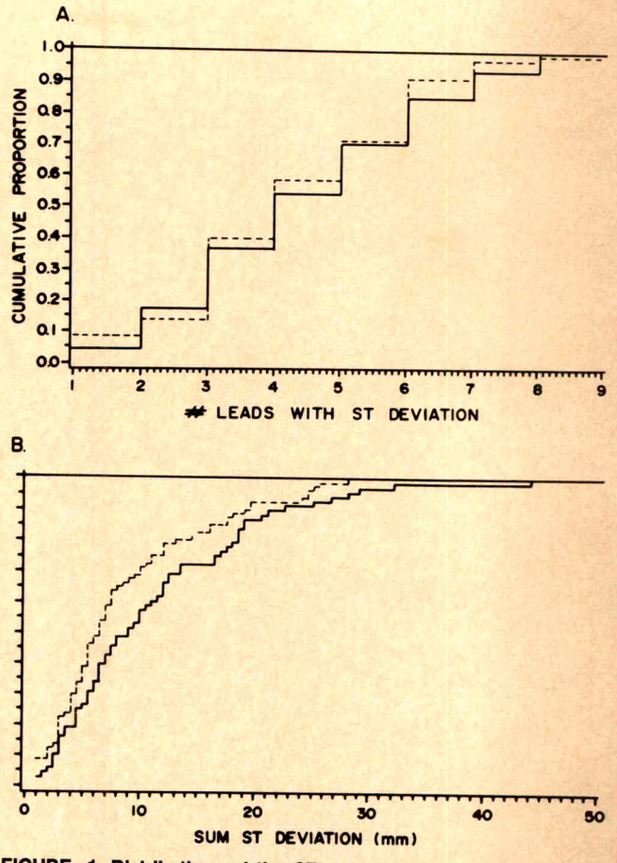

FIGURE 1. Distributions of the ST-segment parameters. Anterior and inferior acute myocardial infarct locations are combined. In *A*, the cumulative proportion of patients with from 1 to 9 leads of ST-segment deviation is shown. (See text.) In *B*, the sum of ST-segment deviation in millimeters is shown.

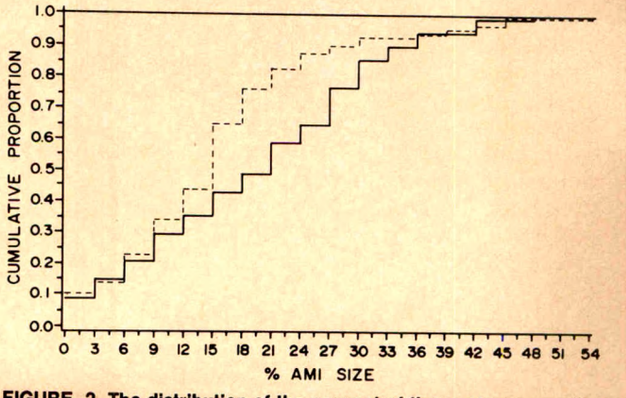

FIGURE 2. The distribution of the percent of the acute myocardial infarct (AMI) size from the predischarge standard 12-lead electrocardiogram is shown for all patients.

TABLE III Duration of Chest Pain Versus Absolute Median Difference Between Predicted and Measured AMI Size

AMI Location	Pain Duration (hrs)	Pts (n)	Difference in AMI Size
Anterior	0–2	22	5.7
	2–4	22	4.5
	4–6	9	6.9
	6–8	15	5.7
Inferior	0–2	37	4.8
	2–4	24	6.6
	4–6	8	6.0
	6–8	11	5.1

AMI = acute myocardial infarction.

influenced the results in this study include the limitations intrinsic to the electrocardiogram such as lack of equipment standardization, degree of patient recumbency, respiratory variation, chest wall dimensions and lung volume. Finally, it is essential that the formulas proposed in this study be validated in a comparable test population before general application.

In the anterior AMI group, the number of leads with ST↑ was a more important variable (r = 0.72) than ΣST (r = 0.52) for predicting AMI size. Using precordial mapping studies, Murray et al[27] also found a significant correlation between the number of sites with ST↑ and a radionuclide estimate of myocardial necrosis. Cohen et al[28] determined that the percent of anterior wall asynergy during left anterior descending coronary artery angioplasty correlated with both the number leads with ST↑ and ΣST↑ on a simultaneous 12-lead electrocardiogram. Hackworthy et al[7] have demonstrated an excellent correlation between ΣST↑ and final QRS score by the simplified Selvester system.[15]

The ΣST in leads II, III and aVF is a more important variable for predicting inferior AMI size (r = 0.61) than the number of leads with STΔ (r = 0.50). The study by Cohen et al[28] also showed good correlations between the percent of inferior wall asynergy and both the number of leads with ST↑ and ΣST↓.

The ΣST↓ V_1 through V_3 provided some additional information. Precordial ST↓ with inferior AMI has been associated with a larger size, more frequent complications and a poorer prognosis.[5,6,29,30] However, others have indicated that ST↓ is simply a reciprocal electrical phenomenon.[31] In patients with inferior AMI, Hlatky et al[6] reported a relation between ST↓ V_1 through V_3 and QRS evidence of posterior involvement. However, they found that the ratio of initial ST↓ to final QRS points in V_1 through V_3 was much lower than the ratio of initial ST↑ to final QRS points in II, III and aVF. In the present study, inclusion of ΣST↓ V_1 through V_3 in the model increased the R^2 value only slightly when optimally weighted at a 1:4 ratio with the ΣST↑ II, III, aVF (from 37% to 39%). Thus, these results support the concept that the ΣST↓ V_1 through V_3 is primarily the reciprocal of ΣST↑ in II, III and aVF, but it may also be minimally indicative of additional ischemia.

Recent studies have investigated the relation between the extent of STΔ and subsequent AMI size. In a study by Bar et al,[8] patients were randomized to either intravenous streptokinase or control therapy. Limitation of AMI size occurred primarily in patients with the greatest admission ΣST↑. Hackworthy et al[32] found that rapid resolution of ΣST during the first 8 hours was associated with spontaneous opening of the left anterior descending artery and smaller anterior AMI. No such relations were found in patients with inferior AMI.

With the many emergent therapeutic alternatives for AMI size limitation, methods that can quickly identify the patients most likely to benefit are necessary. The formulas proposed in the present study indicate the "natural" extent of the evolving AMI, and thus may be valuable both in patient selection for acute intervention and in the subsequent evaluation of the efficacy of such therapy.

Usefulness of Lactate Dehydrogenase and Lactate Dehydrogenase Isoenzymes for Diagnosis of Acute Myocardial Infarction

GREGG J. REIS, MD, HARVEY W. KAUFMAN, MD, GARY L. HOROWITZ, MD, and RICHARD C. PASTERNAK, MD

The usefulness of lactate dehydrogenase (LD) and LD isoenzymes in the diagnosis of acute myocardial infarction (AMI) is controversial. The present study reviewed 507 consecutive patients in whom creatine kinase, creatine kinase isoenzymes, LD and LD isoenzymes were ordered over a 1-month period. Of these, 249 had an insufficient number of serial enzyme determinations to establish a laboratory diagnosis of AMI. After excluding an additional 11 patients for other reasons, 247 patients remained for analysis. Of these, only 2 (0.8%) had myocardial infarction by standard clinical criteria with normal creatine kinase and creatine kinase-MB but elevated LD and abnormal LD isoenzymes. Seven patients (7 of 247, 2.8%) had false-positive LD isoenzymes. Thus, the routine use of LD and LD isoenzymes was of no use in most patients (96%) and led to the incorrect diagnosis of AMI more than 3 times as often as it helped with a correct diagnosis. Total 1-month charges for all the LD and LD isoenzymes obtained equalled $42,450. Therefore, it appears that LD and LD isoenzymes are not routinely useful in the diagnosis of AMI and may result in considerable unnecessary expense. It is suggested that LD and LD isoenzymes be ordered only under suspicion of late presentation (>48 hours) of AMI.

(Am J Cardiol 1988;61:754–758)

Over the last 30 years, serial serum enzyme determinations have become the "gold standard" by which acute myocardial infarction (AMI) is diagnosed. This period has seen a gradual change in both the enzymes measured and the methods used, as older assays have been supplemented by more sensitive and specific techniques. The first serum enzyme reported elevated in AMI, in 1954, was asparatate aminotransferase.[1] The introduction of lactate dehydrogenase (LD)[2] and its isoenzymes[3,4] over the next several years provided increased specificity. However, with the introduction of creatine kinase (CK),[5] and particularly the MB isoenzyme,[6] an even more sensitive and specific assay was introduced. Numerous studies have confirmed the value of the CK-MB assay for the diagnosis of AMI.[7–11]

The use of LD and its isoenzymes has been more controversial. Several recent articles[12–18] recommend that CK and CK-MB be the only enzyme studies performed for the routine diagnosis of AMI. However, other analyses of available data[8,11,19–24] have recommended routine measurement of LD and LD isoenzymes, or measurement in cases of burns or trauma.[25] The present study was designed to determine the incremental benefits and potential costs of LD and LD isoenzymes in the diagnosis of AMI. Whereas previous studies have focused on patients admitted to coronary care units, this study also included patients in whom a relatively low suspicion of AMI led to admission to an electrocardiographically monitored bed *outside* of the intensive care unit.

Methods

The patient population consisted of 507 consecutive patients in whom CK, CK-MB, LD and LD isoenzymes

From the Charles A. Dana Research Institute and Harvard-Thorndike Laboratory, and the Cardiovascular Division and Department of Pathology, Beth Israel Hospital, Boston, Massachusetts. Manuscript received October 1, 1987; revised manuscript received December 15, 1987, and accepted December 16.

Address for reprints: Richard C. Pasternak, MD, Beth Israel Hospital, 330 Brookline Avenue, Boston, Massachusetts 02215.

were measured at Beth Israel Hospital during a 1-month period. The patients were identified by review of the computerized records of the chemistry laboratory. If patients had consecutive enzyme measurements extending into the preceding or following month, these also were included. In order to have sufficient enzyme measurements for inclusion into the study, at least 3 values of CK and CK-MB over 48 hours and at least 1 value of LD and LD isoenzymes were obtained.

All our samples were handled according to our laboratory's standard procedures. They were centrifuged upon receipt and the serum was separated into 3 aliquots for proper storage until analysis, which always occurred within 24 hours. The original aliquot was used to measure total CK and LD, a frozen aliquot was used for CK isoenzymes and a room-temperature aliquot for LD isoenzymes. Total CK and LD activities were determined at 37° using Roche CK-NAC reagent and Roche LD reagent on a Roche COBAS-BIO centrifugal analyzer (Roche Diagnostic Systems). Activities of CK and LD isoenzymes were determined by agarose gel electrophoresis using Corning reagents (Corning Medical) and scanning densitometry using a CDS-200 densitometer (Beckman Instruments) in the fluorescent mode. Each agarose gel was visually examined to establish the presence of CK-MB before quantitation. As has been standard practice in our laboratory for many years, specimens in which total LD was within the normal range did not undergo LD isoenzyme analysis.

All serum enzyme values were reviewed by a clinical pathologist unaware of the patient history. This analysis alone served to initially classify them as positive for infarction, negative for infarction or equivocal.

Positive CK and CK-MB were defined as (1) total CK >200 IU/liter with CK-MB ≥5% on 1 specimen, or (2) total CK ≤200 IU/liter, but with CK-MB ≥5% on peak specimen, and rise and fall on serial specimens. Equivocal CK and CK-MB consisted of CK-MB ≥5%, with total CK ≤200 IU/liter and without typical rise and fall. Positive LD isoenzymes were defined as LD1 ≥LD2 on any specimen; otherwise, patients were classified as having negative LD isoenzymes.

We reviewed the charts of all patients in whom total CK, CK-MB or LD isoenzymes were abnormal (CK >200 IU/liter, CK-MB ≥5% of total CK or LD1 ≥LD2), or in whom CK rose ≥50% from baseline values. Patients with entirely normal, CK, CK-MB *and* LD isoenzymes were characterized as negative for infarction without further review. In patients whose charts were reviewed, clinician's discharge diagnosis, discharge status, clinical history and electrocardiograms were noted. Five patients transferred from other institutions with documented AMI but whose enzyme values had not yet returned to normal were excluded, as were 2 patients whose charts could not be located. Four patients with cardiac enzyme elevation after cardiac surgery also were excluded.

Unequivocal electrocardiographic changes were defined as persistent new Q waves; equivocal changes as persistent ST- or T-wave abnormalities, transient Q waves or a conduction disturbance.

The diagnosis of AMI was based on the standards of the World Health Organization as revised in 1979.[26] Definite AMI was defined as (1) positive CK and CK-MB, or (2) unequivocal electrocardiographic changes. Patients with positive LD isoenzyme values were considered to have definite AMI if they had equivocal or unequivocal electrocardiographic changes or positive CK-MB *and* elevated LD in a typical pattern for AMI. Possible AMI was defined as equivocal electrocardiographic or enzymatic abnormalities. In the absence of these changes, patients were classified as negative for AMI.

Laboratory tests were ordered as part of the routine care of these patients, with both house officers and attending physicians able to initiate these orders. Total laboratory charges were calculated from the per-test charges in effect at the time of the study. Charges were $6 per total LD assay and $42 per LD isoenzyme analysis.

Test performance parameters were defined as follows: true positive: patients with a positive test result and definite AMI; false positive: patients with a positive test result but without definite AMI; true negative: patients with a negative test result and without definite AMI; false negative: patients with a negative test result but with definite AMI; sensitivity: (all true positives)/(all patients with definite AMI); specificity: (all true negative)/(all patients without definite AMI).

Results

Of the 507 consecutive patients in whom some measurement of CK and LD were made during the 1-month period of this study, 249 (49%) had insufficient serial enzymes (fewer than 3 values of CK and CK-MB, or no measurement of LD isoenzymes) to be included. Many of these patients had enzyme studies performed for noncardiac conditions. However, as has been noted in previous studies,[21] it is likely that many tests were ordered in a manner that precluded their use in diagnosing AMI, even though the tests were ordered for that purpose. In order to ascertain whether any of the excluded patients may have had positive enzyme studies on the first 2 specimens, and thus had not had a third sample drawn, the charts of all excluded patients with CK-MB >10 IU/liter, or with LD1 ≥LD2 on any specimen, were reviewed. Of the 249 excluded patients, 14 met 1 or both of these criteria; of these, 9 were undergoing cardiac surgery, 1 had rhabdomyolysis and 4 had a single value of LD1 ≥LD2. These 4 patients had another value of LD isoenzymes within 16 hours of the abnormal value with LD1 <LD2, had no diagnostic electrocardiographic changes and were not considered to have had an AMI by their physicians.

As noted, 11 patients with adequate enzyme studies were excluded after chart review revealed conditions (cardiac surgery, post-AMI transfer, chart unavailable) that could potentially confound analysis of their serum enzymes. Of the remaining 247 patients, 29

TABLE I Summary of Laboratory and Clinical Findings

	Definite AMI			Possible AMI
	+CK/+MB (n = 20)	−CK/+MB (n = 7)	+LD only (n = 2)	(n = 6)
Age (yrs)	73 ± 2	78 ± 1	59 ± 1	76 ± 3
CK peak (IU/liter)	906 ± 219	126 ± 8	546 ± 344	195 ± 42
MB peak (IU/liter)	95 ± 41	12 ± 0	15 ± 11	13 ± 4
LD peak (IU/liter)	735 ± 240	278 ± 40	533 ± 219	246 ± 59
LD1 ≥ LD2	11 (55%)	1 (14%)	2 (100%)	0
ECG changes				
Q-wave	7 (35%)	1 (14%)	1 (50%)	0
Non-Q-wave	12 (60%)*	6 (86%)*	1 (50%)	3 (50%)
Chest pain	15 (75%)	6 (86%)	2 (100%)	4 (67%)
Death	6 (30%)	2 (28%)	0	0

Figures for age and enzyme values represent mean ± standard error of the mean within each group.

* Includes 1 patient in each group with left bundle branch block.

AMI = acute myocardial infarction; CK = creatine kinase (normal ≤200 IU/liter); +CK/+MB = CK > 200 IU/liter, MB ≥ 5%; −CK/+MB = CK ≤200 IU/liter, MB ≥5% with typical serial rise and fall; ECG = electrocardiogram; LD = lactate dehydrogenase (normal ≤200 IU/liter); LD1,LD2 = LD isoenzymes 1 and 2; +LD only = LD1 ≥ LD2 with normal CK and MB; MB = creatinine kinase MB isoenzyme (normal <5% of total CK).

(12%) had definite AMI and 6 (3%) possible AMI. The results of enzyme studies, electrocardiographic analysis and clinical outcome are listed in Table I. It should be noted that the mean total CK in the patients listed as LD+ only is markedly elevated at 546 IU/liter. This was due to 1 patient who had a peak CK of 1,033 IU/liter with only 3% MB fraction on the initial specimen. As this was considered to be nondiagnostic, the positive LD isoenzyme analysis was taken as the only diagnostic enzyme marker of AMI.

Positive LD isoenzymes were noted in a total of 21 (9%) patients. Of these, 12 had unequivocally positive CK-MB values. There were 7 (2.8%) patients with positive LD isoenzymes in the absence of positive CK-MB, electrocardiographic or clinical criteria for infarction (false-positive LD isoenzymes). Of these 7 patients, 4 had a single elevated LD value with LD1 ≥LD2, but in each of these 4 cases there were other normal LD measurements within 24 hours of the single abnormal value. This was felt to be most consistent with a laboratory error or with hemolysis. One patient with widespread carcinoma of the lung had persistently elevated LD1 over several weeks. In the remaining 2 cases, there were several elevated LD values with LD1 ≥LD2 on at least 1 specimen without satisfactory explanation.

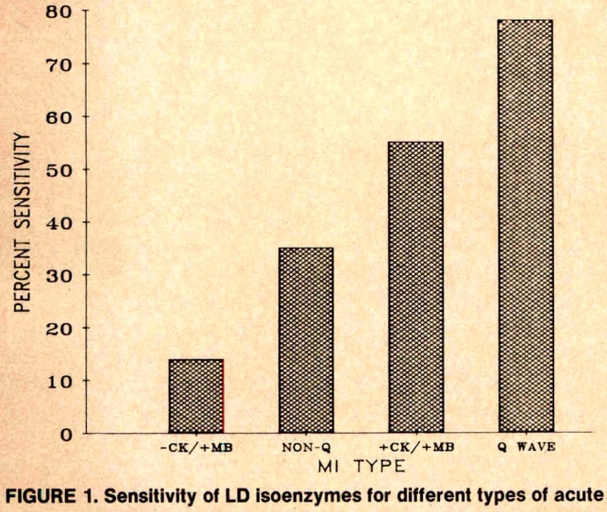

FIGURE 1. Sensitivity of LD isoenzymes for different types of acute myocardial infarction (MI). −CK/+MB = CK ≤200 IU/liter, CK-MB ≥5%, with pattern of serial rise and fall; +CK/+MB = CK >200 IU/liter, CK-MB ≥5%.

In only 2 cases (2 of 247, 0.8%), therefore, did LD isoenzymes provide the *only* confirmatory enzymatic evidence for a true AMI. Both patients had a clear onset of chest pain >48 hours (3 and 7 days, respectively) prior to initial enzyme measurements.

In our population, the sensitivity and specificity of LD isoenzymes for definite infarction were 48% and 97%, respectively. If possible infarctions were to be considered with true infarctions, sensitivity would fall to 40%. Sensitivity was lowest for infarctions with normal total CK but elevated CK-MB (14%) (when a high sensitivity would be most desirable), and highest for Q-wave infarctions (78%) (Figure 1).

A total of 2,035 LD assays and 720 LD isoenzyme assays were performed. Total charges for the 1-month period were $42,450, or an average of $83 per patient. If the 2 patients in whom the LD was the only positive enzyme are considered the only clinically useful result, the charge per useful result was $21,225!

Discussion

In the present study, measurement of LD and LD isoenzymes was not useful in the routine diagnosis of AMI in the vast majority of patients and resulted in a 2.8% incidence of false-positive results. In fact, among 247 patients, there were only 2 clinically helpful results in which true-positive LD isoenzyme studies helped to make the diagnosis of AMI in the patients presenting late (>48 hours) after the onset of symptoms. Despite a specificity of 97%, there were still 7 cases in which false-positive LD isoenzymes could have resulted in an incorrect diagnosis of AMI.

These findings support those of Heller et al,[27] who found that only 1% of patients with negative CK-MB had positive LD isoenzymes. Galen and Gambino,[8] in a study of 100 patients, found no cases in which LD isoenzymes were the only diagnostic marker of AMI. The rare cases in which LD isoenzymes may be useful can be predicted by awareness of the typical decay curves of CK, CK-MB and LD,[17,28] which suggest that patients presenting >48 hours after the onset of chest pain will have the highest probability of positive LD isoenzymes with normal CK and CK-MB. Patients with normal CK-MB and elevated but falling total CK values are most likely to be those presenting 48 to 96 hours after AMI.

The sensitivity and specificity of LD isoenzymes have been examined in many previous studies[11] and have averaged approximately 80 and 94%, respective-

ly. In contrast, the sensitivity of LD isoenzyme analysis for AMI in the present study (48%) was considerably lower and varied with the type of infarction. Out of 29 definite infarctions in our study, 9 (31%) were Q-wave (transmural), 18 (62%) were non-Q-wave (nontransmural) and there were 2 patients with preexisting left bundle branch block. There were 7 patients with "microinfarctions," defined as normal total CK but elevated CK-MB in a typical pattern for infarction.[29] LD isoenzyme sensitivity for "microinfarctions" has been reported to be only 10 to 28%[28-30] and only 1 of 7 patients (14%) in our group had abnormal LD isoenzymes. This was unfortunate, for additional confirmatory evidence of AMI would have been most helpful in this population. Sensitivity was higher for larger infarctions—55% in "macroinfarctions" (elevated total CK) and 78% in Q-wave infarcts. The relatively low sensitivity in the present study was related, at least in part, to the inclusion of patients outside of the coronary care unit. These were patients with a lower prior probability of infarction and generally smaller infarctions. Previous studies have generally included only patients admitted to a coronary intensive care unit. The low sensitivity of the LD isoenzyme assay makes it an especially poor test to "rule out" AMI and a negative result does not significantly alter the probability of an AMI having taken place.

In spite of the relatively high specificity of LD isoenzymes (97%), the number of false-positive results exceeded the number of *helpful* true positives, making the test potentially more misleading than useful. Fisher[12] noted an 8% incidence of positive LD isoenzymes in a group of patients without AMI. Galen et al[8] found 1 case of false-positive LD isoenzymes among 100 patients. The routine measurement of LD and LD isoenzymes in a population with a low prevalence of AMI further increases the risk of erroneous diagnosis of AMI, due to the relatively high number of false positives in relation to useful true positives, as was observed in the present study.

A potential source of bias in our study was the exclusion of a large number of patients. None of the patients excluded for inadequate enzyme studies clearly had an AMI; they were excluded because it was felt that AMI could not be ruled out. Indeed, 4 of these patients had positive LD isoenzymes without other clinical criteria for AMI and, had they been included, the number of false positives would have been higher. It is conceivable that some patients in the group with entirely negative serum enzyme studies (whose charts were not reviewed) had AMI indicated by electrocardiographic criteria only. If this was true, the number of false-negative tests would have been higher and the sensitivity correspondingly lower than previously stated.

It should be emphasized that laboratory charges, rather than actual costs, are cited to provide some insight into the fiscal impact of routine use of LD and LD isoenzymes. The actual costs of laboratory tests are difficult to assess, whereas charges provide a convenient benchmark for analysis and are grossly related to costs. Although savings from selective use of LD and LD isoenzymes would be considerable, they would certainly be less than indicated by the charge data.

Clinical implications: Patients with the highest probability of a useful positive LD isoenzyme result are those with a clinical history of chest pain beginning >48 hours prior to admission and with nondiagnostic CK-MB studies. In these cases, LD isoenzymes can be requested by the clinician even if such procedures are not performed routinely. Because LD isoenzymes are stable for several days at room temperature,[11] serum can be held aside for later analysis if it becomes necessary. Given the very high predictive value of CK-MB analysis, it is recommended that this assay be performed first in all cases. Only if CK-MB results are negative *and* there is a high suspicion of AMI presenting late, should LD isoenzyme analysis be requested.

Acknowledgment: The authors would like to thank Lee Goldman, MD, for helpful review and suggestions.

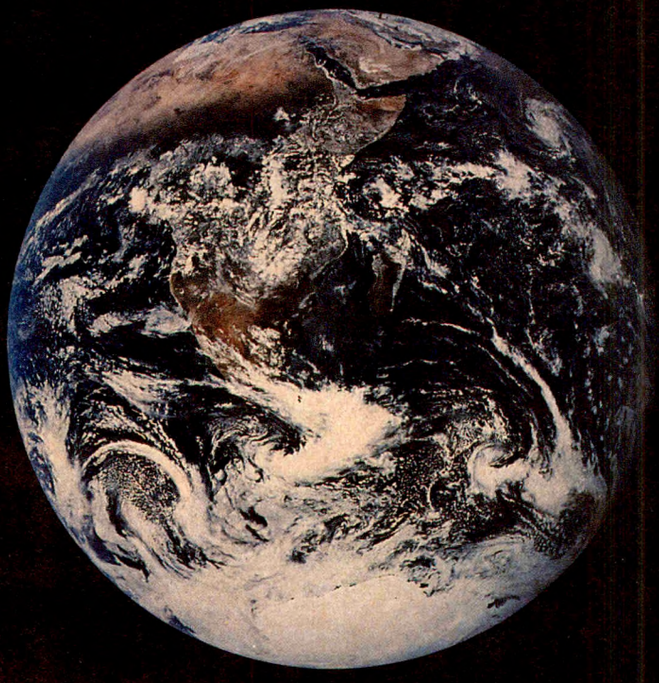
Introducing cardiovascular ultrasound imaging that's worlds apart from the rest.

we never stop asking "What if..."



The new standard in excellence from Hewlett-Packard is here. It's called the HP SONOS 1000. And it opens up a whole new world of performance and functionality. Through revolutionary advancements in proprietary imaging technology and custom integrated-circuit design, the HP SONOS 1000 redefines high performance in ultrasound technology.

New precision imaging electronics and wide-aperture transducers provide higher cardiac image resolution than previously available. Third generation HP color flow technology assures the most accurate and complete presentation of cardiac blood flow. And the highly sensitive Doppler design easily detects the most subtle flow disturbances.

Coupled with new display and review modes plus dual transducer connections, the HP SONOS 1000 sets a whole new standard for today. And a new foundation for tomorrow. And it's only an upgrade away for existing HP ultrasound systems.

Call us at: **1-800-637-3747** (in MA, 1-617-687-1501 ext. 2475), and see the future of ultrasound today.

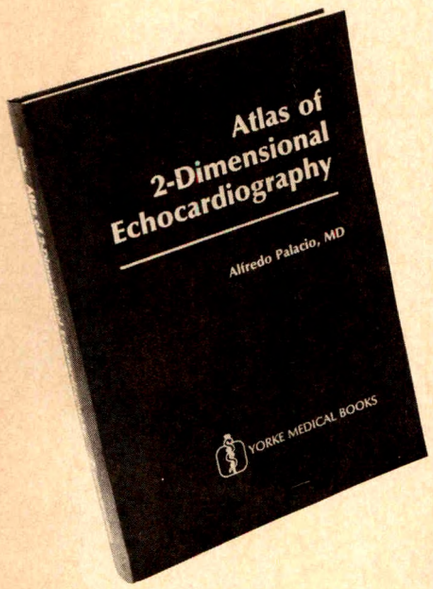
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts
ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ × 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ × 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

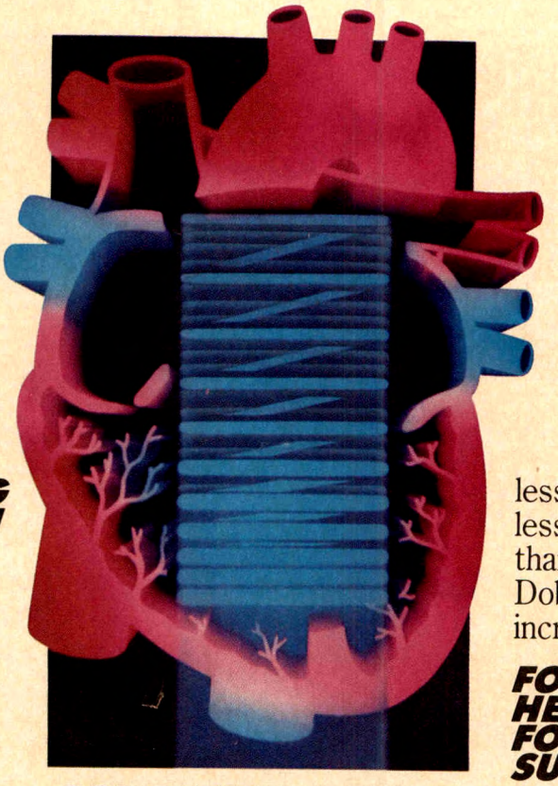
PERFUSION PRESSURE FALLING?

ADD INOTROPIC FORCE



WITHOUT INDUCING VASOCONSTRICTION

Dobutrex is a myocardial stimulant with virtually no vasoconstrictor effects. It works directly to increase myocardial contractility in patients suffering from heart failure.

FOR PATIENTS WITH ACUTE CONGESTIVE HEART FAILURE

Dobutrex quickly increases cardiac output, stroke volume, and organ perfusion. At the same time, Dobutrex reduces left ventricular filling pressure and systemic resistance, with little increase in heart rate.*

FOR PATIENTS WITH HEART FAILURE SECONDARY TO ACUTE MI

For MI patients who are not hypotensive or who have elevated filling pressures... Dobutrex maintains perfusion pressure by increasing cardiac output and decreasing vascular resistance.

Blood and oxygen are supplied to the myocardium in proportion to demand—with less increase in heart rate and less potential for arrhythmias than other catecholamines. Dobutrex does not significantly increase blood pressure.*

FOR PATIENTS WITH HEART FAILURE FOLLOWING CARDIAC SURGERY

Dobutrex improves the contractility of the depressed myocardium following cardiac surgery.

Afterload decreases in proportion with increases of cardiac output. As a result, Dobutrex reduces the risk of pulmonary edema and post-operative hypertension.

*Excess dosage of dobutamine may produce unwanted alterations in blood pressure, heart rate, or ventricular ectopic activity.

DOBUTREX®
dobutamine hydrochloride

Dobutrex® Solution

dobutamine hydrochloride injection

Brief Summary. Consult the package insert for prescribing information.

Clinical Pharmacology: Dobutrex Solution is a direct-acting inotropic agent whose primary activity results from stimulation of the ß receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward baseline values.

The onset of action of Dobutrex Solution is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

Indications and Usage: Dobutrex Solution is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

Contraindications: Dobutrex Solution is contraindicated in patients with idiopathic hypertrophic subaortic stenosis and in patients who have shown previous manifestations of hypersensitivity to Dobutrex.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex Solution may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10% of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5% have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex Solution may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

3. *Hypersensitivity*—Reactions suggestive of hypersensitivity associated with administration of Dobutrex Solution, including skin rash, fever, eosinophilia, and bronchospasm, have been reported occasionally.

4. Dobutrex Solution contains sodium bisulfite, a sulfite that may cause allergic-type reactions, including anaphylactic symptoms and life-threatening or less severe asthmatic episodes, in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than in nonasthmatic people.

Precautions: 1. During the administration of Dobutrex Solution, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex Solution.

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex Solution is instituted.

3. Animal studies indicate that dobutamine may be ineffective if the patient has recently received a ß-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex Solution following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex Solution for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clincial studies in which Dobutrex Solution was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10- to 20-mm increase in systolic blood pressure and an increase in heart rate of 5 to 15 beats/minute have been noted in most patients. (*See* Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5% of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3% of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex Solution have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex Solution until the patient's condition stabilizes. Because the duration of action of Dobutrex Solution is short, usually no additional remedial measures are necessary.

Direct and Autonomically Mediated Effects of Oral Flecainide

PAOLO ALBONI, MD, NELLY PAPARELLA, MD, RICCARDO CAPPATO, MD, and GIAN CARLO CANDINI, PhD

This study was undertaken to determine if oral flecainide exerts autonomically mediated actions in addition to its direct depressant effect. Electrophysiologic studies were performed twice in each of 15 patients (mean age 59 years) with normal resting and intrinsic heart rate and normal A-H interval. In the first study, the variables of sinus node and atrioventricular node were evaluated both in the basal state and after autonomic blockade (propranolol 0.2 and atropine 0.04 mg/kg). Oral flecainide was administered for 4 to 5 days (200 to 250 mg daily) and the study was then repeated using the same methods. From comparison of data obtained in the 2 studies in the basal state, the overall effect of flecainide was evaluated and by comparing those obtained after autonomic blockade, the direct action of the drug was assessed. The overall effect of flecainide on sinus node was slight; sinus cycle length, corrected sinus node recovery time and sinoatrial conduction time did not change significantly after the drug. In contrast, after autonomic blockade the variables of sinosal automaticity were increased significantly ($p < 0.01$). Flecainide significantly prolonged the atrioventricular node variables both in the basal state and after autonomic blockade ($p < 0.01$), but the degree of increase was more marked after autonomic blockade ($p < 0.05$). These data show dual effects of oral flecainide: a direct depressant action and an autonomically mediated opposing action, likely of vagolytic type.

(Am J Cardiol 1988;61:759–763)

The electrophysiologic properties of flecainide have been examined in cardiac tissue preparations and the drug has shown direct depressant action on the cardiac fibers.[1-4] In the clinical setting flecainide prolonged atrial, atrioventricular (AV) nodal and infranodal conduction and to a slighter extent atrial, AV nodal and ventricular refractory periods.[5-9] The autonomic effects of the drug have not been investigated in great detail. It has only been shown by Cowan and Vaughan Williams,[1] both in vivo in the pithed rat and in vitro in isolated rabbit atria, that the drug has no significant antisympathetic effects. The same investigators have also demonstrated that flecainide has no "calcium-antagonist" action. The present study determines whether oral flecainide exerts autonomically mediated action in man, in addition to its direct depressant effect. We used a study protocol that investigates the different modes of action of an antiarrhythmic drug (Figure 1).

Methods

Patients: Electrophysiologic studies were performed in 15 patients (7 men and 8 women), 38 to 72 (mean 59 ± 10) years of age. The following criteria were used: (1) normal sinus rate (60 to 100 beats/min) in several resting standard electrocardiograms and no evidence of sinus node dysfunction in a 24-hour electrocardiographic recording and (2) normal observed intrinsic heart rate and normal A-H interval (<120 ms). The predicted intrinsic heart rate was estimated for each patient using the linear regression equation derived by Jose et al,[10] relating intrinsic heart rate to age.

All patients were studied for dizziness or syncope or involvement of intraventricular conduction. Ten patients had organic heart disease and 5 had no signs of underlying heart disease. Fourteen patients had syncope or dizziness, 3 right bundle branch block, 1 left bundle branch block and 2 bifascicular block. All

patients were in New York Heart Association class I. No patient had a recent myocardial infarction. Electrolytes and T_3 and T_4 values were within the normal range at the time of the study. All cardioactive medications and drugs having effects on the autonomic system were terminated before catheterization for a period that exceeded 5 half-lives of any agent.

Procedures: Informed signed consent was obtained from each patient and the studies were performed in the postabsorptive nonsedated state. A quadripolar catheter was introduced percutaneously via the femoral vein and positioned in the high lateral right atrium for stimulation and recording the atrial electrocardiogram. Another bipolar catheter was positioned across the tricuspid valve to record His bundle activity. Multiple surface electrocardiographic leads I, II, III and V_1 were recorded simultaneously with the intracardiac bipolar electrograms (frequency setting 0 to 20 Hz for surface electrocardiograms and 40 to 500 Hz for intracardiac electrocardiograms). All recordings were made at paper speeds of 50 to 100 mm/s. Atrial stimulation was performed using a programmable stimulator, the induced stimuli being 2 times the diastolic threshold and 2 ms in duration.

Ten minutes after the introduction of the catheters, the mean sinus cycle length was obtained by averaging 10 consecutive sinus cycles. Sinus node recovery time was measured by atrial pacing at 5 different rates, starting at a rate 20 beats/min above the spontaneous sinus rate to a rate of 170 to 180 beats/min. Pacing was performed for 60 seconds at each level. Ten sinus cycles were analyzed after termination of pacing and the longest interval was used to calculate the sinus node recovery time. The maximum corrected sinus node recovery time was calculated as previously described.[11,12] Sinoatrial conduction time was estimated by the continuous pacing method described by Narula et al[13]; the atria were paced at a rate of 6 to 7 beats/min higher than the sinus rate.

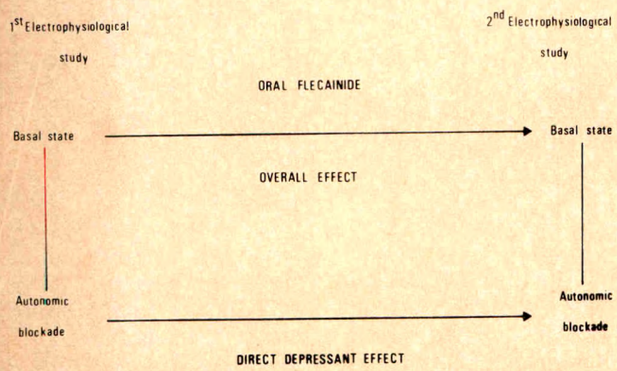

FIGURE 1. Study design. The electrophysiologic study was performed twice in each patient. In the first study the variables of sinus node and atrioventricular node, highly conditioned by autonomic system, were evaluated both in the basal state and after pharmacologic autonomic blockade. Oral flecainide was administered for 4 to 5 days and the electrophysiologic study was then repeated with the same methods. By comparing the data obtained in the 2 studies in the basal state, the overall effect of flecainide was evaluated. By comparing those obtained after autonomic blockade the direct action of the drug was assessed.

The following variables of AV nodal conduction were evaluated: A-H interval during sinus rhythm, A_1-H_1 interval at atrial cycle length of 600 ms, the longest atrial paced cycle for Wenckebach block and the AV nodal effective and functional refractory periods. To determine the latter, comparable atrial cycle lengths (A_1-A_1) were scanned with extrastimuli (A_2) after every eighth beat at progressively decreasing (by 10 ms) coupling intervals.

After this autonomic blockade was achieved.[10,12,14-16] Propranolol 0.2 mg/kg of body weight was administered intravenously over a period of 3 minutes. After 10 minutes, atropine sulfate 0.04 mg/kg was administered intravenously over 1 minute. After atropine administration, the shortest 10 consecutive sinus cycles were used to determine the mean intrinsic sinus cycle length. This reached a plateau at approximately 4 minutes and remained stable for approximately 30 minutes. At 5 minutes after atropine administration, measurements of sinus node and AV node variables were repeated, similar to those obtained in the basal state. These measurements were completed in less than 30 minutes. At the end of the study oral flecainide was administered at the dosage of 200 or 250 mg daily (patients weighing >70 kg) in 2 divided doses for 4 to 5 days. Electrophysiologic studies were then repeated with the same method, both during the basal state and after autonomic blockade, 2 hours after the last dose of flecainide. At the end of the electrophysiologic study, blood samples were drawn for the determination of plasma flecainide level[17] (therapeutic range 200 to 1000 μg/ml). Blood pressure was recorded by sphygmomanometer.

Statistical evaluations were performed using the Wilcoxon test (p value significant at ≤ 0.05). Results are given as mean ± standard deviation.

Results

Sinus nodal function: In the basal state flecainide did not significantly change sinus cycle length, corrected sinus node recovery time or sinoatrial conduction time (mean increases 3 ± 7%, 14 ± 37% and 8 ± 27%, respectively) (Figure 2, Table I). On the contrary, after autonomic blockade, flecainide significantly prolonged intrinsic sinus cycle length (13 ± 7%, $p < 0.01$), intrinsic corrected sinus node recovery time (56 ± 62%, $p < 0.01$) and intrinsic sinoatrial conduction time (33 ± 36%, $p < 0.01$). In all patients the intrinsic heart rate observed was within the normal range. The longest sinus node recovery time was always the first postpacing escape sinus beat in both studies. The degree of increase induced by the drug in sinus cycle length and corrected sinus node recovery time was significantly more marked after autonomic blockade than in the basal state ($p < 0.01$), whereas the degree of change in sinoatrial conduction time did not show significant differences.

A_1-H_1 = A_1-H_1 interval at pacing cycle length of 600 ms; PCL for WB = pacing cycle length for Wenckebach block; other abbreviations as in Table I.

Atrioventricular nodal conduction: Flecainide significantly prolonged A-H interval, A_1-H_1 interval at cycle length of 600 ms (comparable in 14 patients) and pacing cycle length for Wenckebach block both in the basal state (14 ± 13%, $p < 0.01$; 22 ± 32%, $p < 0.01$ and 15 ± 11%, $p < 0.01$, respectively) and after autonomic blockade (+24 ± 13%, $p < 0.01$; 39 ± 19%, $p < 0.01$ and 18 ± 7%, $p < 0.01$, respectively) (Figure 3, Table II). The degree of increase induced by the drug in A-H and A_1-H_1 intervals was significantly more marked after autonomic blockade than in the basal state ($p < 0.01$ and < 0.05, respectively), whereas the degree of change in pacing cycle length for Wenckebach block did not show significant differences. Wenckebach periods occurred in all patients proximal to the His bundle.

The driving cycle length used for the determination of the refractory periods ranged from 550 to 650 ms (mean 603 ± 23). The AV nodal effective and functional refractory periods were comparable only in 3 patients; in the remainder the AV node effective refractory period was shorter than the atrial functional re-

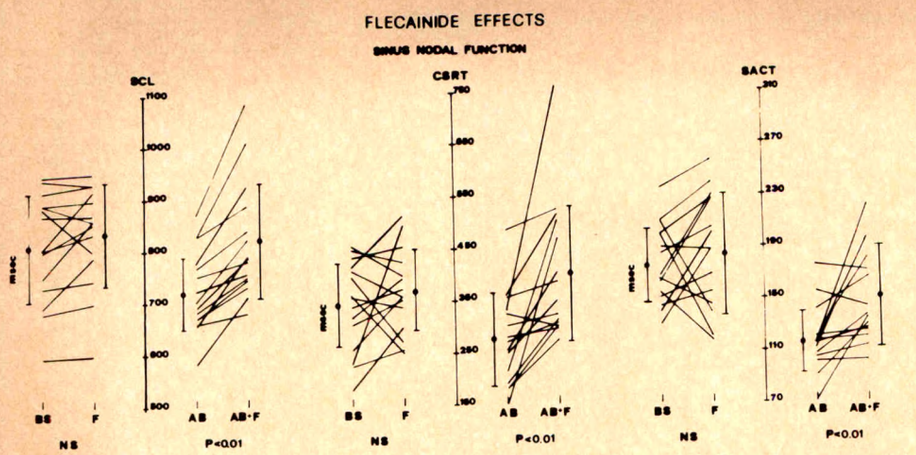

FIGURE 2. The effects of oral flecainide (F) on the electrophysiologic variables of sinus nodal function both in the basal state (BS) and following autonomic blockade (AB) are shown graphically. The means ± standard deviation are represented by the vertical bars on either side. CSRT = corrected sinus node recovery time; SACT = sino-atrial conduction time; SCL = sinus cycle length.

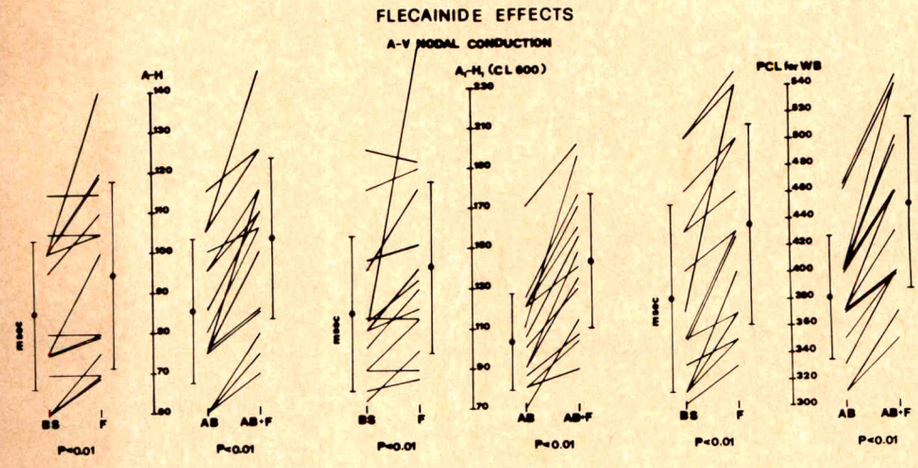

FIGURE 3. The effects of flecainide on the variables of atrioventricular nodal conduction in the basal state and after autonomic blockade. PCL for WB = pacing cycle length for Wenckebach block; other abbreviations as in Figure 2.

fractory period. For this reason, statistical evaluations were not performed.

The H-V and QRS intervals did not change in any patient after autonomic blockade; after flecainide administration, the former increased from a mean of 48 ± 7 to 56 ± 11 ms (percentage increase 16 ± 12%, $p < 0.01$) and the latter from a mean of 107 ± 29 to 121 ± 28 ms (percentage increase: 15 ± 7%, $p < 0.01$).

The plasma flecainide concentrations ranged from 287 to 688 μg/ml (mean 407 ± 103).

In the basal state and after autonomic blockade, flecainide did not change significantly systolic and diastolic pressure.

No major side effects were experienced after either autonomic blockade or flecainide administration. Minor side effects were transient blurring of vision in 1 patient and nausea in another after flecainide, and dryness of the mouth in all patients after autonomic blockade.

Discussion

Oral flecainide was initially prescribed at a daily dosage of 400 to 600 mg. Some investigators[18,19] then suggested that a lower daily dose (200 mg) may be effective, while reducing the incidence of toxicity to a more acceptable level. The electrophysiologic effects of flecainide have been widely investigated after intravenous administration, whereas there are few studies on its effects after oral administration and only at high dosage (300 to 500 mg daily) in patients with supraventricular or ventricular tachycardias.[5–9] In these studies flecainide induced minimal variations in the electrophysiologic variables of sinus node function, whereas it significantly prolonged A-H, H-V and QRS intervals with mean increases over control values of 13 to 39%, 40 to 67% and 14 to 28%, respectively. We administered flecainide at a lower dosage (200 to 250 mg daily) on the basis of these most recent data.

In our study, in the basal state flecainide did not change significantly sinus cycle length, corrected sinus node recovery time and sinoatrial conduction time. It increased significantly the A-H interval by 14% over the control value, A_1-H_1 interval by 22%, pacing cycle length for Wenckebach block by 15%, H-V interval by 16% and QRS complex by 15%. Our results obtained in the basal state are therefore similar to published data,[5–9] with our conduction time increases at the lower end or under the ranges previously reported, very likely due to the lower dose of oral flecainide we administered.

To evaluate the mechanism of action of oral flecainide we used a method previously adopted by us[20–23] and later by Lewis et al.[24] We selected patients with normal sinus rate in the basal state, normal intrinsic

heart rate and normal A-H interval to carry out the investigation in a group of patients with fairly homogeneous sinus and AV nodal functions.

The data obtained after autonomic blockade show that oral flecainide has a direct depressant effect on sinus nodal function and AV nodal conduction: it prolonged all the intrinsic electrophysiologic variables of the 2 nodes. This effect is consistent with the previous findings obtained in cardiac tissue preparations.[1-4] Moreover, our results show that the direct depressant effect of oral flecainide is significantly more marked than the overall effect; in fact the percentage increases in sinus cycle length, corrected sinus node recovery time, A-H and A_1-H_1 intervals were significantly greater after autonomic blockade than in the basal state. This suggests dual actions of flecainide on sinus nodal automaticity and AV nodal conduction in man; one being direct and the other mediated through the autonomic system, which counteracts the first action. Whether the indirect effect is due to a β-adrenergic action or to a vagolytic action is not possible to define in the clinical setting at present. On the basis of experimental data, the former action appears very unlikely, since flecainide partly counteracts the enhanced automaticity induced by isoproterenol in the sinus node of isolated rabbit atria[1] as well as in Purkinje fibers,[4] even if a significant β-blocking effect did not emerge. However, this behavior tends to exclude a β-adrenergic effect, even if it has not been studied specifically. A vagolytic effect of the drug appears more likely also because most class IA antiarrhythmic drugs, such as quinidine, procainamide, diphenylhydantoin and disopyramide,[22,23,25-28] and class IC drugs, such as propafenone and encainide,[21,29] have been shown to have this action.

The overall effects on AV conduction after flecainide alone were more pronounced that those for the sinus node. This suggests that the vagus system has less effect on the AV node compared with the sinus node; hence more depression was evident. This is compatible with previous observations[30,31] showing that the sinus node is more influenced by vagal innervation compared with the AV node.

The effects of flecainide on the parasympathetic system have not been investigated in the experimental setting; this problem warrants more detailed study because a drug with vagolytic action must be administered with caution to patients with glaucoma or urinary retention, particularly in association with other drugs having this autonomic effect. Moreover, our data suggest that flecainide would be expected to have greater clinical impact for patients with sinus node dysfunction or AV nodal conduction disturbances due to its direct negative chronotropic and dromotropic effects. For this reason, the drug should be administered with caution to patients with transplanted hearts that lack vagal innervation.

Noninvasive Evaluation of Indecainide for Serious Ventricular Tachyarrhythmia

PHILIP J. PODRID, MD, STEPHAN HOHNLOSER, MD, and BERNARD LOWN, MD

Indecainide, a new class 1C agent, was administered to 16 patients with a history of ventricular fibrillation or ventricular tachycardia. Evaluation of drug effect consisted of acute testing with 125 mg followed by a period of maintenance therapy. Efficacy, as evaluated with both ambulatory monitoring and exercise testing, was defined as total elimination of runs of ventricular tachycardia, >90% reduction in couplets and >50% decrease in ventricular premature complex. During acute drug testing 9 of the 16 patients responded to the drug. Four patients did not receive maintenance therapy with indecainide, because of toxic side effects. Of the remaining 12 patients, 7 responded to indecainide based on monitoring, 5 responded judged by exercise testing and 4 when both monitoring and exercise testing were considered. There was no correlation between dose, blood level of drug and effect on arrhythmia. In this small group acute drug testing did not appear to predict the response to the drug during maintenance therapy. Neurologic side effects were reported by 5 patients. Aggravation of arrhythmia occurred in 5 patients, 3 of whom had this complication during acute drug testing and 2 during maintenance therapy. Left ventricular ejection fraction, measured before and during therapy, decreased from an average of 43% to 35% ($p < 0.005$). A reduction was observed irrespective of baseline left ventricular function. Indecainide is an effective antiarrhythmic agent in a small number of highly selected patients with serious ventricular arrhythmia, but potentially serious side effects limit its usefulness.

(Am J Cardiol 1988;61:764–769)

Several new antiarrhythmic drugs are now available for treatment of patients with serious ventricular arrhythmia. When evaluated with noninvasive methods each of these agents is effective in only 40 to 60% of patients.[1-4] Furthermore, side effects are frequent. There is need for a highly effective and safe agent for suppressing ventricular arrhythmia and preventing sudden death. Indecainide is a new, potent antiarrhythmic drug.[5] Little data have been reported to date about its efficacy and safety in patients presenting with life-threatening ventricular tachyarrhythmias. The present study reports our experience with indecainide in 16 patients presenting with symptomatic ventricular tachycardia (VT) or ventricular fibrillation (VF) refractory to other antiarrhythmic drugs.

Methods

The study population consisted of 16 patients (11 men, 5 women) ages 22 to 76 years (mean 53). Coronary artery disease was present in 7 patients, idiopathic dilated cardiomyopathy in 5 and in 4 no structural disease was documented by cardiac catheterization or echocardiography. Presenting arrhythmia was VF in 4 patients and VT in 12, 9 of whom had sustained VT with hemodynamic instability (syncope or hypotension) and 3 who had runs of nonsustained VT associated with presyncope. In no patient was the arrhythmia the result of an acute myocardial infarction or other precipitating factor. Each patient had been re-

fractory to quinidine, disopyramide and procainamide with documented recurrence of arrhythmia at a time when blood levels were in a defined therapeutic range. An average of 5.5 drugs[3-8] had been ineffective before entry into this study and indecainide was the first investigational drug tested.

The protocol for a noninvasive drug evaluation has been reported previously.[6,7] After admission, antiarrhythmic therapy was withdrawn. Diuretics, digoxin and antianginal medications including β blockers, nitrates and calicum antagonist agents were continued if clinically indicated. After a washout period extending for at least 4 half-lives of the previously administered antiarrhythmic drug, patients underwent baseline studies, including 48 hours of continuous ambulatory monitoring and an exercise test on a motorized treadmill adhering to a Bruce protocol.

Data recorded from each 24-hour ambulatory monitoring period included the total and hourly number of ventricular premature complexes (VPCs), couplets and runs of VT. For the purpose of analysis, the 2 monitor recordings were compared to establish the reproducibility of each form of arrhythmia and the hourly number of each form averaged over the 48 hours. Routine chemistry evaluations and a complete blood count were obtained during this period. Left ventricular ejection fraction was measured by a gated blood pool radionuclide angiogram using technetium-99m pyrophosphate. For patients with a high density of VPCs (>10% of QRS complexes) a list mode format was utilized as previously reported.[8] This permitted the analysis of ejection fraction using only those sinus beats not immediately preceded by a VPC.

At the conclusion of baseline study, the effect of indecainide on arrhythmia was evaluated in 2 ways. Acute drug testing[7,9] involved administration of a single large dose of drug, while short-term maintenance therapy involved multiple doses given during several days of therapy.[6,7] The protocol for acute drug testing has been previously reported.[9,10] On the day of the test, each patient underwent a 30-minute period of continuous electrocardiographic recording by trendscription[11] and a brief period of exercise on a bicycle ergometer. At the conclusion of this baseline period, indecainide (125 mg) was administered orally and monitoring by trendscription continued for 3 hours. Each hour bicycle ergometry was repeated, an electrocardiogram was recorded for measurement of intervals and bloods were drawn for determination of indecainide levels. At the conclusion of the acute drug test, maintenance therapy with indecainide was begun at a dose of 50 mg 3 times daily. After at least 48 hours of therapy the dose could be increased to 75 mg 3 times daily if there were no side effects and if arrhythmia was still present as judged by continuous telemetered monitoring. After an additional 48 hours of therapy the dose could be increased further to a maximum of 100 mg 3 times daily. At the completion of the dosing period, 24-hour ambulatory monitoring, exercise testing on a motorized treadmill and a radionuclide angiogram were repeated. Routine chemistries and an indecainide blood level, drawn 2 hours after a dose, were also obtained.

Criteria for drug efficacy during acute drug testing and short-term maintenance therapy, as evaluated by monitoring and exercise testing, included[6,7]: (1) $\geq$50% reduction in VPCs, (2) $\geq$90% decrease in couplets and (3) total elimination of runs of VT.

Analyses of serum for the levels of indecainide and its metabolite, desisopropyl indecainide, were performed by the sponsoring pharmaceutical company.[12]

Statistical analyses were performed using the Student *t* test for paired and unpaired data and chi square. Data are expressed as mean ± standard error of the mean. Significance was defined as $p < 0.05$.

Results

Control studies: The number of VPCs during the monitoring period was 6,408 ± 1,156 daily (1,620 to 14,939) or 267/hour. When the 2 days were compared, the hourly number of VPCs for each patient was not statistically different and the total number of VPCs was reproducible. Each patient had frequent couplets with an average of 623 ± 216 daily (41 to 1,660). Runs of nonsustained VT, 52 ± 18 (4 to 273) daily, were present in 14 patients. For each patient the number of couplets and runs of VT was reproducibly present during both 24-hour monitoring periods.

During control, the exercise duration was 475 seconds (190 to 1,025 seconds) and the peak sinus rate achieved was 152 beats/min (99 to 200). With exercise 153 ± 29 VPCs were induced. Each patient had frequent couplets, with 16 ± 4 per test. Runs of VT were induced in 13 patients and there were 9 ± 5 runs per test. The average left ventricular ejection fraction was 41% (range 20 to 71%). In 7 patients the ejection frac-

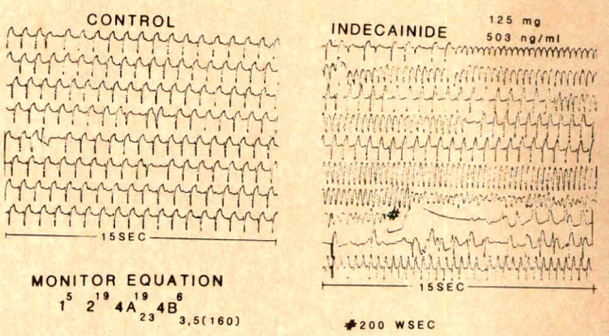

FIGURE 1. Aggravation of arrhythmia during acute drug testing. The patient had a history of sustained ventricular tachycardia. During control monitoring there were 5 hours of grade 1 (1^5) ventricular premature complexes, 19 hours of frequent grade 2 ventricular premature complexes (2^{19}) and 19 hours of couplets with up to 23 episodes/hour ($4A^{19}_{23}$). Nonsustained ventricular tachycardia was present for 6 hours with up to 3 runs/hour, 5 beats in length and at a rate of 160 ($4B^{6}_{3,5(160)}$). Two hours after receiving 125 mg of indecainide and with a blood level of 503 ng/ml, the patient spontaneously developed long runs of ventricular tachycardia and finally went into ventricular fibrillation requiring defibrillation.

tion was >50% (average 62%) while in 9 patients it was <50% (average 23%).

Acute drug test: During acute testing, 9 of the 16 patients (56%) responded to indecainide at 2 hours. The peak indecainide blood level in the responders was 832 ± 120 ng/ml and 44 ± 7 ng/ml for its metabolite, desisopropyl indecainide. In the 6 nonresponders the indecainide and metabolite levels were similar, 631 ± 103 ng/ml and 41 ± 4 ng/ml, respectively (difference not significant). Three patients experienced an aggravation of arrhythmia 2 to 3 hours after receiving indecainide (Figure 1). One patient developed sustained VT with hypotension, which, unlike the clinical VT, could not be reverted with lidocaine or cardioversion. After 6 hours of sustained VT with dopamine support for maintenance of blood pressure, he was cardioverted. Two patients developed VF for the first time. The blood levels of indecainide and its metabolite at the time of aggravation were 578, 884 and 503 ng/ml (average 655) and 34, 59 and 42 ng/ml (average 45), respectively. These were not significantly different from the levels in patients who did not exhibit aggravation. There were no associated QRS or QT interval changes in these 3 patients.

Short-term maintenance therapy: Twelve patients underwent repeat ambulatory monitoring while receiving indecainide therapy; 4 others were excluded, 3 with aggravation of arrhythmia during acute drug testing and 1 patient who developed severe neurologic side effects after 2 days of therapy with indecainide

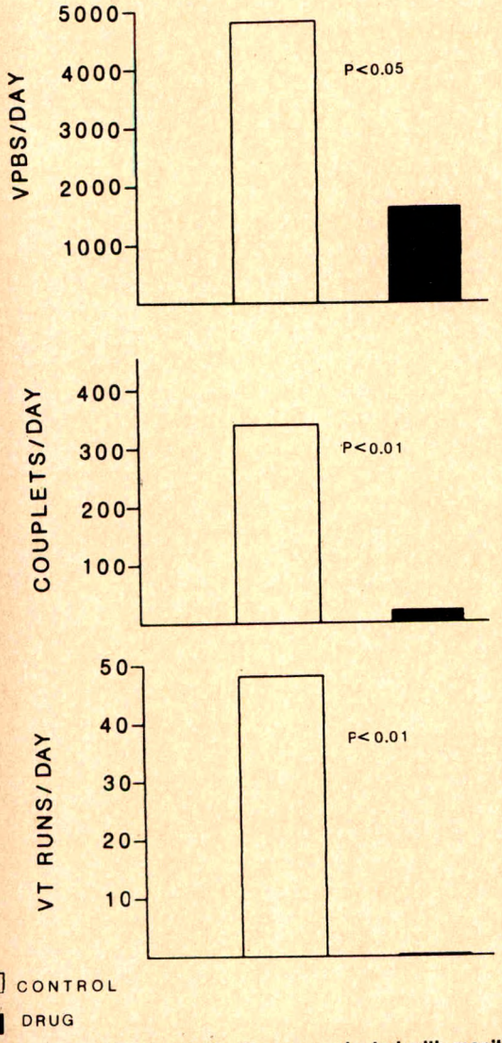

FIGURE 2. Results of indecainide therapy evaluated with monitoring. Among the 7 patients who responded to indecainide, ventricular premature beats (VPBs) per day were reduced by 67% from 4,814 to 1,624 ($p < 0.05$), couplets were reduced by 95% (334 to 18, $p < 0.01$). Runs of ventricular tachycardia (VT) (47/day) were eliminated ($p < 0.01$).

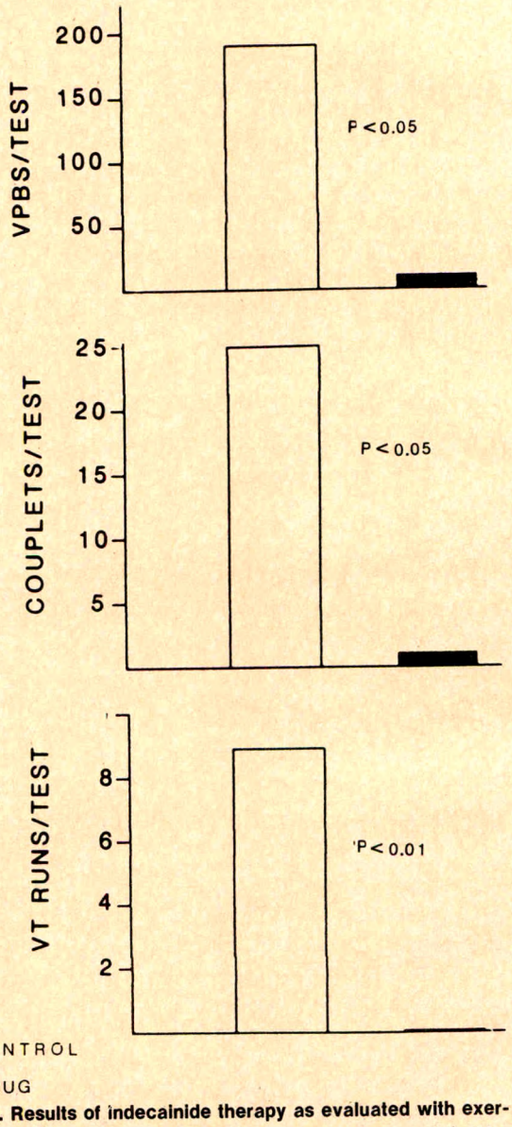

FIGURE 3. Results of indecainide therapy as evaluated with exercise testing. In the 5 patients who responded, the number of ventricular premature beats (VPBs) decreased from 189 to 23 per test or 88% ($p < 0.05$). Couplets were reduced from 25 to 2 per test (92%, $p < 0.05$) while runs of ventricular tachycardia (VT) were eliminated ($p < 0.05$).

150 mg daily. Based on criteria, 7 patients (58%) responded to indecainide as evaluated with monitoring. Daily VPCs decreased from 4,814 to 1,624 (67%, $p < 0.05$), couplets were reduced by 95%, from 334 to 18 daily ($p < 0.01$) (Figure 2) and runs of VT (average 47 daily) were eliminated ($p < 0.01$). Among the 5 nonresponders, there was no statistically significant change in daily VPCs (10,088 vs 10,346) couplets (701 vs 241) or runs of VT (87 vs 70).

Five of 13 patients (38%) showed a response to indecainide with exercise testing. In the responders the number of VPCs per test was reduced from 189 to 23 (88%, $p < 0.05$), couplets decreased from 25 to 2 per test (92%, $p < 0.05$), while runs of VT were eliminated ($p < 0.01$) (Figure 3). Exercise test duration was not significantly different (452 vs 497 seconds, difference not significant). Among the 8 nonresponders there was no significant change in exercise test duration and no significant change in frequency of VPCs, couplets or runs of VT.

When assessment of efficacy was based on the results of monitoring and exercise testing, 4 of the 16 patients originally entered (25%) responded to indecainide (Figure 4). The daily dose used was 150 mg in 4, 225 mg in 7 and 300 mg in 1. The average blood levels of drug and metabolite were 346 and 81 μg/ml, respectively, in responders compared with 448 and 78 μg/ml in the nonresponders (difference not significant).

Comparison between acute and maintenance therapy: Acute drug testing and short-term maintenance therapy was completed by 12 patients (Figure 5). All 4 patients who responded during maintenance therapy responded acutely. Of the 3 patients who did not respond acutely indecainide was ineffective in each. Therefore, 7 of 12 patients (58%) had concordant responses, but in this small group this was not statistically significant (difference not significant).

Blood levels of indecainide achieved acutely were significantly higher than those during maintenance (752 vs 417 ng/ml, $p < 0.005$). In the 7 patients who had concordant results, the average indecainide blood level was higher during the acute drug test (Table I). The average level of metabolite was higher during maintenance therapy. The same relation was observed in the 5 patients with a discordant response.

Left ventricular function: The average left ventricular ejection fraction during baseline in the 12 patients who completed the protocol was 43 ± 7% and was reduced to 35 ± 5% during indecainide therapy ($p < 0.005$) (Table II). Both responders and nonresponders had a similar decrease in ejection fraction during drug therapy. In 6 patients with normal ventricular function (≥50%), the drug reduced the ejection fraction from 62 to 49% ($p < 0.01$) and in the 6 with impaired function it was reduced from 24 to 21% ($p < 0.01$).

Side effects: The most common noncardiac side effects were neurologic. Lightheadeness was reported by 4 patients while 1 patient experienced confusion and thought disorders. In 3 patients there was nondose-related, marked QRS widening. Blood levels were not significantly different in those with side effects compared to those without toxic effects. Aggravation of arrhythmia was observed in 5 patients (31%). In 3 exacerbation of arrhythmia occurred during acute drug testing. One patient who received 150 mg daily for 4 days developed sustained VT for the first time on the treadmill. The fifth patient only had nonsustained VT during exercise, while with indecainide therapy he developed nonsustained VT during ambulatory monitoring and sustained VT during exercise testing. In

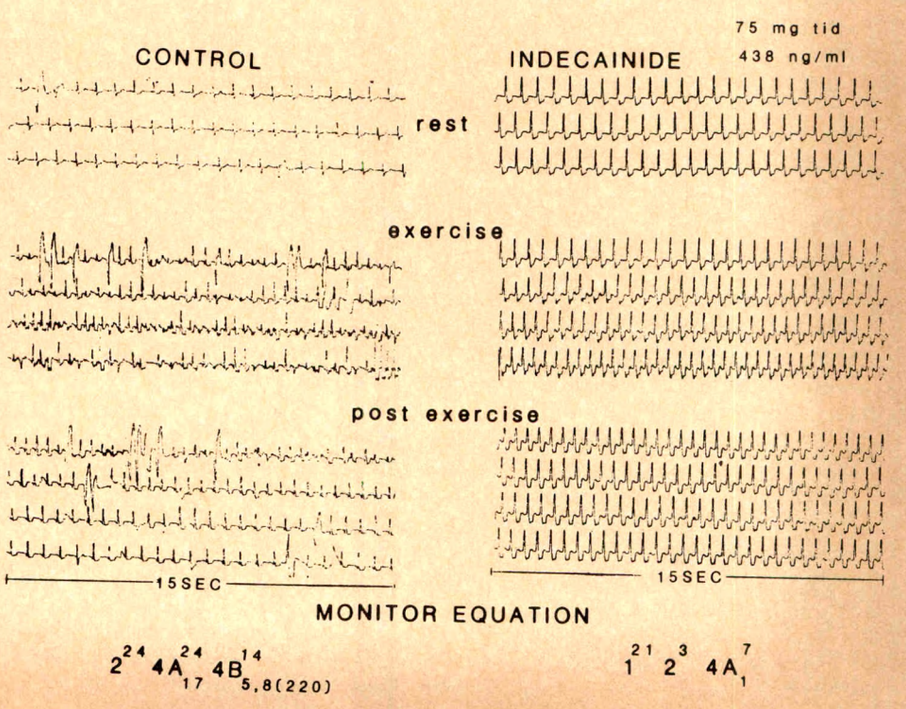

FIGURE 4. Responder to indecainide. In control the patient had frequent ventricular premature beats, couplets and runs of ventricular tachycardia induced by exercise. Ambulatory monitoring demonstrated 24 hours of frequent (>30/hour) ventricular premature complexes (2^{24}), 24 hours of couplets with as many as 17/hour ($4A^{24}_{17}$) and 14 hours of ventricular tachycardia. There were as many as 5 runs/hour, 8 beats in length at a rate of 220 ($4B^{14}_{5,8(220)}$). During indecainide therapy marked QRS widening occurred. Arrhythmia with exercise was eliminated, while ambulatory monitoring demonstrated 21 hours of infrequent (<30/hour) ventricular premature complexes, 3 hours of frequent ventricular premature complexes (2^{3}) and 7 couplets during the day ($4A^{7}_{1}$).

TABLE I Blood Levels

	Drug (ng/ml)	Metabolite (ng/ml)	p Value
Acute drug test

Concordancy (n = 7)	846/431	50/85	NS
Discordancy (n = 5)	753/409	32/60	

NS = difference not significant.

TABLE II Effect of Indecainide on Left Ventricular Function

		Ejection Fraction		
	No.	Control (%)	Drug (%)	p Value
Overall	12	43	35	<0.005
Responders	4	45	38	<0.05
Nonresponders	8	41	34	<0.05
EF >50%	6	62	49	<0.01
EF <50%	6	24	21	<0.01

EF = ejection fraction.

these 2 patients indecainide had been ineffective during acute drug testing. The blood levels of indecainide and its metabolite were similar to those of patients who did not have aggravation.

Discussion

Indecainide is similar to other membrane-active drugs because it reduces the maximum rate of increase in phase 0 of the action potential and decreases conduction velocity through the myocardium.[13] There is a slow rate of tissue repolarization. The drug has little effect on the effective refractory period of the myocardium. In the canine Purkinje fiber, the drug shortens the action potential duration, while it lengthens it within the ventricular muscle.[13] These features are typical for drugs within the 1C subclass of antiarrhythmic agents, which include encainide[14] and flecainide.[15] Indecainide has no effect on sinus node automaticity or the slope of phase 4 of Purkinje fibers in the ventricle.[13,16] In the atrium, the drug shortens action potential duration, but has little effect on the refractory periods.[13]

There are only a few studies involving indecainide therapy in humans. Horowitz et al[5] administered intravenous drug to 10 patients with inducible VT. At a dose of up to 90 mg/kg, there was no effect on sinus node function or the refractory periods of the atrial and ventricular myocardium. The drug did significantly slow conduction through the atrioventricular node and His Purkinje tissue, but prolonged the AH, HV and QRS intervals, similar to the effects of encainide and flecainide.[14,15] Only 1 patient was rendered noninducible after intravenous indecainide therapy. However, similar to encainide[17] and flecainide,[18] the drug did significantly prolong the VT cycle length from 248 to 320 ms ($p < 0.001$).

In a study by Morganroth et al,[19] 14 patients with frequent VPCs and nonsustained VT received 150 to 300 mg of indecainide daily. In 11 patients (85%) VPCs were reduced by 90%, and in 12 patients (86%) VT was eliminated. Similar results were reported by Krejci,[20] Siddoway[21] and their co-workers. In a comparative study with disopyramide involving 231 patients, indecainide reduced VPCs by 93% while with disopyramide there was an 80% decrease in VPCs ($p < 0.05$).[22] However, the 2 drugs were of equivalent efficacy for the suppression of runs of VT.

Data about the effect of indecainide on spontaneous arrhythmia in patients with a history of sustained tachyarrhythmias are lacking. In the present study indecainide significantly reduced the frequency of VPCs, couplets and eliminated VT in 7 patients as evaluated with monitoring and in 5 of 13 patients based on exercise. When both monitoring and exercise testing were considered, only 4 of the 16 patients (25%) responded to indecainide.

In this small group indecainide was less effective when compared with other investigational drugs evaluated with the same protocol in patients with life-threatening ventricular arrhythmia refractory to conventional agents.[1-4] As with other drugs, no correlation was noted between drug efficacy and the dose used, the serum blood level achieved or changes on the electrocardiogram.

An important concern is the ability to predict drug effect. In our experience with quinidine,[9] mexiletine[2] and propafenone,[3] acute drug testing is predictive of the response to maintenance therapy, with an 80 to 88% concordancy. Acute drug testing with indecainide did not appear to correlate with the effect of maintenance therapy, although it does appear that failure to respond acutely will predict inefficacy of the drug

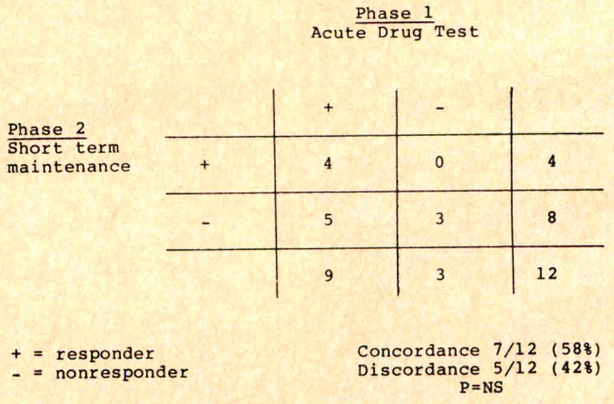

FIGURE 5. Correlation between phase 1 and phase 2 studies. Of the 12 patients undergoing acute drug testing and maintenance therapy with indecainide, (58%) had concordant results, while 5 (42%) who responded to the drug acutely did not respond during maintenance therapy. NS = difference not significant.

when given on a long-term basis. However, the number of patients is small. Studies involving more patients are necessary to better define this relation. The discordance may be related to higher peak indecainide levels during acute drug testing compared with maintenance therapy (752 vs 417 μg/ml).

Worrisome are the side effects we encountered. In this study indecainide only infrequently produced neurologic symptoms, similar to the comparative study of Morganroth et al.[22] Of particular concern is cardiac toxicity. In our patients, indecainide significantly reduced the left ventricular ejection fraction in 9 of 12 patients, although no patient developed signs or symptoms of failure, perhaps because of a brief period of dosing. Of even greater concern is the drug-induced aggravation of arrhythmia. This complication has been reported to occur in 11% of antiarrhythmic drug studies[23,24] and especially in patients with a history of sustained ventricular tachyarrhythmia.[23,25] In the study of Morganroth et al,[22] aggravation of arrhythmia was observed in 12 of 114 patients (11%) receiving indecainide. In the present studies, indecainide aggravated arrhythmia in 5 of 16 patients (31%). There were no electrocardiographic changes associated with aggravation and blood levels were similar to those achieved in patients without this complication. As with other drugs, this life-threatening complication urges cautious use of indecainide, especially in patients with a history of sustained VT or VF with impaired left ventricular function.

Coupling Intervals of Ventricular Extrastimuli Causing Resetting of Sustained Ventricular Tachycardia Secondary to Coronary Artery Disease: Relation to Subsequent Termination

MARK E. ROSENTHAL, MD, NICHOLAS J. STAMATO, MD, JESUS M. ALMENDRAL, MD, CHARLES D. GOTTLIEB, MD, and MARK E. JOSEPHSON, MD

Single and double ventricular extrastimuli (VE) delivered during sustained, uniform ventricular tachycardia (VT) are able to reset or terminate the tachycardia. The relation between the coupling intervals of single and double VE resetting VT and those terminating it was examined in 80 uniform, morphologically distinct VT occurring in 52 patients. Of the 80 tachycardias receiving single VE, 41 were reset and 8 terminated. The corrected coupling interval of single VE first causing resetting was 0.81 ± 0.08 compared with 0.66 ± 0.06 for termination ($p < 0.001$). Forty-two tachycardias received double VE with 33 being reset and 13 terminating. The corrected coupling interval of double VE at which resetting was first seen was 0.86 ± 0.08 compared with 0.73 ± 0.05 for termination ($p < 0.001$). If the longest corrected coupling interval causing resetting was ≥0.75, then 7 of 34 tachycardias terminated with single VE and 13 of 31 terminated with double VE compared with only 1 of 46 terminating with single VE and 0 of 10 with double VE if resetting was not observed by a corrected coupling interval of 0.75 ($p < 0.01$ and $p < 0.02$, respectively). If the longest corrected coupling interval at which resetting occurred was ≥0.75, the predictive value for VT termination was 21% with single VE and 42% with double VE compared with only 2% with single VE and none with double VE if resetting was not observed by this corrected coupling interval. Thus, critical coupling intervals can be identified during the delivery of premature extrastimuli where if resetting has not occurred, termination is unlikely. Potential applications of these findings in algorithms for antitachycardia pacemakers exist.

(Am J Cardiol 1988;61:770–774)

Programmed ventricular extrastimuli delivered during sustained, uniform ventricular tachycardia (VT) may reach the site of tachycardia origin and cause resetting or termination of the rhythm.[1,2] The ability of different modalities of programmed ventricular stimulation to terminate VT has been evaluated and incorporated into protocols for tachycardia termination, both in the electrophysiology laboratory and in chronically implanted antitachycardia devices.[3–16]

We and others have shown that resetting or entrainment (i.e., continuous resetting) of VT may be demonstrated before termination as increasingly premature ventricular extrastimuli (VE) are delivered or incremental ventricular pacing is performed during VT.[2,12–14] The present study expands our prior observations and examines the relation between the coupling intervals of single and double VE that reset sustained VT and those that terminate it. Potential applications of these findings for the development of more efficient algorithms for the delivery of single or double extrastimuli in antitachycardia devices are discussed.

Methods

Study population: Eighty uniform, morphologically distinct VTs occurring in 52 patients with prior myo-

From the Clinical Electrophysiology Laboratory, Hospital of the University of Pennsylvania, Cardiovascular Section, and Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania. This study was supported in part by grants HL28093 and HL07346 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland, and grants from the American Heart Association, Southeastern Pennsylvania Chapter, Philadelphia. cardial infarction were included for analysis. The patient population was 49 men and 3 women with a mean age of 60.5 ± 9.5 years.

All 80 tachycardias were either directly induced by programmed electrical stimulation or resulted from stimulation during previously induced VT. The mean cycle length of the tachycardias studied was 365 ± 58 ms and all were hemodynamically well tolerated. The tachycardia cycle length was required to be stable over 20 consecutive beats, not varying by more than 20 ms. Fifty-nine tachycardias were studied while the patient was receiving antiarrhythmic therapy while 21 were studied with the patient withdrawn from all antiarrhythmic agents.

Electrophysiologic studies: Electrophysiologic studies were performed in the postabsorptive state following the percutaneous insertion of 1 to 5 quadripolar electrode catheters with 5-mm interelectrode spacing. Programmed stimulation was performed with a custom-designed programmable stimulator (Bloom Associates, Ltd.) that delivered bipolar, rectangular 1-ms pulses at twice the diastolic threshold. Data obtained during the procedure were displayed on a multichannel oscilloscope (Electronics for Medicine VR-16) and recorded with an ink jet recorder (Siemens Elema, Mingograph) at paper speeds of 100, 200, and 250 mm/s and simultaneously recorded on magnetic tape. Surface electrocardiographic leads I, aVF and V_1 were recorded with intracardiac electrograms that were filtered between 30 and 500 Hz. Previously described stimulation techniques, using 1 to 3 VE and rapid ventricular pacing, were used to initiate VT.[6,17]

Delivery of extrastimuli during ventricular tachycardia: Premature extrastimuli delivered during VT were given at the right ventricular apex at twice the diastolic threshold. Single VE (S_1) were introduced in all 80 VT with an initial coupling interval to the prior tachycardia beat (V) equal to 20 ms less than the tachycardia cycle length. S_1 was delivered with increasing prematurity with the V-S_1 interval decreased by 10-ms intervals until 1 of 3 outcomes occurred. First, ventricular refractoriness at the pacing site was reached; second, a sustained change (lasting >30 seconds) in the tachycardia cycle length or morphology occurred or third, termination was observed. Double VE were delivered during 41 VT in the following fashion: the coupling interval of S_1 was fixed so that it did not cause resetting of the VT. This was done by setting the V-S_1 interval 20 ms greater than the longest coupling interval at which resetting occurred, or 20 ms beyond the effective refractory period at the pacing site during VT if resetting was not observed during the introduction of single VE. The second VE (S_2) was then delivered with increasing prematurity, beginning at an S_1-S_2 interval equal to the tachycardia cycle length. S_1S_2 was then decreased by 10-ms intervals until one of the previously described endpoints was reached.The V-S_1 interval remained fixed and therefore only S_2 was allowed to interact with the site of tachycardia origin.

The complete stimulation protocol was not performed during all VT if the patient became hemodynamically unstable during the pacing protocol, if a new morphology of VT was initiated during the introduction of premature extrastimuli or if the VT terminated.

Single and double VE were delivered at least twice at each coupling interval to document reproducibility. When termination occurred, VT was generally not reinitiated to systematically assess the reproducibility of termination nor was a tachycardia termination window defined.

Measurements and definitions: Intervals were measured between the rapid deflections of intracardiac electrograms recorded at the site of pacing.

Resetting of VT with single or double VE occurred if: the pause following ventricular premature extrastimulation was less than fully compensatory by at least 20 ms and the same morphology of VT resumed immediately after premature stimulation with no significant change (<20 ms) from the original tachycardia cycle length.

Acceleration of VT was defined as occurring if there was at least a 20-ms decrease in tachycardia cycle length, after premature stimulation, which was sustained. Changes in the tachycardia QRS morphology concomitant with acceleration were noted.

The coupling intervals for single and double VE were corrected for tachycardia cycle length in the following manner. Corrected coupling interval for single VE = V-S_1 interval/VT cycle length. Corrected coupling interval for double VE = V-S_2 interval/2(VT cycle length).

Statistical analysis: Continuous variables were expressed as the mean ± standard deviation and compared using the unpaired *t* test. Categorical variables were compared using the chi square test.

Results

Single ventricular extrastimuli: Eight of 80 tachycardias (10%) were terminated with single VE while 41 (53%) were reset. Seven of 8 tachycardias were reset at longer V-S_1 coupling intervals before termination. The mean corrected coupling interval of single VE that initially reset VT was 0.81 ± 0.08 compared with a mean corrected coupling interval of 0.66 ± 0.06 that terminated VT ($p < 0.001$). There was no significant difference between the shortest coupling intervals of single VE which captured during those tachycardias that terminated and those that did not. An example of resetting and subsequent termination of the same VT by increasingly premature single VE is shown in Figure 1.

One tachycardia was accelerated during the delivery of single VE without a change in QRS morphology. Six VTs changed morphology after premature stimulation, 4 of which were more rapid than the baseline tachycardia, for an overall incidence of stimulation-induced acceleration of 6.3%. In no instance was degeneration to ventricular fibrillation observed.

Double ventricular extrastimuli: Double VE were delivered during 41 VTs. Thirty-three (80%) were reset and 13 (32%) were subsequently terminated. Twelve of 13 tachycardias were first reset with V-S_2 coupling intervals that exceeded the V-S_2 intervals at which termination was observed. The mean corrected coupling interval at which double VE initially reset VT

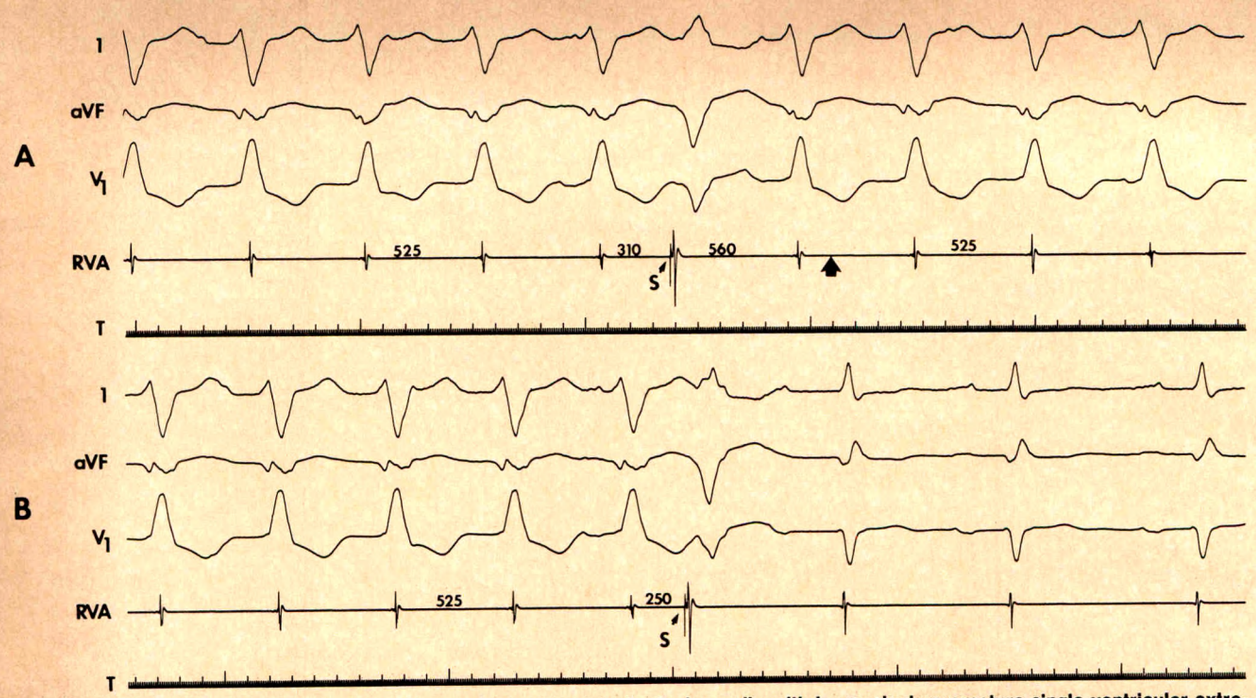

FIGURE 1. Resetting and termination of uniform, sustained ventricular tachycardia with increasingly premature single ventricular extrastimuli. Surface electrocardiographic leads I, aVF and V_1 are displayed with an intracardiac recording from the right ventricular apex (RVA). In *A*, a single ventricular extrastimulus (S) is delivered with a coupling interval to the prior tachycardia beat of 310 ms. The resulting pause of 560 ms, measured at the RVA, is less than fully compensatory; the tachycardia is therefore reset. The *bold upright arrow* indicates where a fully compensatory right ventricular apical electrogram would occur. Note that after premature extrastimuli, the tachycardia resumes without a change in morphology or cycle length. In *B*, a single extrastimulus (S) delivered at the RVA with a coupling interval of 250 ms terminates the tachycardia. T = time lines.

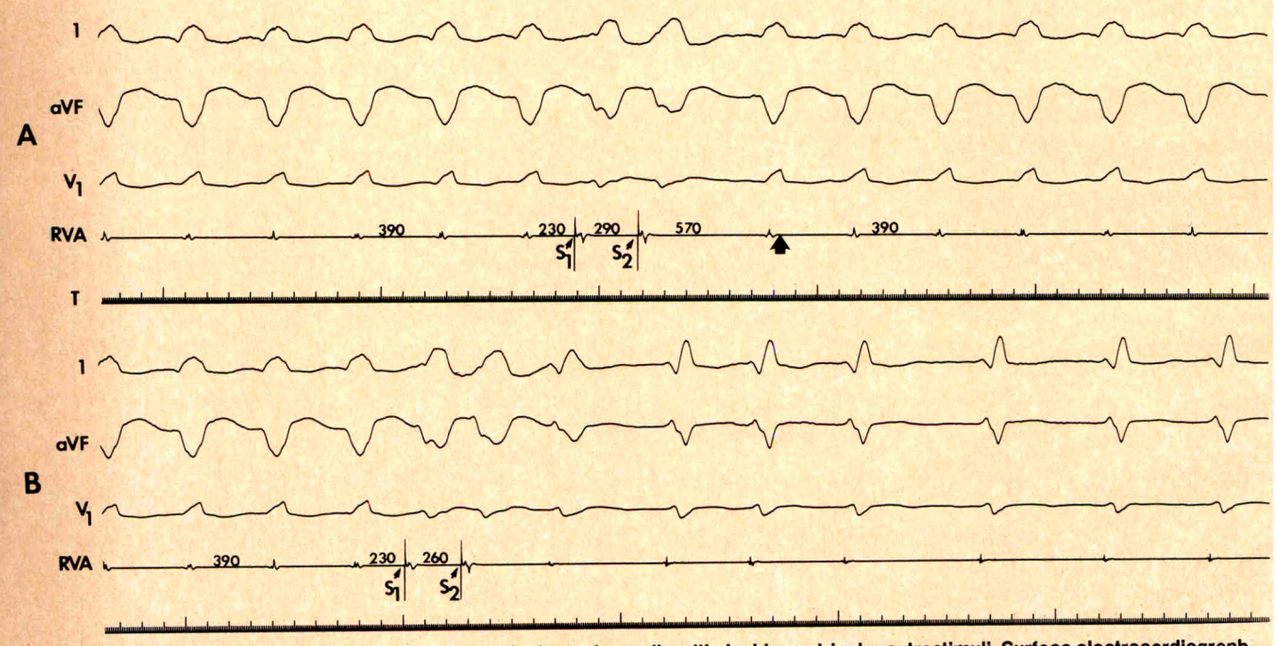

FIGURE 2. Resetting and termination of sustained ventricular tachycardia with double ventricular extrastimuli. Surface electrocardiographic leads I, aVF and V_1 as well as an intracardiac recording from the right ventricular apex (RVA) are displayed. Single extrastimuli did not reset this tachycardia and therefore the coupling interval of the first extrastimulus (S_1) is set at 230 ms, 20 ms greater than the effective refractory period during ventricular tachycardia. In *A*, the interval between S_1 and the second extrastimulus (S_2) was set at 290 ms and resulted in a pause of 570 ms. This is less than fully compensatory (*bold arrow* demonstrates the timing of a fully compensatory electrogram) and therefore the tachycardia is reset. In *B*, the S_1-S_2 interval is 260 ms and termination of ventricular tachycardia occurs with the resumption of the baseline rhythm, atrial fibrillation. T = time lines.

was 0.86 ± 0.08 compared with a mean corrected coupling interval of 0.73 ± 0.05 for tachycardia termination ($p < 0.001$). An example of resetting and later termination of the same VT with double VE is shown in Figure 2.

No tachycardias were accelerated without a change in QRS morphology. Five tachycardias changed morphology after double VE with a decrease in the tachycardia cycle length in 2. The overall incidence of tachycardia acceleration was 4.9%. Degeneration to ventricular fibrillation was not seen.

Use of resetting to identify tachycardias that terminated: Because resetting of VT preceded termination in 90% of the tachycardias that were terminated, a corrected coupling interval at which tachycardia resetting was first observed was sought to identify tachycardias that would subsequently be terminated. For single VE, if resetting was first observed at a V-S_1 interval ≥75% of the tachycardia cycle length (corrected coupling interval ≥0.75), then 7 of 34 tachycardias were terminated compared with only 1 of 46 tachycardias when resetting was not observed by a corrected coupling interval of 0.75 ($p < 0.01$). For double VE, if the corrected coupling interval at which resetting was first observed was ≥0.75, then 13 of 31 tachycardias terminated compared with 0 of 10 tachycardias that terminated if resetting was not observed by a corrected coupling interval of 0.75 ($p < 0.02$). Using a value of 0.75, the predictive value for tachycardia termination was 21% for single VE and 42% for double VE if resetting was first observed at coupling intervals above this value. If resetting was not observed by a corrected coupling interval equal to 0.75, the predictive value for tachycardia termination was 2% for single VE and 0% for double VE (Table I).

TABLE I Relation Between Longest Corrected Coupling Interval Causing Resetting and Subsequent Termination

	Longest Corrected Coupling Interval Causing Resetting ≥0.75	
	SVE	DVE
Predictive value for termination	19%	42%
	<0.75	
Predictive value for no termination	98%	92%

DVE = double ventricular extrastimuli; SVE = single ventricular extrastimuli.

Discussion

Programmed ventricular extrastimuli have been shown to be efficacious for the termination of sustained, uniform VT.[2,6,9-16] Previous reports have demonstrated single VE to be effective in terminating VT in up to 53% of patients, with 8 to 48% of tachycardia episodes being successfully terminated.[2,6,9-16] In these studies, double VE terminated VT in up to 75% of patients with 11 to 58% of tachycardia episodes being terminated.[2,6,9-16] Both of these pacing modalities have been shown to be inferior to bursts of rapid ventricular pacing for tachycardia termination.[2,6,9-15] However, they are generally considered to be safer in that the incidence of VT acceleration or degeneration to ventricular fibrillation is less common with these modalities than with bursts of rapid ventricular pacing.[3,4,7-9] Therefore, some means to "screen" for potential efficacy of single and double VE for tachycardia termination early in their delivery would be useful in identifying tachycardias that require more aggressive pacing methods.

This report is the first to examine the potential role for the resetting response in algorithms for pacing termination of VT. Previously, termination of sustained VT has been shown to be preceded by entrainment during incremental ventricular pacing.[2,12-14] Similarly, resetting of VT was demonstrated before termination during the delivery of increasingly premature single and double VE.[2]

This study extends these observations by analyzing the coupling intervals with which single and double VE first reset and subsequently terminate VT.

As diastole was scanned with increasingly premature VE, the incidence of tachycardia termination with a single extrastimulus was 21% if resetting was first observed with a coupling interval ≥75% of the tachycardia cycle length, and only 2% if resetting was not observed by this coupling interval. Similarly, as diastole was scanned with the second of 2 VE, the incidence of termination was 42% if resetting was observed by a corrected coupling interval of 0.75, and 0% if resetting was not observed by this coupling interval.

The findings of this study have potential utility in automatic, adaptive, antitachycardia pacemakers. Such a device could detect tachycardia resetting by monitoring the return cycle at the pacing site following premature extrastimulation. If resetting was not detected with single VE by a coupling interval equal to 75% of the tachycardia cycle length, then the unit could automatically shift to the delivery of double VE as the next pacing modality. The V-S_1 interval would automatically be set at a predetermined percentage of the tachycardia cycle length determined during baseline electrophysiologic testing and diastole would be scanned with S_2. If resetting was observed in either instance by a corrected coupling interval ≥0.75, the remainder of diastole would be scanned until either termination occurred or refractoriness was reached before resorting to a more aggressive mode of pacing. In this way, these safer but less efficacious pacing modalities could be more efficiently used.

Theoretical considerations: The tachycardias included in this study were all the result of programmed electrical stimulation, with the vast majority occurring in patients with coronary artery disease. The underlying mechanism of VT in this setting is thought to be due to reentry.[1,6] Resetting of reentrant VT occurs when a premature extrastimulus is able to enter the circuit, collide with the prior orthodromic wavefront retrogradely and propagate antegradely over the excitable gap to exit the circuit early (Figure 3). Termination may occur when a sufficiently premature extrastimulus results in block in both limbs of the circuit, extinguishing

the tachycardia (Figure 3). This study demonstrates that early penetration of programmed extrastimuli into the circuit, indicated by resetting of VT, is usually a prerequisite for subsequent termination.

Limitations and conclusions: The VT included in this study were all uniform, hemodynamically well tolerated and with a stable cycle length. The findings cannot be extended beyond this subgroup. However, it is this specific group of tachycardias in which antitachycardia pacing would be applied.

The method in which premature VE were delivered could have influenced the success rate for tachycardia termination. Ventricular extrastimuli were delivered at twice diastolic threshold. Since increased current strength has been shown to facilitate tachycardia termination,[18] the use of higher currents might have increased the incidence of termination. It is also possible that a more closely coupled S_1 during the delivery of double VE might have led to maximal "peeling back" of intervening tissue refractoriness and easier access to the circuit with a greater incidence of termination. In this study, only S_2 interacted with the tachycardia circuit and comparison with extrastimulus techniques in which S_1 was made more premature during the delivery of double extrastimuli is not possible.

This study demonstrates that resetting of VT with single and double VE usually occurs at longer extrastimulus coupling intervals than termination. As increasingly premature extrastimuli are used to scan diastole, a critical coupling interval can be identified where if resetting has not occurred, termination is unlikely. This finding has potential applications in the development of more efficient uses of single and double VE in antitachycardia pacemakers capable of adaptive pacing modalities.

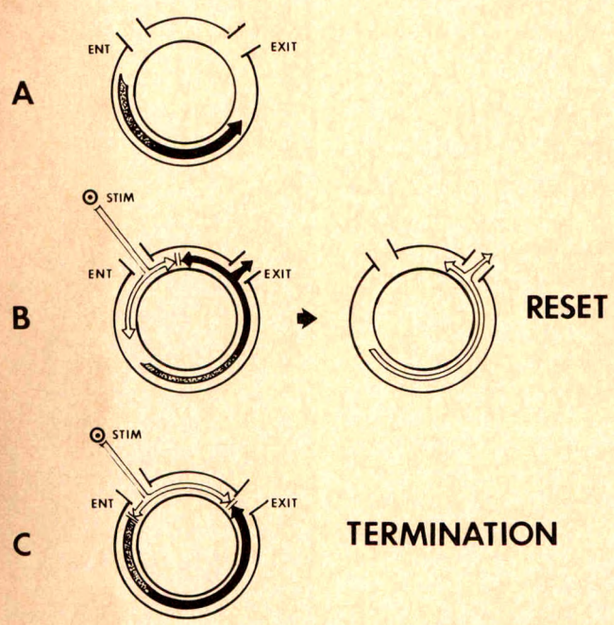

FIGURE 3. In *A*, a schematic representation of the reentrant circuit is illustrated with separate entrance (ent) and exit sites. During ventricular tachycardia, a wavefront is shown propagating through the tissue of the reentrant circuit (*arrow*). The *black portion* of the arrow represents fully refractory tissue while the *dotted portion* represents partially refractory tissue. In *B*, a premature ventricular stimulus (stim) introduced during the tachycardia results in a wavefront of depolarization (*open arrow*), which enters the reentrant circuit and conducts antegradely over fully excitable tissue while it collides retrogradely with the already propagating wavefront (*black and dotted arrow*). The premature wavefront (*open arrow*) then propagates around the circuit to the exit site, leading to the less than compensatory pause and resetting of the tachycardia. In *C*, a more premature ventricular extrastimulus (stim) results in a wavefront of depolarization (*open arrow*), which enters the circuit at a time when it collides retrogradely with the previously propagating wavefront (*black and dotted arrow*) and encounters antegrade tissue incapable of sustaining further propagation. As a result, circus movement in the circuit is extinguished and tachycardia terminates.

The Anyfingers Patch.

All nitroglycerin patches work.

But Nitro-Dur is the one nitroglycerin patch that works so readily, any fingers can easily open and apply it...even stiff fingers, clumsy fingers, arthritic fingers guided by presbyopic eyes.

Test it yourself. To see how easy handling Nitro-Dur can be, open one and handle it yourself. Compare it with other patches.

Compare its thinness, its comfort, its appearance. Nitro-Dur clings bulklessly and bulgelessly to the skin, so thin that pores and texture show through... so discreet about its presence that it's nearly invisible. Handle one and see. Handling is believing!

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System

Easy to open... apply... remove.

5 mg patch, actual size.

Please see next page for brief summary of prescribing information. Copyright © 1988, Key Pharmaceuticals, Inc., Kenilworth, NJ 07033. All rights reserved.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System

- **Easy opening**—even for arthritic hands.
- **Round-the-clock cling**—lies flat, holds tight.
- **Hard to notice, easy to wear**—semitransparent, soft and flexible.
- **Push-button removal**—just a press in the center raises the rim for easy lift-off.

BRIEF SUMMARY

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia.

WARNINGS: The NITRO-DUR system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued.

NITRO-DUR is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

Pregnancy: Pregnancy Category C. Animal reproduction studies have not been conducted with NITRO-DUR. It is also not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when NITRO-DUR is administered to a nursing woman.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing NITRO-DUR therapy. If headache persists, the NITRO-DUR dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the NITRO-DUR dosage should be reduced or use of the product discontinued.

CAUTION: Federal law prohibits dispensing without prescription. EDP #1030160

CARDIOLOGIST—BC/BE sought to join a large hospital-based multispecialty clinic. University affiliated residency program. Excellent fringe benefits. Competitive salary. California license required. Send CV to Aung-Win Chiong, MD, THE PERMANENTE MEDICAL GROUP, INC., P.O. Box 254999, Sacramento, CA 95865-4999, or call (916) 973-5748. An equal opportunity employer.

PEDIATRIC CARDIOLOGIST: Position available for BC/BE pediatric cardiologist. Qualifications to include expertise in echocardiography. Forward CV to: Director, Pediatric Cardiology, Likoff Cardiovascular Institute, Hahnemann University, Suite 6328, N.C.B., Broad and Vine, Philadelphia, PA 19102.

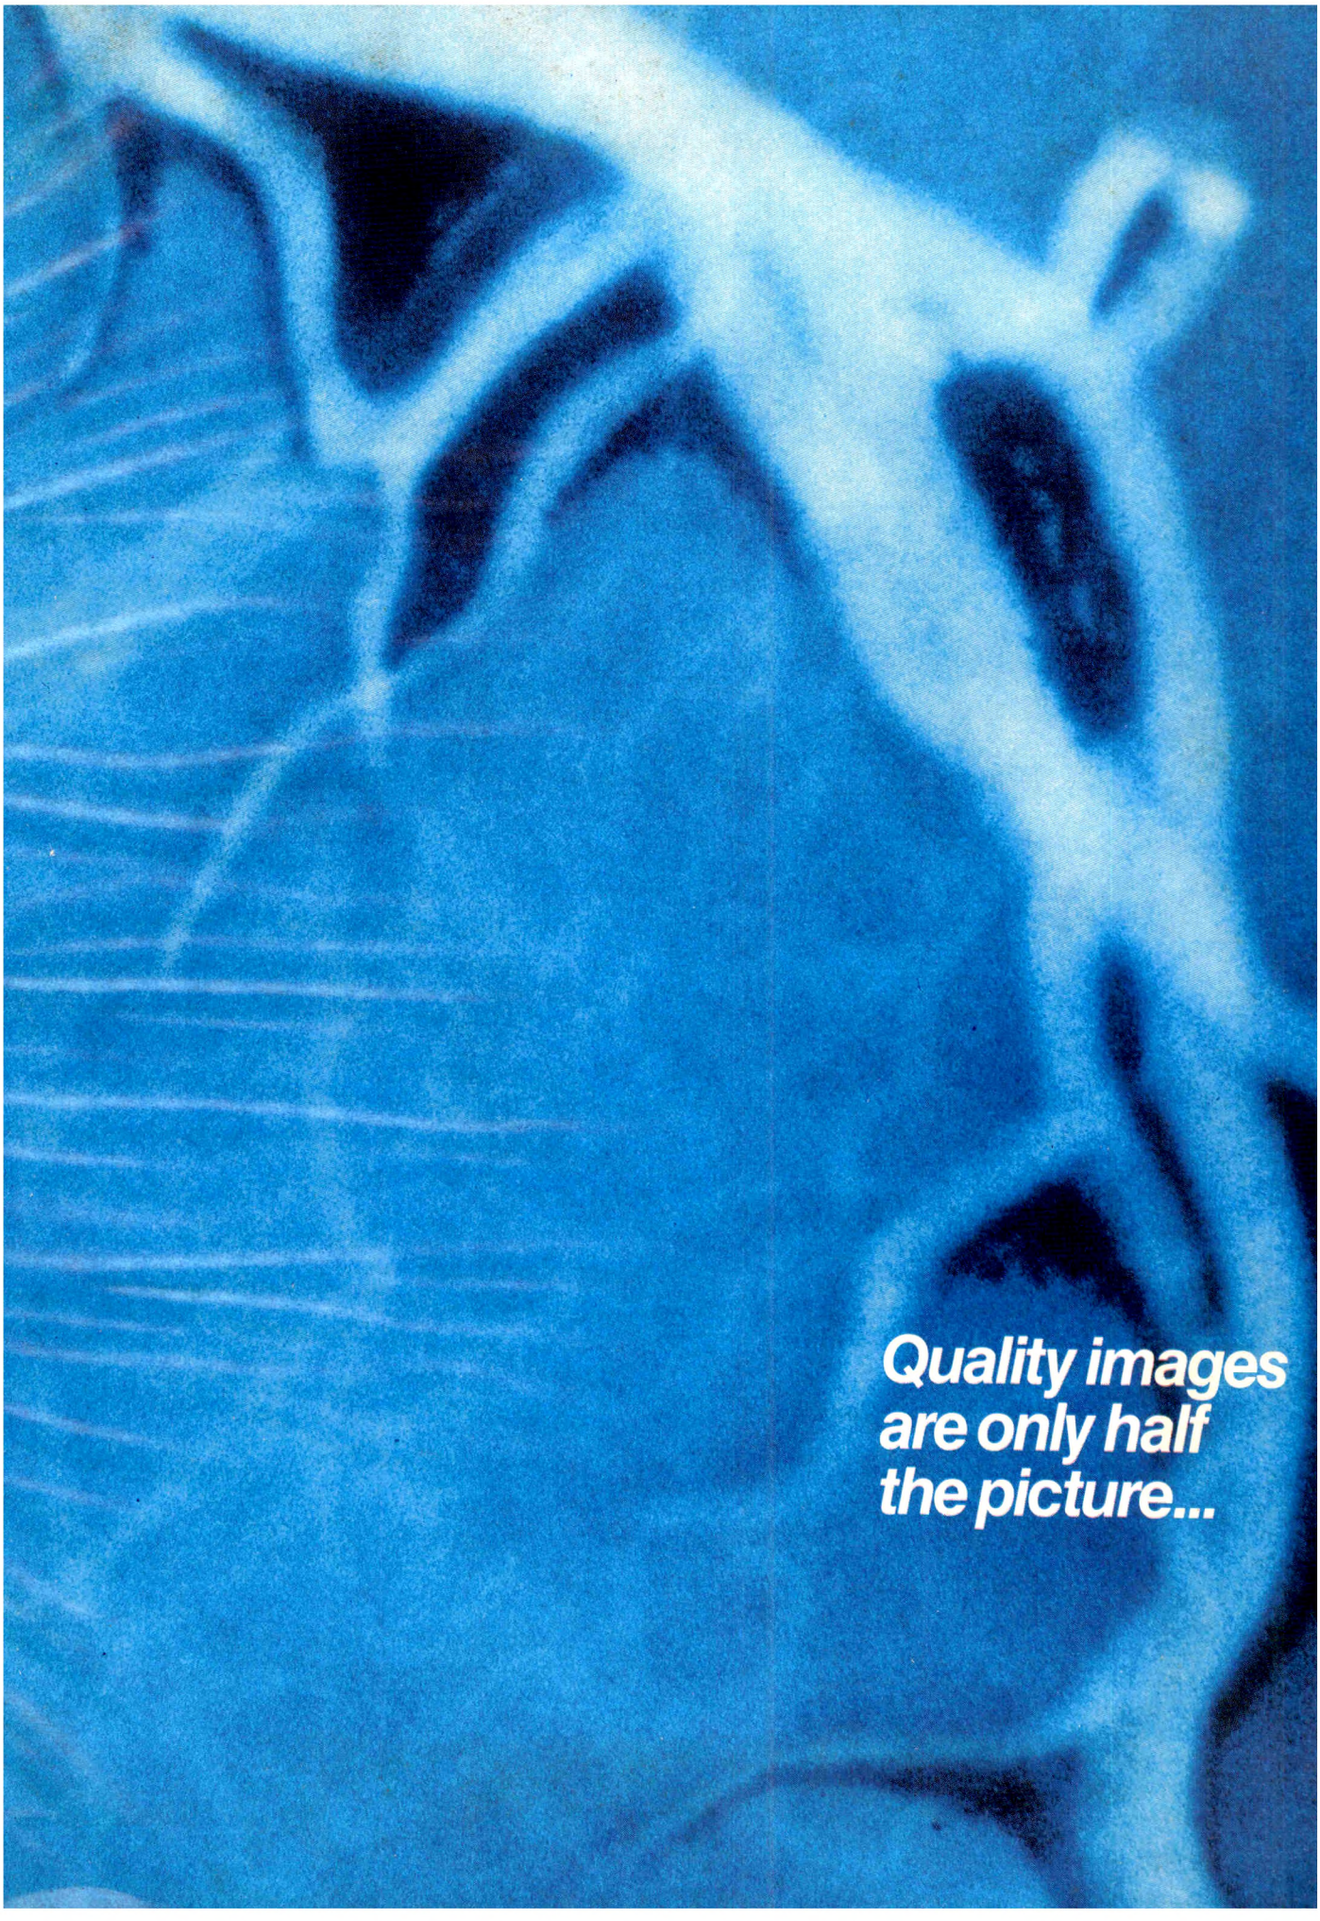
CARDIOLOGIST—To join 5 FACC cardiologists in Northwestern PA. Consultative, invasive and non-invasive practice. Immediate opening. Reply Box 810, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGISTS
Invasive and Non-Invasive

This 180 physician, multispecialty group currently has associateships available in the above specialties. The group is hospital-based in Northeastern Pennsylvania at the New York State border. Our state of the art facility offers medical school teaching affiliations as well as clinical research opportunities. Residency programs are conducted in Internal Medicine and General Surgery. A program in Cardiology is being developed. Physicians seeking challenging and rewarding practice opportunities, excellent salaries and benefits, combined with rural living and endless recreational opportunities are encouraged to submit a letter and Curriculum Vitae to:

GUTHRIE *Clinic Ltd.*
Sayre, PA 18840
(717) 888-5858

ATTN: Donald R. Weaver, M.D.
Medical Director



Quality images
are only half
the picture...

Lower cardiovascular ris

Coronary and ventricular imaging procedures demand a higher level of performance from contrast media: quality images plus limited interference with cardiac function. Hexabrix is an ideal choice for cardiac imaging for just that reason.

Less effect on cardiac and renal function

Hexabrix offers less interference with cardiac function and less risk of nephrotoxicity when compared with conventional contrast media.[1-4] This is particularly important for procedures such as PTCA, where larger volumes of contrast media are necessary.

Lowest osmolality

Of the three newer contrast agents, Hexabrix offers the lowest osmolality per milligram of iodine (600 mOsm/kg H_2O, versus 796 mOsm for iopamidol-370 and 844 mOsm for iohexol-350). The lower osmolality of Hexabrix reduces undesirable fluid shifts into the vascular space.

F R O M M A L

equally important.

Lower risk of clotting *in vitro*

Studies have demonstrated that Hexabrix has a stronger inhibitory effect on red blood cell clotting *in vitro* than iopamidol or iohexol.[5,6]

Lower viscosity

Hexabrix provides a lower viscosity than iohexol-350 or iopamidol-370, for ease of injection, especially in higher-volume procedures.

Please see the following page for references and brief summary of prescribing information.

Quality images and the lowest osmolality

HEXABRIX†

(ioxaglate meglumine 39.3%/ ioxaglate sodium 19.6% injection)

Changing the look of medicine

N C K R O D T

HEXABRIX† (ioxaglate meglumine 39.3%/ioxaglate sodium 19.6% injection)

HEXABRIX®

Each milliliter of HEXABRIX contains 393 mg of ioxaglate meglumine, 196 mg of ioxaglate sodium and 0.10 mg edetate calcium disodium as a stabilizer. The solution contains 3.48 mg (0.15 mEq) sodium in each milliliter and provides 32% (320 mg/mL) organically bound iodine.

CONTRAINDICATIONS

HEXABRIX is contraindicated for use in myelography. Refer to PRECAUTIONS concerning hypersensitivity. Hysterosalpingography should not be performed during the menstrual period; in pregnant patients; in patients with known infection in any portion of the genital tract; or in patients in whom cervical conization or curettage has been performed within 30 days. Arthrography should not be performed if infection is present in or near the joint.

WARNINGS

Serious or fatal reactions have been associated with the administration of iodine containing radiopaque media. It is of utmost importance to be completely prepared to treat any contrast medium reaction.

As with any contrast medium, serious neurologic sequelae, including permanent paralysis, can occur following cerebral arteriography, selective spinal arteriography and arteriography of vessels supplying the spinal cord. The injection of a contrast medium should never be made following the administration of vasopressors, since they strongly potentiate neurologic effects.

In patients with subarachnoid hemorrhage, a rare association between contrast administration and clinical deterioration, including convulsions and death, has been reported. Therefore, administration of intravascular iodinated contrast media in these patients should be undertaken with caution.

A definite risk exists in the use of intravascular contrast agents in patients who are known to have multiple myeloma. In such instances anuria has developed, resulting in progressive uremia, renal failure and eventually death. Although neither the contrast agent nor dehydration has separately proved to be the cause of anuria in myeloma, it has been speculated that the combination of both may be a causative factor. The risk in myelomatous patients is not a contraindication to the procedure; however, partial dehydration in the preparation of these patients for the examination is not recommended since this may predispose to precipitation of myeloma protein in the renal tubules. No form of therapy, including dialysis, has been successful in reversing the effect. Myeloma, which occurs most commonly in persons over 40, should be considered before instituting intravascular administration of contrast agents.

Administration of radiopaque materials to patients known or suspected to have pheochromocytoma should be performed with extreme caution. If, in the opinion of the physician, the possible benefits of such procedures outweigh the considered risks, the procedures may be performed; however, the amount of radiopaque medium injected should be kept to an absolute minimum. The blood pressure should be assessed throughout the procedure, and measures for treatment of a hypertensive crisis should be available.

Since intravascular administration of contrast media may promote sickling in individuals who are homozygous for sickle cell disease, fluid restriction is not advised.

In patients with advanced renal disease, iodinated contrast media should be used with caution and only when the need for the examination dictates, since excretion of the medium may be impaired. Patients with combined renal and hepatic disease, those with severe hypertension or congestive heart failure and recent renal transplant recipients present an additional risk.

Renal failure has been reported in patients with liver dysfunction who were given an oral cholecystographic agent followed by an intravascular iodinated radiopaque agent and also in patients with occult renal disease, notably diabetics and hypertensives. In these classes of patients there should be no fluid restriction and every attempt made to maintain normal hydration prior to contrast medium injection, since dehydration is the single most important factor influencing further renal impairment.

Caution should be exercised in performing contrast medium studies in patients with endotoxemia and/or those with elevated body temperatures.

Reports of thyroid storm occurring following the intravascular use of iodinated radiopaque agents in patients with hyperthyroidism or with an autonomously functioning thyroid nodule, suggest that this additional risk be evaluated before use of this drug. Iodine-containing contrast agents may alter the results of thyroid function tests which depend on iodine estimation, e.g., PBI, and may also affect results of radioactive iodine uptake studies. Such tests, if indicated, should be performed prior to the administration of this preparation.

PRECAUTIONS

Diagnostic procedures which involve the use of iodinated intravascular contrast agents should be carried out under the direction of personnel skilled and experienced in the particular procedure to be performed. All procedures utilizing contrast media carry a definite risk of producing adverse reactions. While most reactions are minor, life-threatening and fatal reactions may occur without warning, and this risk must be weighed against the benefit of the procedure. A fully equipped emergency cart, or equivalent supplies and equipment, and personnel competent in recognizing and treating adverse reactions of all types should always be available. If a serious reaction should occur, immediately discontinue administration. Since severe delayed reactions have been known to occur, emergency facilities and competent personnel should be available for at least 30 to 60 minutes after administration. (See ADVERSE REACTIONS.)

Preparatory dehydration is dangerous and may contribute to acute renal failure in infants, young children, the elderly, patients with pre-existing renal insufficiency, patients with multiple myeloma, patients with advanced vascular disease and diabetic patients.

Acute renal failure has been reported in diabetic patients with diabetic nephropathy and in susceptible non-diabetic patients (often elderly with pre-existing renal disease) following the administration of iodinated contrast agents. Therefore, careful consideration of the potential risks should be given before performing this radiographic procedure in these patients.

Severe reactions to contrast media often resemble allergic responses. This has prompted the use of several provocative pretesting methods, none of which can be relied on to predict severe reactions. No conclusive relationship between severe reactions and antigen-antibody reactions or other manifestations of allergy has been established. The possibility of an idiosyncratic reaction in patients who have previously received a contrast medium without ill effect should always be considered. Prior to the injection of any contrast medium, the patient should be questioned to obtain a medical history with emphasis on allergy and hypersensitivity. A positive history of bronchial asthma or allergy (including food), a family history of allergy, or a previous reaction or hypersensitivity to a contrast agent may imply a greater than usual risk. Such a history may be more accurate than pre-testing in predicting the potential for reaction, although not necessarily the severity or type of reaction in the individual case. A positive history of this type does not arbitrarily contraindicate the use of a contrast agent when a diagnostic procedure is thought essential, but does call for caution. (See ADVERSE REACTIONS.)

Prophylactic therapy including corticosteroids and antihistamines should be considered for patients who present with a strong allergic history, a previous reaction to a contrast medium, or a positive pre-test since in these patients the incidence of reaction is two to three times that of the general population. Adequate doses of corticosteroids should be started early enough prior to contrast medium injection to be effective and should continue through the time of injection and for 24 hours after injection. Antihistamines should be administered within 30 minutes of the contrast medium injection. Recent reports indicate that such pre-treatment does not prevent serious life-threatening reactions, but may reduce both their incidence and severity. A separate syringe should be used for these injections.

General anesthesia may be indicated in the performance of some procedures in selected patients; however, a higher incidence of adverse reactions has been reported in these patients, and may be attributable to the inability of the patient to identify untoward symptoms or to the hypotensive effect of anesthesia which can prolong the circulation time and increase the duration of contact of the contrast agent.

Angiography should be avoided whenever possible in patients with homocystinuria because of the risk of inducing thrombosis and embolism.

PRECAUTIONS FOR SPECIFIC PROCEDURES

Pediatric Angiocardiography: It is advisable to monitor for ECG and vital signs changes throughout the procedure.

When large individual doses are administered, sufficient time should be allowed for any observed changes to return to or near baseline prior to making the next injection.

Caution should be used when making right heart injections in patients with pulmonary hypertension or incipient heart failure, since this may lead to increased right side pressures with subsequent bradycardia and systemic hypotension. Patients with pulmonary disease present additional risks.

Caution is advised in cyanotic infants since apnea, bradycardia, other arrhythmias and a tendency to acidosis are more likely to occur.

Since infants are more likely to respond with convulsions than are adults, the amount of total dosage is of particular importance. Repeated injections are hazardous in infants weighing less than 7 kg, particularly when these infants have pre-existing compromised right heart function or obliterated pulmonary vascular beds.

Selective Coronary Arteriography with or without left ventriculography: During the administration of large doses of HEXABRIX, continuous monitoring of vital signs is desirable. Caution is advised in the administration of large volumes to patients with incipient heart failure because of the possibility of aggravating the pre-existing condition. Hypotension should be corrected promptly since it may result in serious arrhythmias.

Special care regarding dosage should be observed in patients with right ventricular failure, pulmonary hypertension, or stenotic pulmonary vascular beds because of hemodynamic changes which may occur after injection into the right heart outflow tract.

Peripheral Arteriography: Moderate decreases in blood pressure occur frequently with intra-arterial (brachial) injections. This change is usually transient and requires no treatment; however, the blood pressure should be monitored for approximately ten minutes following injection.

Extreme caution during injection of the contrast agent is necessary to avoid extravasation and fluoroscopy is recommended. This is especially important in patients with severe arterial disease.

Cerebral Angiography: Cerebral angiography should be performed with special caution in patients with advanced arteriosclerosis, severe hypertension, cardiac decompensation, senility, recent cerebral thrombosis or embolism, and migraine.

Intra-Arterial Digital Subtraction Angiography: The risks associated with IA-DSA are those usually attendant with catheter procedures. Following the procedure, gentle pressure hemostasis is required, followed by observation and immobilization of the limb for several hours to prevent hemorrhage from the site of arterial puncture.

Patient motion, including respiration and swallowing, can result in misregistration leading to image degradation and non-diagnostic studies.

Intravenous Digital Subtraction Angiography: The risks associated with IV-DSA include those usually attendant with catheter procedures and include intramural injections, vessel dissection and tissue extravasation. The potential risk is reduced when small test injections of contrast medium are made under fluoroscopic observation to insure that the catheter tip is properly positioned and, in the case of peripheral placement, that the vein is of adequate size.

Patient motion, including respiration and swallowing, can result in misregistration leading to image degradation and non-diagnostic studies.

Peripheral Venography: Special care is required when venography is performed in patients with suspected thrombosis, phlebitis, severe ischemic disease, local infection or a totally obstructed venous system.

Extreme caution during injection of contrast media is necessary to avoid extravasation and fluoroscopy is recommended. This is especially important in patients with severe arterial or venous disease.

Excretory Urography: Infants and small children should not have any fluid restrictions prior to excretory urography. (See WARNINGS and PRECAUTIONS concerning preparatory dehydration.)

Contrast Enhancement in Body Computed Tomography: Patient cooperation is essential since patient motion, including respiration, can markedly affect image quality. The use of an intravascular contrast medium can obscure tumors in patients undergoing CT evaluation of the liver, resulting in a false negative diagnosis. Dynamic CT scanning is the procedure of choice for malignant tumor enhancement.

Arthrography: Strict aseptic technique is required to prevent the introduction of infection. Fluoroscopic control should be used to insure proper introduction of the needle into the synovial space and prevent extracapsular injection. Aspiration of excessive synovial fluid will reduce the pain on injection and prevent the dilution of the contrast agent. It is important that undue pressure not be exerted during the injection.

Hysterosalpingography: Caution should be exercised in patients suspected of having cervical or tubal carcinoma to avoid possible spread of the lesion by the procedure. Delayed onset of pain and fever (1-2 days) may be indicative of pelvic infection.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term animal studies have been performed to evaluate carcinogenic potential. However, animal studies suggest that this drug is not mutagenic and does not affect fertility in males or females.

Pregnancy Category B: Reproduction studies have been performed in rats and rabbits at doses up to two times the maximum adult human dose and have revealed no evidence of impaired fertility or harm to the fetus due to HEXABRIX. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: Ioxaglate salts are excreted unchanged in human milk. Because of the potential for adverse effects in nursing infants, bottle feedings should be substituted for breast feedings for 24 hours following the administration of this drug.

Pediatric Use: Safety and effectiveness in children has been established in pediatric angiocardiography and intravenous excretory urography. Data have not been submitted to support the safety and effectiveness of HEXABRIX in any other indication.

(Precautions for specific procedures receive comment under that procedure.)

ADVERSE REACTIONS

Adverse reactions to injectable contrast media fall into two categories: chemotoxic reactions and idiosyncratic reactions.

Chemotoxic reactions result from the physiochemical properties of the contrast media, the dose and the speed of injection. All hemodynamic disturbances and injuries to organs or vessels perfused by the contrast medium are included in this category.

Idiosyncratic reactions include all other reactions. They occur more frequently in patients 20 to 40 years old. Idiosyncratic reactions may or may not be dependent on the dose injected, the speed of injection, the mode of injection and the radiographic procedure. Idiosyncratic reactions are subdivided into minor, intermediate and severe. The minor reactions are self-limited and of short duration; the severe reactions are life-threatening and treatment is urgent and mandatory.

NOTE: Not all of the following adverse reactions have been reported with HEXABRIX. Because HEXABRIX is an iodinated intravascular contrast agent, all of the side effects and toxicity associated with agents of this class are theoretically possible, and this should be borne in mind when HEXABRIX is administered.

Severe, life-threatening anaphylactoid reactions, mostly of cardiovascular origin, have occurred following the administration of HEXABRIX as well as other iodine-containing contrast agents. Most deaths occur during injection or 5 to 10 minutes later; the main feature being cardiac arrest with cardiovascular disease as the main aggravating factor. Isolated reports of hypotensive collapse and shock are found in the literature. Based upon clinical literature, reported deaths from the administration of conventional iodinated contrast agents range from 6.6 per 1 million (0.00066 percent) to 1 in 10,000 patients (0.01 percent).

Regardless of the contrast agent employed, the overall estimated incidence of serious adverse reactions is higher with coronary arteriography than with other procedures. Cardiac decompensation, serious arrhythmias, or myocardial ischemia or infarction may occur during coronary arteriography and left ventriculography.

The most frequent adverse reactions are nausea, vomiting, facial flush and a feeling of body warmth. These are usually of brief duration. In double-blind clinical trials, HEXABRIX produced less discomfort upon injection (pain and heat) when compared to various other contrast agents. Other reactions include the following:

Hypersensitivity reactions: Dermal manifestations of urticaria with or without pruritus, erythema and maculopapular rash. Dry mouth. Sweating. Conjunctival symptoms. Facial, peripheral and angioneurotic edema. Symptoms related to the respiratory system include sneezing, nasal stuffiness, coughing, choking, dyspnea, chest tightness and wheezing, which may be initial manifestations of more severe and infrequent reactions including asthmatic attack, laryngospasm and bronchospasm with or without edema, pulmonary edema, apnea and cyanosis. Rarely, these allergic-type reactions can progress into anaphylaxis with loss of consciousness, coma, severe cardiovascular disturbances, and death.

Cardiovascular reactions: Generalized vasodilation, flushing and venospasm. Occasionally thrombosis or, rarely, thrombophlebitis. Extremely rare cases of disseminated intravascular coagulation resulting in death have been reported. Severe cardiovascular responses include rare cases of hypotensive shock, coronary insufficiency, cardiac arrhythmia, fibrillation and arrest. These severe reactions are usually reversible with prompt and appropriate management; however, fatalities have occurred.

Technique reactions: Extravasation with burning pain, hematomas, ecchymosis and tissue necrosis, vascular constriction due to injection rate, thrombosis and thrombophlebitis.

Neurological reactions: Spasm, convulsions, aphasia, syncope, paresis, paralysis resulting from spinal cord injury and pathology associated with the syndrome of transverse myelitis, visual field losses which are usually transient but may be permanent, coma and death.

Other reactions: Headache, trembling, shaking, chills without fever, hyperthermia and lightheadedness. Temporary renal shutdown or other nephropathy.

Pediatric angiocardiography has been complicated by intramural injection with marked adverse effects on cardiac function.

During selective coronary arteriography with or without left ventriculography, patients may have clinically insignificant ECG changes. The following adverse effects have occurred in conjunction with the administration of iodinated intravascular contrast agents for this procedure: hypotension, shock, anginal pain, myocardial infarction, cardiac arrhythmias (bradycardia, ventricular tachycardia, ventricular fibrillation) and cardiac arrest. Fatalities have been reported. Complications to the procedure include dissection of coronary arteries, dislodgement of atheromatous plaques, perforation, hemorrhage and thrombosis.

Following peripheral arteriography, hemorrhage and thrombosis have occurred at the puncture site of the percutaneous injection. Brachial plexus injury has been reported following axillary artery injection.

The major causes of cerebral arteriographic adverse reactions appear to be repeated injections of the contrast material, administration of doses higher than those recommended, the presence of occlusive atherosclerotic vascular disease and the method and technique of injection. Adverse reactions are normally mild and transient. A feeling of warmth in the face and neck is frequently experienced. Infrequently, a more severe burning discomfort is observed. Transient visual hallucinations have been reported. Serious neurological reactions that have been associated with cerebral angiography and not listed under Adverse Reactions include stroke, amnesia and respiratory difficulties. Visual field defects with anopsia and reversible neurological deficit lasting from 24 hours to 48 hours have been reported. Confusion, disorientation with hallucination, and absence of vision sometimes lasting for one week have also been reported. Cardiovascular reactions that may occur with some frequency are bradycardia and either an increase or decrease in systemic blood pressure. The blood pressure change is transient and usually requires no treatment. Arthrography may induce joint pain or discomfort which is usually mild and transient but occasionally may be severe and persist for 24 to 48 hours following the procedure. Effusion requiring aspiration may occur in patients with rheumatoid arthritis. Fever and pain, cramping and tenderness of the abdomen have been reported following hysterosalpingography.

OVERDOSAGE

Overdosages may occur. The adverse effects of overdosage are life-threatening and affect mainly the pulmonary and cardiovascular systems. The symptoms may include cyanosis, bradycardia, acidosis, pulmonary hemorrhage, convulsions, coma and cardiac arrest. Treatment of an overdose is directed toward the support of all vital functions and prompt institution of symptomatic therapy.

Ioxaglate salts are dialyzable.

The intravenous LD_{50} values of HEXABRIX (in grams of iodine/kilogram body weight) were 11.2 g/kg in mice, >8 g/kg in rats, >6.4 g/kg in rabbits and >10.2 g/kg in dogs.

DOSAGE AND ADMINISTRATION

Details on dosage are provided in the package insert. *CONSULT FULL PACKAGE INSERT BEFORE USE.*

Validation of Double-Spike Electrograms as Markers of Conduction Delay or Block in Atrial Flutter

FRANCISCO G. COSIO, MD, FERNANDO ARRIBAS, MD, JOSE MARIA BARBERO, MD, CARLOS KALLMEYER, MD, and ANTONIO GOICOLEA, MD

Recent mapping studies of atrial flutter have shown that fragmented electrograms can be found in most cases from the posterior, posteroseptal and posterolateral walls of the right atrium. The fragmentation pattern most often consists of a double spike. To further assess double-spike electrograms as a possible marker of conduction delay, bipolar electrograms were continuously recorded during atrial overdrive pacing of common flutter from the right atrium (7 patients) and from the proximal coronary sinus (5). Baseline double-spike separation of 50 to 130 ms was unchanged in 1 patient and slightly increased (5 to 25 ms) in 4 by coronary sinus pacing. The electrogram sequence was unchanged and the surface morphology was similar to that of basal flutter. Right atrial pacing decreased double-spike separation by 25 to 85 ms from basal values of 45 to 175 ms (23 to 83%), suggesting fusion in the area of fragmented electrograms. These findings suggest that double-spike electrograms represent activation on both sides of a conduction delay zone. The changes induced in these electrograms by pacing from the anterior right atrium and the coronary sinus are consistent with flutter circuits rotating counterclockwise (frontal plane) in the posterior right atrial wall in common atrial flutter.

(Am J Cardiol 1988;61:775–780)

The mechanism of atrial flutter has been studied in experimental and naturally occurring animal models.[1–5] Reentry has been the common underlying mechanism, conduction delay or block being essential either as a generator of a fixed obstacle for the activation front[2–4] or by slowing conduction velocity in part or all the circuit.[1,4]

Human flutter is defined largely on an electrocardiographic basis, considering atrial wave cycle length and morphology.[6,7] The changes induced in flutter cycles by overdrive pacing or extrastimuli[8,9] support a reentrant mechanism; however, little information is available on the configuration of the reentrant circuits and the participation of localized conduction delays.

Recent clinical mapping studies,[10–12] including work from our laboratory, suggest that most flutter circuits are contained in the right atrium, have a rather large amplitude and rotate around the inferior vena cava. Abnormal, fragmented electrograms suggesting areas of abnormal conduction have been recorded within the circuit in both human and animal flutter.[5,11–13]

The present study reports the changes induced by overdrive pacing in the fragmentation pattern that help understand the meaning of these abnormal electrograms and shed new light on the mechanisms underlying atrial flutter.

Methods

We reviewed the recordings obtained during atrial pacing in 11 patients with atrial flutter. Two conditions had to be fulfilled by all participants: identification during atrial mapping of a large right atrial circuit and a record of fragmented electrograms inscribing double-spike patterns. Clinical and electrocardiographic data are listed in Table I. All patients had a clinical indication for flutter cardioversion and gave consent for it and the complementary mapping procedure. The

COLD = chronic obstructive lung disease; CS = coronary sinus; DS Sep = double-spike separation; DS Site = location of the double-spike electrograms; HBP = high blood pressure; HPRA = high posterior right atrium; LPLRA = low posterolateral right atrium; LPRA = low posterior right atrium; LSRA = low septal right atrium; Mapping (%) = percent of the flutter cycle covered by the recorded electrograms; MPLRA = midposterolateral right atrium; MPRA = midposterior right atrium; P = paced; RA = right atrium; WPW = Wolff-Parkinson-White syndrome.

study was approved by the Hospital Research Committee.

Quadripolar catheter-electrodes were introduced through a right antecubital vein and 1 or 2 femoral veins under local anesthesia. Bipolar (1-cm separation) electrograms were amplified and filtered (40 to 500 Hz) in Electronics for Medicine amplifiers. Recordings were made at a paper speed of 100 mm/s. Amplifier gain was adjusted to make recorded electrograms 2 to 3 cm in size. Surface orthogonal leads X, Y and Z (Frank) or standard leads I, II and III were used as reference.

Mapping procedure: A quadripolar catheter-electrode was advanced to the coronary sinus, with recordings obtained from the most distal position attainable to the proximal portions, at intervals of 1 to 2 cm. Another quadripolar catheter electrode was advanced to the right atrial appendage and recordings obtained from the distal (appendage) and proximal (right atrial "roof") pairs of electrodes. One or both of these catheters were left in place as fixed endocardial references for the remainder of the recordings obtained sequentially by means of a third or still a fourth catheter-electrode. Electrode position was checked by biplane fluoroscopy. Using the entrance of both venae cavae as references, the right atrial wall was divided into "septal," "posterior," "lateral" and "anterior," with 3 recording levels made in each: "high" (cranial), "mid" and "low" (caudal). In some cases we made detailed recordings around the superior or inferior vena cava entrances, or both.

Maps were constructed on a schematic representation of both atria, as shown in Figure 1. The onset of activation (0 point) was ascribed arbitrarily. The electrograms were timed at the onset of the first sharp deflection. If electrogram duration was increased to ≥50 ms or if there were double or multiple spikes, the electrograms were represented by a double figure, indicating the onset and end.

Pacing procedure: Pacing was from the coronary sinus in 5 patients and from the high or mid anterior right atrium in 7. One patient was paced from both sites. Progressively shorter cycle lengths were used, in 10 to 20 ms runs, until sinus rhythm or atrial fibrillation resulted. Four endocardial recordings were obtained during pacing in 10 patients and 3 in 1 (the area with double-spike electrograms was included in all cases).

For the sake of clarity some of the recordings have been eliminated from the figures shown.

Statistical analysis: Student *t* test for paired data was used to analyze the statistical significance of the observed differences.

Results

Baseline data: Clinical and electrophysiologic features are listed in Table I. Flutter cycle length ranged from 180 to 300 ms. All patients with cycles longer than 250 ms were receiving antiarrhythmic drugs. Flutter wave pattern was "common" in 8, "rare" (positive waves in inferior leads) in 1 and characterized by low-voltage activity in 2. All patients not showing a common flutter pattern were receiving antiarrhythmic drugs.

Flutter maps covered 56 to 100% of the cycle length and were compatible in all cases with large circuits contained in the right atrium. Activation followed a caudocranial direction on the septal right atrium and a craniocaudal direction on the lateral and anterior walls. The circuit was closed by means of a "return" path between the inferior vena cava and the tricuspid valve. Activation of the coronary sinus proceeded from right to left in all cases. A typical map is shown in Figure 1.

Fragmented "double spike" electrograms were recorded from the posterior, posterolateral or posteroseptal wall. Double-spike separation measured between the onset of each spike ranged from 45 to 175 ms. Although the stability of the double-spike electrograms was remarkable for recording periods of up to 20 minutes while the recording position was stable, small displacements of ≤1 cm could change the double-spike to a single-spike electrogram.

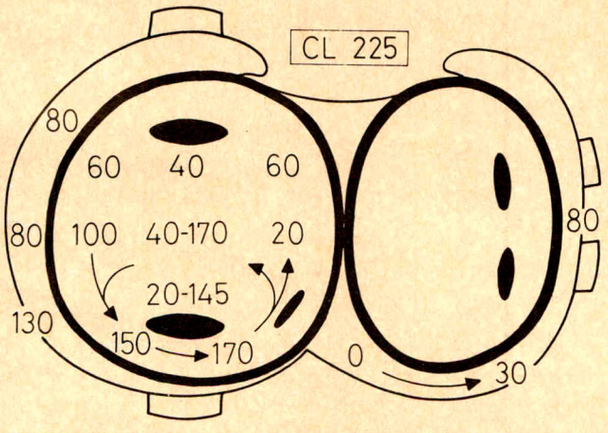

FIGURE 1. Typical flutter map obtained from patient 6. The atria are represented from an "anterior" view, as if the ventricles had been cut off and the atria were seen with a wide-angle lens from the tricuspid and mitral rings. The anterior wall is represented "outside" the tricuspid ring. The openings of the coronary sinus, venae cavae and left pulmonary veins are shown. The onset of activation is arbitrarily assigned. The *arrows* indicate the suggested activation pathway. The double figures indicate areas of fragmented electrograms and mark the onset and end of local electrograms.

Changes in double-spike electrograms during pacing: Complete capture of the atria was shown during pacing by surface and endocardial recordings. Double-spike separation changes followed 2 different patterns related to the pacing site.

Coronary sinus pacing produced no change in 1 patient and a slight increase in 4 (Figure 2). Baseline separation ranged from 50 to 130 ms and the increase recorded in these 4 cases ranged from 5 to 25 ms (6 to 50%). Mean baseline separation of 70 ± 35 ms (standard deviation) increased to 84 ± 30 ms ($p < 0.05$). The increase was related to pacing cycle length (Figure 3).

In 7 cases pacing was in the high or mid anterior right atrium. Baseline separation ranged from 45 to 175 ms (83 ± 43) and during pacing it decreased consistent-

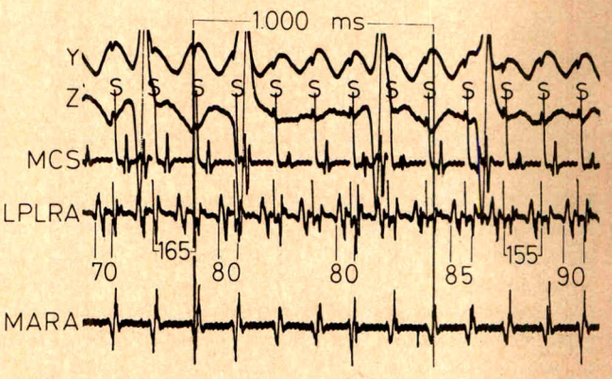

FIGURE 2. Effect of coronary sinus stimulation in patient 5. Surface leads Y and Z (Frank) and endocardial electrograms from midcoronary sinus (MCS), low posterolateral right atrium (LPLRA) and midanterior right atrium (MARA) are shown. Pacing artifacts are best seen at MCS. A double-spike electrogram is recorded at LPLRA. As pacing cycle length decreases from 165 ms (*left*) to 155 ms (*right*), separation between the 2 spikes at LPLRA increases from 70 to 90 ms. Note that flutter waves remain negative in lead Y during overdrive pacing. S = stimulus artifact.

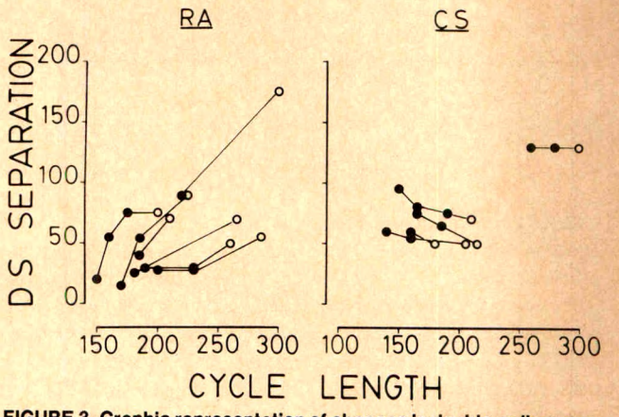

FIGURE 3. Graphic representation of changes in double-spike separation induced by pacing in the anterior right atrium and coronary sinus. All values are in ms. *Open circles* indicate basal flutter values and *solid circles* pacing-induced cycle lengths. CS = coronary sinus pacing; DS = double spike; RA = right atrial pacing.

ly by 15 to 75 ms (23 to 89%) to a mean of 38 ± 25 ($p < 0.01$) (Figure 4). Of 4 cases paced at more than 1 cycle length, 2 showed a progressive fusion of the double spike and 2 showed a decrease in separation with the initial pacing run but without additional decreases with shorter cycle lengths (Figure 3).

The pattern of double-spike capture was also different. Pacing from the coronary sinus captured both components simultaneously, whereas pacing from the right atrium consistently resulted in advancement (capture) of the second component of the double spike one cycle earlier than the first (Figure 4).

Patterns of flutter interruption: In the case of patient 8, a decrease in spike separation from 55 to 30 ms at a pacing cycle length of 230 ms and no further narrowing occurred with a 200 ms cycle; however, a change in electrogram sequence led to flutter interruption at this shorter cycle (Figure 5). Six other patients developed sinus rhythm after complete disorganiza-

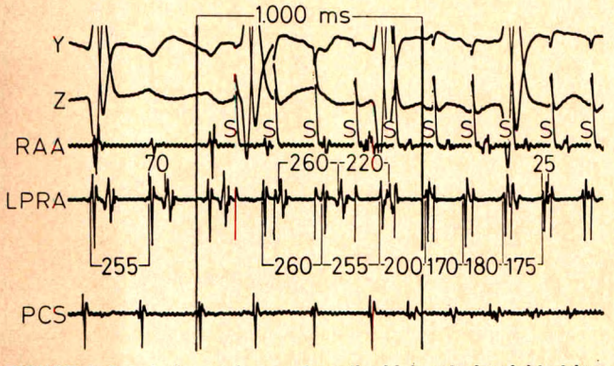

FIGURE 4. Onset of a pacing run from the high anterior right atrium in patient 10. Surface leads Y and Z (Frank) and endocardial electrograms from the right atrial appendage, low posterior right atrium and proximal coronary sinus are shown. Atrial capture occurs with the third pacing stimulus at the right atrial appendage. One cycle later, the second component of the double-spike electrogram of the low posterior right atrium is advanced (indicating capture), while the first component still has not changed sequence. As the paced captured cycle stabilizes at 175 ms, the 2 spikes have almost fused completely into 1. LPRA = low posterior right atrium; PCS = proximal coronary sinus; RAA = right atrial appendage; S = stimulus artifact.

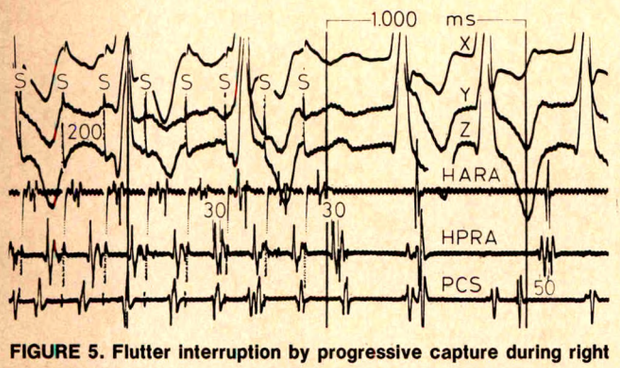

FIGURE 5. Flutter interruption by progressive capture during right atrial pacing in patient 8. Surface leads X, Y and Z (Frank) and endocardial electrograms from high anterior right atrium, high posterior right atrium and proximal coronary sinus are shown. With a pacing cycle length of 200 ms, progressive change in electrogram sequence develops (note the change in temporal relation between the high posterior right atrium and the proximal sinus) and flutter waves become positive in lead Y and Z. When pacing stops, flutter has been substituted by an atrioventricular reentrant tachycardia using a left-sided accessory pathway. Fragmented electrograms are now slightly wider than during pacing. HARA = high anterior right atrium; HPRA = high posterior right atrium; PCS = proximal coronary sinus; S = stimulus artifact.

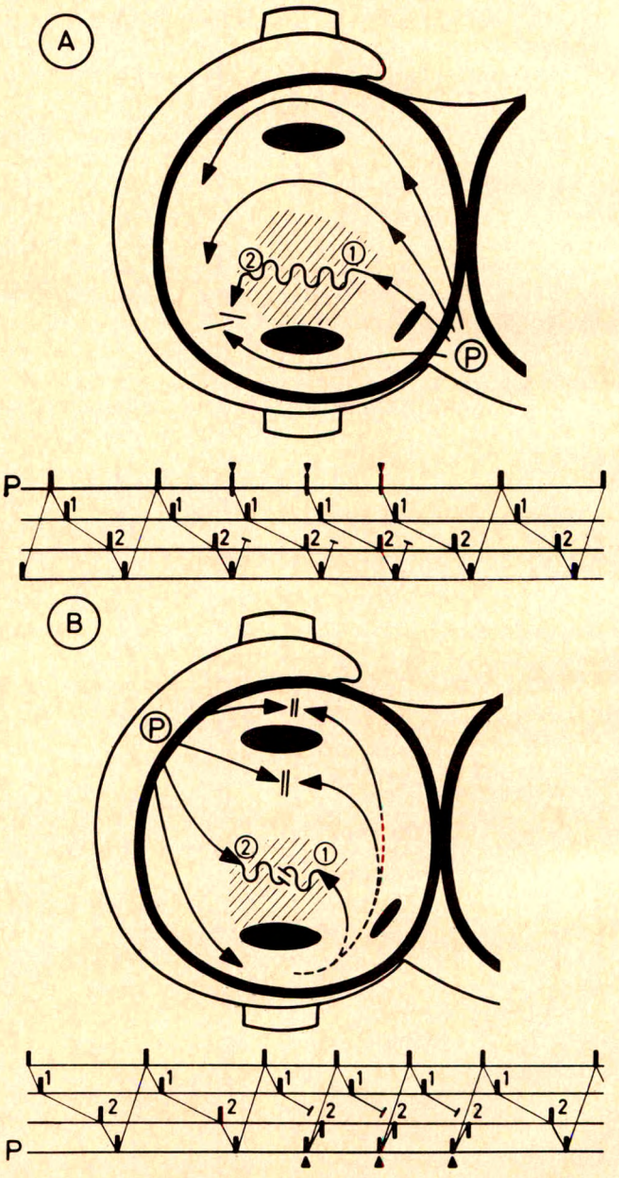

FIGURE 6. *A*, schematic representation of the events proposed during entrainment with orthodromic penetration of the abnormal conduction area. *B*, events proposed during entrainment with antidromic penetration of the abnormal conduction area. Two consecutive activation cycles are shown, the last paced cycle and the preceding entrained cycle. The tail of the before-last cycle has been marked by an interrupted trace. Numbers 1 and 2 mark the postulated origins of the first and second spike of the double electrograms. P = pacing site.

tion of flutter. In 3 this period of disorganization lasted 1 to 5 seconds and in the remaining 3 it was sustained as atrial fibrillation for 30 seconds to 3 hours.

Discussion

Our group of patients was selected in order to study the effect of orthodromic and antidromic penetration of the abnormal electrogram zone. As we knew the direction of flutter activation we could establish that pacing from the coronary sinus entered this area orthodromically, whereas penetration during anterior right atrial pacing was antidromic (Figure 6). Coronary sinus pacing did not change electrogram sequence or flutter wave morphology, the only change observed being a slight widening of double-spike separation probably due to some degree of decremental conduction. This was consistent with the situation described as "concealed entrainment,"[14,15] in which the flutter circuit is entrained but fusion cannot be demonstrated (Figure 6A). Fusion would probably be demonstrated if recordings were obtained from the area between the inferior vena cava and the tricuspid ring.

Pacing from the anterior right atrium consistently narrowed double-spike separation, with the particular feature of advancing the second spike 1 cycle before the first. This most likely represents antidromic penetration of the abnormal electrogram area and fusion in its midst with the orthodromic activation front (Figure 6B). Such reproducible behavior rules out the possibility of the double-spike electrograms being due to motion artifacts. Bipolar recordings would seem to be picking up 2 activation fronts, close anatomically but widely separated in time.

This situation may be due to an area of slow conduction separating 2 fast conduction zones, in this case the 2 spikes representing entrance and exit of the activation front in the slow conduction area (Figure 7) as proposed by Brachman et al[16] in ventricular reentrant circuits. This interpretation also is supported by the work of Gardner et al[17] in infarcted ventricular myocardium showing that fragmented, double- or multiple-spike electrograms are inscribed as an activation front crosses an area where normal myocardial fibers are separated by areas of necrosis. Another possibility is that a "line" of complete block may be present as in 1 of the canine flutter models of Boineau et al.[4] Our mapping technique was too crude to allow us to separate these 2 possibilities, and, although we can propose that conduction delays in the posterior right atrium seem to underlie most atrial flutter circuits in men, we cannot say if conduction through this area constitutes part of the circuit or if the area acts only as a barrier, "enlarging" the central anatomic obstacle made by the inferior vena cava. On the other hand, we have not ruled out the presence of more areas of slow conduction in other parts of the circuit that seem to constitute an obligatory "return" pathway, particularly in the caudal parts of the right atrium that are anatomically more complex and technically more difficult to map, as is the area around the inferior vena cava, coronary sinus and tricuspid valve. Klein et al[18] described slow conduction in this area in 2 cases of atrial flutter undergoing epicardial mapping in the operating room.

Anisotropic conduction[19] could play a role in these conduction delays because the activation front seemed to course perpendicularly to the middle and posterior internodal pathways in the posterior atrial wall. Conduction across parallel bundles of myocardial fibers can be quite slow and inscribe fragmented local electrograms.[20]

Another important question is the possible participation of these conduction abnormalities in the flutter circuit. The observations during flutter interruption in patient 8 are suggestive in this respect. Maximal reduction in fragmentation width occurred in this patient at a pacing cycle length of 230 ms, but it was necessary to reduce cycle length to 200 ms to penetrate the circuit deeply enough to change the overall electrogram sequence, and this led to flutter interruption. If this means inversion of conduction through the double-spike zone, then conduction would appear to be slower in the orthodromic than in the antidromic sense. Indeed, when flutter was substituted by a reentrant atrioventricular tachycardia using a left anomalous pathway, activation entered this area in the same direction as the flutter circuit and the local electrogram was wider than during pacing from the anterior right atrium at a much shorter cycle length. Unfortunately, all the other patients developing sinus rhythm went through periods of disorganization and we could not reproduce this observation.

Future studies should try to establish whether the block or slow conduction are unidirectional and if a critical degree of delay in this area during its orthodromic penetration by coronary sinus pacing is a sufficient and necessary condition for atrial flutter induction.

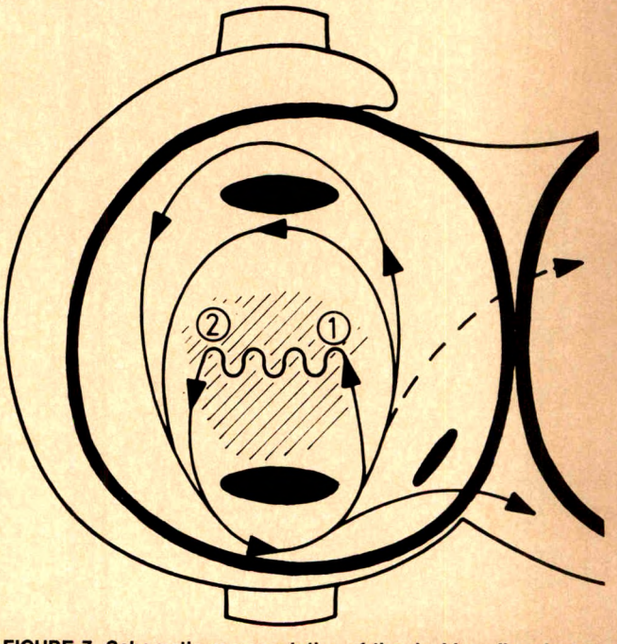

FIGURE 7. Schematic representation of the double-spike electrogram area conceived as a slow-conduction zone supporting the flutter circuit. The numbers indicate the suggested origin of the first and second spike of the electrograms.

Characteristics of Entrainment During Autodecremental Atrial and Ventricular Stimulation

AGUSTIN CASTELLANOS, MD, LIAQAT ZAMAN, MD, PEDRO FERNANDEZ, MD, BOLIVAR PORTILLO, MD, BAROUH V. BERKOVITS, EE, and ROBERT J. MYERBURG, MD

The entrainment characteristics of orthodromic circus movement tachycardias occurring during autodecremental atrial and ventricular stimulation were studied in 9 patients with manifest Wolff-Parkinson-White syndrome. The phenomenon occurred in 34 of 38 episodes of tachycardia during autodecremental atrial stimulation. It was not seen in 4 episodes because the first impulse penetrating the circuit terminated the arrhythmia. Invariably, the HH and VV intervals were not equal to, but longer than, the stimulus-stimulus intervals, thus not fulfilling the definition of "classic" (constant cycle length) entrainment postulated by Okumura et al. Furthermore, the first 2 of the 3 diagnostic criteria were not demonstrated and the third only could be demonstrated in 7 episodes. Tachycardia termination was achieved in all 38 episodes. Entrainment occurred during autodecremental ventricular stimulation in 79 of 80 episodes, with the AA and $H^{-}H^{-}$ intervals (when visible) being equal to the corresponding paced cycle lengths. Moreover, the intervals between the last paced ventricular beat and the first ventricular beat of the resumed tachycardia were invariably longer than the last stimulus-stimulus intervals. These characteristics were those which Okumura et al attributed to "concealed" entrainment. Tachycardia termination was achieved in 77 of 80 episodes.

In summary: (1) autodecremental atrial pacing produced a specific form of entrainment that did not fulfill the "classic" definition of Okumura et al; (2) autodecremental ventricular pacing consistently produced "concealed" entrainment; and (3) autodecremental stimulation was very effective in terminating 115 of 118 (98%) of episodes of circus movement tachycardias.

(Am J Cardiol 1988;61:781–786)

In 1983, Waldo et al[1] showed that entrainment of circus movement tachycardias during overdrive pacing constituted an excellent model for the understanding of a variety of electrophysiologic phenomena occurring in patients with reentrant circuits. Most studies[1–4] dealing with overdive pacing of circus movement tachycardias have been performed using constant cycle lengths during each pacing run. Therefore, it seemed of interest to discuss the characteristics of the entrainment observed with the recently introduced self-adapting autodecremental mode of stimulation, in which the pacing cycle lengths decrease during each pacing run.[4,6]

Methods

Patients: Nine patients with manifest Wolff-Parkinson-White syndrome and orthodromic circus movement tachycardia of the usual (short RP interval) type constitute the basis of this report. Pertinent information is listed in Table I.

Electrophysiologic studies: These were performed in accordance with previously described criteria,[4,5,7] after explaining the procedure and obtaining informed consent. Briefly, the technique consisted of introducing tetrapolar catheter electrodes to pace, record, or both, from several atrial (A) sites, the His (H) bundle and right ventricle (V). At least 3 surface leads were obtained simultaneously with the intracardiac leads using Electronics for Medicine or Gould ES 1000 recorders.

TABLE I Clinical Data

Pt	Age (yr), Sex	Organic Heart Disease	Location of Accessory Pathway	Tachycardia Cycle Length (ms)	Drug
1	55, F	0	LFW	315–320	0
				265–275	I
2	58, M	0	LFW	370–390	0

A = amiodarone; AS = anteroseptal; DC = dilated cardiomyopathy; FL = flecainide; I = isoproterenol; LFW = left free wall; PS = posteroseptal; RFW = right free wall.

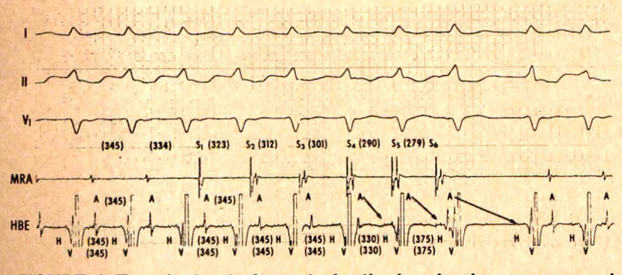

FIGURE 1. Transient entrainment of orthodromic circus movement tachycardia during autodecremental high right atrial stimulation in a patient with a right free wall accessory pathway. Note that during entrainment (oblique arrows from A to H), the HH and VV intervals were not equal to, but longer than, the corresponding stimulus-stimulus (S) intervals. A = atrial electrograms; H = His bundle; HBE = His bundle electrographic lead; MRA = mid-right atrium; V = onset of ventricular electrograms. All intervals are expressed in milliseconds.

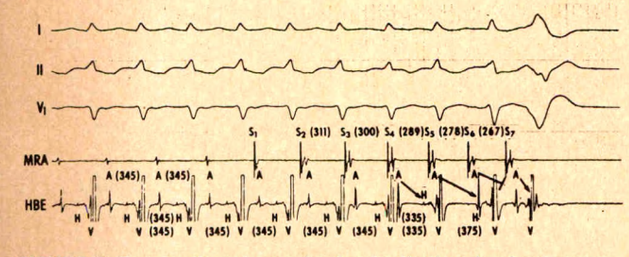

FIGURE 2. Termination of an episode of orthodromic circus movement tachycardia with autodecremental high right atrial stimulation. Presumably, S_6 was blocked in the normal pathway (atrioventricular node) and, as a result, the following impulse which the pacemaker was committed to deliver (because this was the pacing run where it had to emit 7 stimuli) could penetrate the accessory pathway when this structure was no longer refractory. Therefore, S_7 reached the ventricles with a conduction time shorter than that of previous atrial impulses.

At the time of the procedure, 6 patients were not taking any cardioactive medication and 1 was receiving amiodarone. One patient was studied before and after flecainide and 1 before and after a drip infusion of isoproterenol (4 μg/min), given in an attempt to induce this patient's other clinical arrhythmia (atrial fibrillation). The electrophysiologic location of the accessory pathways in every patient is listed in Table I.

Autodecremental pacing: Following completion of the conventional part of the study, the terminals of a ventricular—and subsequently of an atrial—catheter electrode were attached to a specially constructed, self-adapting autodecremental pacemaker (Medtronic) to treat reinduced or spontaneously occurring episodes of circus movement tachycardia.[5] When an activator magnet was placed over the device, it recognized the tachycardia from the intracardiac electrogram and started to emit stimuli.[5] With the program used, each consecutive stimulus (including the first) appeared at intervals 3 to 6% shorter than the cycle length of the tachycardia. Moreover, the initial autodecremental pacing run invariably consisted of 5 stimuli. If the tachycardia was not terminated with this run, the pacemaker delivered 10 beats later 1 additional stimulus in each subsequent run until the arrhythmia was abolished or 14 stimuli emitted. The cycle lengths of the tachycardias ranged between 250 and 395 ms (Table I).

Entrainment (mechanism): During entrainment of a circus movement tachycardia, regardless of the duration (constant or not) of paced cycle lengths, every stimulated impulse penetrates the anterograde limb of the reentry circuit (during atrial pacing) or the retrograde limb (during ventricular pacing) and also collides with the previous retrograde wavefront during atrial pacing or anterograde wavefront during ventricular pacing. Moreover, this occurs in such a way that the tachycardia's potential to resume upon the cessation of pacing is maintained.[1–4,8–11]

Entrainment (definition): Because intervals between electrograms recorded from sites that are essential components of the reentry circuit are equal to the stimulus-stimulus intervals, Okumura et al[2] defined transient "classic" (constant cycle length) entrainment of a tachycardia during rapid stimulation as "an increase in the tachycardia rate to the faster pacing rate." However, as will be demonstrated subsequently, entrainment is best defined during autodecremental pacing as a continuous resetting of the tachycardia circuit.[10]

Entrainment (diagnostic criteria and types): Okumura et al[2] postulated 3 criteria for the diagnosis of "classic" entrainment while pacing the atria: (1) constant fusion except for the last captured beat, which is entrained but not fused; (2) progressive fusion; and (3) localized conduction block to a site(s) for 1 paced beat associated with termination of the tachycardia, followed by activation of that site(s) by the next paced beat from a different direction and with a shorter conduction time. On the other hand, these investigators considered that, during ventricular pacing at constant

cycle lengths, the entrainment was "concealed" if the phenomenon was conceptually present but none of the previous 3 criteria could be demonstrated.

Results

Entrainment during autodecremental atrial pacing: Characteristically, the total number of stimuli in each pacing run did not define how many impulses penetrated the circuit. Thus, in Figure 1 (obtained from a patient with a right free wall accessory pathway), neither S_1, S_2 nor S_3 entered the circuit because the simultaneously occurring HH and VV intervals equalled the tachycardia cycle length (345 ms). Entrainment began when the anterograde atrial impulse produced by S_4 captured the ventricles through the His bundle and thus shortened the corresponding intervals to 330 ms. This impulse also collided, presumably within the accessory pathway, with the retrograde impulse, which, following the simultaneously occurring QRS complex, had penetrated the accessory pathway in a ventricular-auricular direction. The same sequence of events took place after S_5 and S_6. In addition, the ventricular impulse resulting from the QRS complex induced by S_6 (indicated by the longest oblique arrow) penetrated the accessory pathway retrogradely and found no anterograde impulse with which to collide (because atrial pacing had been stopped), and thus was able to reenter the atrioventricular node to resume the tachycardia. During entrainment, the intervals between all recorded atrial electrograms equalled but the HH and VV intervals exceeded the stimulus-stimulus interval (Figure 1). Moreover, there was a gradual increase in the AH intervals. Entrainment was mechanistically present since there was penetration of the anterograde limb and collision, in some part of the circuit, with the preceding retrograde impulse. Indeed, the tachycardia circuit was continually reset.

The *maximal* number of entrained beats in 38 episodes in response to autodecremental atrial stimulation were: 1 in 2 episodes; 2 in 26; 3 in 4 and 4 in 2 (Table II). Entrainment could not be demonstrated in 4 episodes because the first beat penetrating the circuit terminated the arrhythmia.

Okumura's criteria number 1 and 2 for the diagnosis of "classic" entrainment were not met because atrial fusion leading to pure paced atrial beats almost invariably occurred in every pacing run. Furthermore, because entrainment was always seen during a Wenckebach sequence, the last ventricular complex produced by a paced atrial beat appeared at a VV interval which exceeded the corresponding stimulus-stimulus interval (Figure 1).

However, criterion number 3 was observed in 7 episodes (Figure 2). For example, in this figure, S_6 seems to have been blocked at the atrioventricular node, thus terminating the tachycardia. Thereafter, the anterograde impulse produced by S_7 (which had to be emitted because this was the pacing run in which the pacemaker was committed to deliver 7 stimuli) must have reached the accessory pathway when this struc-

ture was no longer refractory from the concealed retrograde conduction into the accessory pathway produced by the next-to-last (narrow) QRS complex. Thus, S_7 was conducted to the ventricles through a different atrioventricular limb (the accessory pathway) than S_6, but with a much shorter conduction time and a wider (preexcited) QRS complex. Consequently, there was a "localized conduction block to sites (atrioventricular node and ventricles) for 1 paced beat associated with termination of the tachycardia followed by activation of those sites by the next paced beat from a different direction (corresponding to the location of the accessory pathway) and with a shorter conduction time."[2]

Tachycardia termination during autodecremental atrial pacing: Tachycardia termination occurred in all 38 episodes treated with autodecremental atrial stimulation when an impulse was blocked at the atrioventricular node and followed by no additional impulse (Figure 3) or followed by 1 more impulse than the pacemaker (because of programming) was committed to deliver (Figure 2). The former was the termination mode in 31 episodes and the latter in 7 episodes. The *minimal* number of paced beats penetrating the circuit required for termination of the tachycardia is shown in Table II.

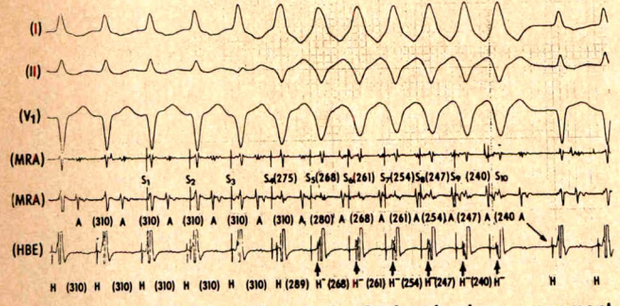

FIGURE 5. Transient entrainment of orthodromic circus movement tachycardia. The characteristics of the phenomenon under consideration were those attributed by Okumura et al[2] to "concealed" entrainment. (See text.)

Entrainment during autodecremental ventricular stimulation: Entrainment (continuous resetting of the tachycardia circuit) was observed in 79 of 80 episodes. The *maximal* number of entrained beats occurring in each episode is presented in Table III (it failed to occur once because the first impulse penetrating the circuit terminated the tachycardia). Again, the total number of stimuli did not define the actual number of impulses entering the circuit. For example, in Figure 4, obtained from a patient with a left free wall accessory pathway, S_1, S_2, S_3 and S_4 failed to penetrate the circuit as determined by the fact that the simultaneously occurring AA and HH intervals equalled the tachycardia cycle length (315 ms). On the other hand, S_5 preexcited the atria through the accessory pathway and thus decreased the AA interval to 270 ms. This impulse (S_5) also penetrated the His bundle retrogradely (as determined by an HH^- interval of 285 ms), reached the atrioventricular node and finally collided in the latter structure with a preceding anterograde atrial impulse.[2,9] Because pacing was stopped after S_5, the atrial impulse produced by this last paced impulse was able to penetrate anterogradely the atrioventricular node and, because there was no retrograde impulse with which to collide (as well as no effective AV nodal refractoriness), it reached the ventricles. Hence, the tachycardia resumed.[2,9]

In Figure 5, obtained from the same patient 5 pacing runs later, only 6 beats penetrated the circuit, although a total of 10 stimuli were delivered. Although transient entrainment was present (from S_5 to S_{10}), the ventricular impulses activated the atria retrogradely via the accessory pathway with a constant (short) ventriculoauricular conduction time and reached, also retrogradely, the atrioventricular node, colliding there with the oncoming anterograde atrial impulses. Consequently, the AA intervals (and the H^-H^- intervals when visible) equalled the stimulus-stimulus intervals.[2,9]

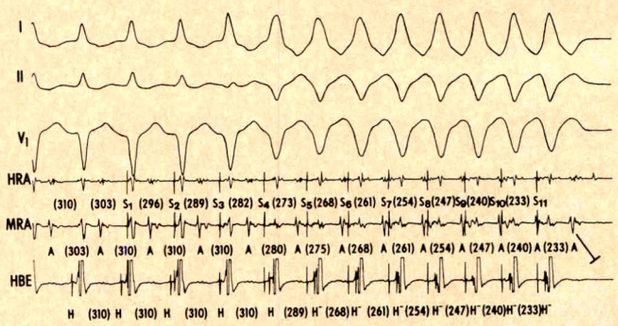

FIGURE 6. Termination of the same episode of orthodromic circus movement tachycardia shown in Figures 4 and 5 with autodecremental ventricular stimulation. Note that the tachycardia ended when, upon cessation of pacing, the atrial impulse produced by the last stimulated beat was unable to traverse the atrioventricular node anterogradely because this structure had been rendered effectively refractory by the preceding anterograde atrial or retrograde ventricular impulses, or both.

Again, as in Figure 4, the atrial impulse produced by the last stimulated beat penetrated the atrioventricular node and, finding no retrograde impulse with which to collide (because pacing had been stopped), traversed this structure to resume the tachycardia. Because the atrioventricular node had been rendered relatively refractory by the last anterograde atrial and (or) retrograde ventricular impulses that had penetrated it, conduction through the atrioventricular node occurred with an AH interval longer than that of the tachycardia. For this reason, the interval between the last paced ventricular beat and the first ventricular beat of the resumed tachycardia was longer than the last stimulus-stimulus interval.

None of the 3 criteria for "classic" entrainment could be demonstrated during autodecremental ventricular pacing. Criteria number 1 and 2 were not present because progressive ventricular fusion leading to pure stimulated beats occurred in each pacing run. Moreover, the interval between the last paced ventricular beat and the first ventricular complex of the resumed tachycardia exceeded the last stimulus-stimulus interval. Criterion number 3 was not seen because either the tachycardia stopped when the last impulse was anterogradely blocked at the atrioventricular node (Figure 6), or, if an additional impulse was emitted, it was conducted retrogradely to the atria via the same (accessory) pathway with the same (short) conduction time. The entrainment, therefore, was considered to have been "concealed."[2]

Tachycardia termination during autodecremental ventricular stimulation: This was achieved in 77 of 80 episodes. The 3 failures occurred in patient 1 during maximal effects of isoproterenol. The *minimal* number of paced beats required to penetrate the circuit and terminate the tachycardia is presented in Table III. Fifty-four episodes terminated, as in Figure 6, with an anterograde block at the atrioventricular node of an impulse reaching the atria retrogradely via the accessory pathway. On the other hand, 23 episodes terminated when a paced ventricular impulse was abruptly blocked retrogradely in the accessory pathway.

Discussion

Entrainment during autodecremental atrial stimulation: Mechanistically, entrainment was indeed present because the electrophysiologic events occurring within the circuit were consistent with the phenomenon under consideration.[1–4,8] Yet, not surprisingly, the definition of Okumura et al[2] for "classic" (constant cycle length) entrainment did not apply because the rate of the tachycardia did not "increase to the faster pacing rate," that is, the HH and VV intervals were not the same, but distinctively longer than the corresponding stimulus-stimulus intervals.[2] Moreover, during autodecremental or constant cycle length, pacing entrainment is *not* best described as an acceleration of the tachycardia rate, for, once paced impulses have penetrated and occupied the reentrant circuit, the original tachycardia impulses are no longer present.[4,5,8,9] For this reaon, defining entrainment as a continuous resetting of the tachycardia circuit seemed more appropriate.[8–10]

Of the 3 diagnostic criteria of Okumura et al,[2] the first 2 could not be demonstrated and the third one only in those episodes were an impulse, presumably blocked at the atrioventricular node, was followed by another (last) impulse which, therefore, reached the ventricle via the accessory pathway (Figure 3).

Entrainment during autodecremental ventricular stimulation: Each time that continuous resetting of the tachycardia circuit occurred, the AA and the H·H· intervals (when detectable) were equal to the stimulus-stimulus intervals. Although this finding was in keeping with Okumura's concept and definition of entrainment ("increase in the rate of the tachycardia to the faster pacing rate"),[2] none of the 3 diagnostic criteria could be demonstrated. Therefore, autodecremental ventricular stimulation, as well as fixed cycle length ventricular pacing, consistently produced "concealed" entrainment.[2]

It should be pointed out that whenever entrainment occurs while pacing the ventricles (autodecrementally or not) and the retrograde impulse penetrates the atrioventricular node slightly after the preceding atrial impulse had entered this structure anterogradely, both impulses presumably collide within the atrioventricular node.[9] If stimulation is performed in such a manner that only 1 additional impulse is delivered in each successive pacing run, the last entrained beat shows an AH interval which increases as the last paced cycle length decreases. Finally, if no retrograde block is present in the accessory pathways at a given pacing run, an anterograde impulse is blocked at the atrioventricular node, entrainment ceases and the tachycardia is terminated.[9] These events take place because the last anterograde atrial impulse is influenced by the aftereffects of the preceding anterograde atrial or retrograde ventricular impulses, or both, which first cause relative refractoriness and finally effective refractoriness. Otherwise, when starting with or using a fixed (longer) number of stimuli, "concealed" entrainment cannot be differentiated from tachycardia termination followed by tachycardia reinitiation.[2,8,9]

Clinical implications: Thirty-eight of 38 episodes and 77 of 80 episodes of tachycardia were terminated with autodecremental atrial and ventricular pacing, respectively. Moreover, the 3 episodes failing with the latter mode responded to the former. The overall success rate (115 of 118 of all episodes, or 98%) indicates that autodecremental pacing is effective in the treatment of tachycardias occurring in patients with manifest Wolff-Parkinson-White syndrome. Because in 3 episodes atrial pacing succeeded when ventricular pacing had failed and because a lesser number of impulses was needed when stimulating from the atria (Tables II and III), it is tempting to conclude that autodecremental atrial stimulation is more "effective" than its ventricular counterpart. However, the number of cases and episodes is too small to reach definite conclusions. Similarly, and in contrast with the study of Charos et al,[6] no comparison was made in the present

work with other (relatively similar) forms of stimulation, such as the constant cycle length overdrive pacing performed by Waldo et al[2] or conventional burst pacing. Hence, no assumptions can be made as to whether autodecremental stimulation is more effective for circus movement tachycardias than those other modes.

Sensitivity of an Automatic External Defibrillator for Ventricular Tachyarrhythmias in Patients Undergoing Electrophysiologic Studies

MARK D. CARLSON, MD, CHARLES S. FREEMAN, RN, HASAN GARAN, MD, and JEREMY N. RUSKIN, MD

An automatic advisory external defibrillator (AED) was activated during all arrhythmias occurring at the time of 77 electrophysiologic studies in 45 patients. Sustained ventricular tachycardia (VT) occurred during 55 studies in 31 patients and nonsustained VT was induced during 10 studies in 9 patients. Ventricular fibrillation was induced 5 times in 5 patients and atrial arrhythmias with a rapid ventricular response occurred during 7 studies in 4 patients. The AED detection algorithm advised "shock" during 36 of 55 (65%) episodes of sustained VT and all 5 episodes of ventricular fibrillation. The device correctly advised "shock" for all 6 episodes of nonsustained VT that spontaneously terminated after analysis was complete. Thus, the sensitivity of the device for all ventricular arrhythmias analyzed was 47 of 66 (71%). The device recommended "shock" for all 31 episodes of rapid VT and 1 of 2 episodes of atrial fibrillation associated with systemic hypotension (32 of 33, 97%). The 19 episodes of VT for which "no shock" was advised were comparatively slow and were hemodynamically well tolerated. The device recommended "no shock" during all 21 episodes of normal sinus rhythm and all 20 episodes of rapid atrial pacing (cycle length 400 ms) analyzed. "No shock" was advised during 4 episodes of sustained narrow QRS complex supraventricular tachycardia and 4 brief episodes of nonsustained VT that terminated before analysis was complete. Thus, in this study the specificity of the AED for wide complex tachycardias was 100%.

(Am J Cardiol 1988;61:787–790)

Survival and neurologic recovery following out-of-hospital cardiac arrest is improved by decreasing the time between the onset of the event and the initiation of cardiopulmonary resuscitation and defibrillation.[1–9] This has been demonstrated in cities where first responders, including the general public, firefighters and police, perform cardiopulmonary resuscitation and emergency medical technicians rather than paramedics administer electrical defibrillation. Studies in Seattle have demonstrated that survival rates (percent of patients discharged alive) among patients treated by first responders using an automatic external defibrillator (AED) compared favorably to rates among patients treated by emergency medical technicians using a standard external defibrillator.[10,11]

Because time to defibrillation remains the most important predictor of survival following out-of-hospital cardiac arrest, many investigators have suggested an expanded role for the AED.[12] Use of the device by police, corporate personnel, nursing home staff members and family members of patients at high risk for cardiac arrest might further shorten time to defibrillation and improve survival. However, since ventricular tachycardia (VT) often precedes ventricular fibrillation (VF), an AED used in the home or workplace should recognize and convert both ventricular arrhythmias.[13] Previous studies have examined the sensitivity and specificity of the AED for VF alone.[10,13,14] This study examines the sensitivity and specificity of a

Total	47	19	71

VT = ventricular tachycardia.

commercially available AED for VT in patients undergoing electrophysiologic evaluation for a variety of cardiac arrhythmias.

Methods

Materials: The AED used (Lifepak 200-Physio-Control Corp.) is designed for use outside the hospital by minimally trained personnel. It is small (12.7 × 23.4 × 33.8 cm) and weighs 7 kg. The device has a rechargeable battery and can deliver up to 20 shocks (200 or 360 joules each) during a 3-hour period.

The AED is activated by opening the display module, thereby activating a message screen. Two 12 × 16 cm oval adhesive electrodes are attached to the patient's chest in standard paddle defibrillator positions. These electrodes serve for both monitoring and defibrillation. After electrode attachment the message screen displays "push to analyze." If VT or VF is sensed, "shock advised" appears on the display screen. The user may administer 200 or 360 joules of direct current electricity by pushing a "shock" button. If neither VT nor VF is detected, the message screen displays "no shock advised."

A digital detector determines chest impedance through the electrodes. Static impedance levels determine electrode-to-skin integrity; dynamic impedance detects respiration, chest compressions and body movements. The impedance detector advises that the electrodes are attached to the patient and that there is no chest movement. This reduces the chance of shocking a patient who has spontaneous respirations or is undergoing cardiopulmonary resuscitation at the time of electrocardiogram analysis. Criteria used to recognize VT include: rate above 120 beats/min, QRS complex duration >160 ms and no apparent P waves preceding complexes. QRS morphologhy is examined to determine the likelihood that the rhythm is ventricular or supraventricular in origin. Important distinguishing factors include the amplitude normalized slew rate and the percentage of isoelectric segment in the rhythm. Higher rates increase the probability that the device will recommend "shock." The shock advisory system detection algorithm examines a 2.7-second segment of the electrocardiogram and internally makes a "shock" or "no shock" determination for that segment. A second determination is made on a subsequent 2.7-second segment. If the determinations match, an advisory is displayed. In cases of disagreement, a third segment is analyzed and that determination is displayed. The entire electrocardiogram analysis process requires 6.6 to 11.1 seconds for completion. A relatively motion-free environment is necessary to provide a "noise-free" signal for analysis. Motion can interrupt rhythm analysis for a maximum of 20 seconds before the message screen reverts to the "push to analyze" standby mode.

Protocol: The AED (Physio Control Lifepak 200) was evaluated during 107 consecutive electrophysiologic studies in 66 patients who underwent programmed cardiac stimulation at this institution for the evaluation of known or suspected cardiac arrhythmias. Before each study, two 12 × 16 cm oval adhesive electrodes (Physio Control Corp.) were attached to each patient in standard defibrillator paddle positions, i.e., left precordial and right infraclavicular positions. The shock advisory system of the Lifepak 200 defibrillator was activated in all patients at the onset of any tachycardia. In 21 consecutive studies performed in 14 patients, the system was activated during normal sinus rhythm. In another 20 studies in 19 patients, the system was activated during atrial pacing at a cycle length of 400 ms.

Results

Arrhythmias occurred during 80 studies in 47 patients. Multiple studies were performed in 24 patients; in 20 patients more than 1 arrhythmia was induced. No arrhythmias were induced during 27 studies in 23 patients. Poor electrode contact prevented the detection algorithm from rendering advice during 3 studies in 2 patients. The final arrhythmia analysis, therefore, included 77 studies in 45 patients (Table I).

The Lifepak 200 defibrillator correctly advised "shock" for 36 of 55 (65%) episodes of sustained VT, all 5 (100%) episodes of VF and the 6 episodes of nonsustained VT that terminated spontaneously after analysis was complete (Table II). "No shock" was correctly advised for 4 episodes of nonsustained VT that terminated spontaneously before analysis was completed. Thus, the sensitivity of the detection algorithm for analyzed VT and VF was 47 of 66 or 71%.

The 19 episodes of sustained VT for which "no shock" was advised occurred in 15 patients. The average cycle length of these tachycardias was longer than that of sustained VT for which "shock" was advised (373 ± 77 ms vs 275 ± 58, $p = 0.0001$) (Figure 1). However, the QRS complexes of these tachycardias were

similar in duration to those of sustained VT for which "shock" was advised (156 ± 35 ms vs 154 ± 28, difference not significant).

The 7 supraventricular arrhythmias were initiated in 4 patients. One automatic atrial tachycardia, 3 episodes of wide QRS complex atrial fibrillation with a rapid ventricular response and 3 cases of narrow QRS complex atrial flutter were observed. The cycle lengths of these tachyarrhythmias varied between 540 and 200 ms. (111 to 300 beats/min). The 3 episodes of wide QRS complex atrial fibrillation occurred in 1 patient with the Wolff-Parkinson-White syndrome. The width of the QRS complex in this patient was 160 ms and the tachycardia cycle length ranged between 260 and 200 ms. (230 to 300 beats/min). The AED advised "shock" in 2 of the 3 episodes. Thus, the overall sensitivity of the detection algorithm for wide QRS complex tachycardias of all types was 49 of 69 or 72%. The remaining 4 cases of supraventricular tachycardia had narrow QRS complexes (80 to 100 ms, mean 85) with cycle lengths ranging between 540 and 300 ms (110 to 200 beats/min). The AED advised "no shock" in all 4 cases. None were rhythms that required electrical cardioversion.

Mode of termination: Ten episodes of VT and 1 episode of atrial fibrillation terminated spontaneously. The remaining arrhythmias (55 VT, 5 VF, 2 atrial fibrillation and 4 supraventricular tachycardia) were sustained and required intervention.

The AED correctly advised "shock" for all 31 ventricular arrhythmias (25 VT, 5 VF) that required direct current electrical countershock because of associated hemodynamic collapse (Table III). The device recommended "shock" for 10 and "no shock" for 19 episodes of VT that were not associated with hemodynamic collapse. Burst rapid ventricular pacing terminated 27 of these arrhythmias. However, 2 of the tachycardias accelerated after rapid ventricular pacing and required electrical countershock for termination. Analysis of these accelerated arrhythmias was not attempted. Statistically significant differences were noted in the mean cycle length of VTs that required electric cardioversion compared with those that were not associated with hemodynamic collapse (261 ± 52 vs 354 ± 74, $p < 0.0001$).

Of the 3 episodes of atrial fibrillation with a rapid ventricular response, 2 required direct current countershock for termination ("shock" was advised for 1 and "no shock" was advised for the other). One episode of atrial fibrillation terminated spontaneously after a "shock" was advised but before it was administered. The 3 episodes of atrial flutter were terminated with atrial pacing. The episode of automatic ectopic atrial tachycardia was not terminated in the laboratory.

Cardioversion: External electrical cardioversion or defibrillation was attempted with the Lifepak 200 defibrillator during 14 episodes of VT and 3 episodes of VF. The device was not used if syncope occurred before it could be activated. Further, only 1 200 joule shock per arrhythmic event was attempted with the Lifepak 200 defibrillator. Additional shocks, when necessary, were administered from a Physio-Control Lifepak 6s defibrillator.

TABLE III Advice for Arrhythmias Associated with Hypotension

Arrhythmia	Shock	No Shock	Sensitivity (%)
VT	26	0	100
Ventricular fibrillation	5	0	100
Wide QRS complex atrial fibrillation	1	1	50
Total	32	1	97

VT = ventricular tachycardia.

The Lifepak 200 AED successfully converted 13 of 14 episodes (93%) of VT and 2 of 3 episodes of VF to normal sinus rhythm. One episode of VT and 1 episode of VF required a second 200 joule countershock from the Lifepak 6s defibrillator to restore sinus rhythm.

Normal sinus rhythm and atrial pacing: The Lifepak 200 shock advisory system was activated during normal sinus rhythm in 14 patients during 21 consecutive studies. The device correctly advised "no shock" in every case. The device also recommended "no shock" during atrial pacing at cycle length 400 ms in 19 patients during 20 studies. The mean QRS complex duration during atrial pacing was 105 ± 21 ms. Further, the device correctly advised "no shock" during 4 episodes of nonsustained VT, which reverted spontaneously to sinus rhythm during analysis and during the 4 episodes of narrow QRS complex supraventricular

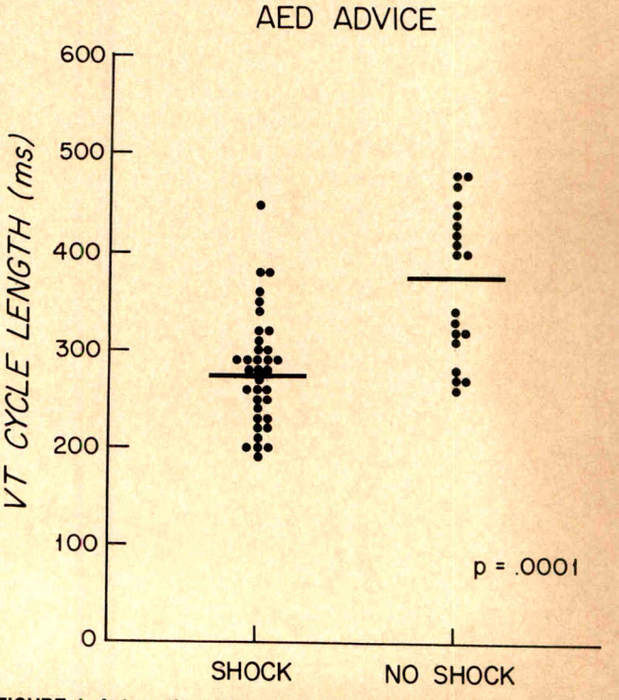

FIGURE 1. Automatic advisory external defibrillator (AED) advice (shock vs no shock) as a function of ventricular tachycardia (VT) cycle length.

tachycardia. Therefore, the specificity of the device for wide QRS complex tachycardias in this study was 100%.

Discussion

Previous studies have evaluated the sensitivity and specificity of various AEDs for VF.[10,14,15] The detection algorithm used in the Lifepak 200 AED is sensitive and highly specific for both VF and VT. In as many as 74% of patients with cardiac arrest, VT precedes VF.[13] Because the automatic advisory defibrillator may be used by family members or other minimally trained persons arriving early at the scene, recognition of VT as well as VF may be important to achieve prompt and effective resuscitation in many patients.

The difference in the sensitivity of the detection algorithm for ventricular arrhythmias associated with hemodynamic collapse (31 of 31, 100%) and those that could be terminated with rapid ventricular pacing is, in part, a reflection of the rate criteria used by the algorithm to classify arrhythmias. The automatic external defibrillator recommended "shock" in 80% (40 of 50) of ventricular arrhythmias with a cycle length <400 ms (150 beats/min) and only 9% (1 of 11) of those with a cycle length ≥400 ms (150 beats/min) (Figure 1). The relative insensitivity of the detection algorithm to slow VT increases its specificity for life-threatening ventricular arrhythmias and reduces the chance of administering inappropriate and potentially harmful shocks to conscious patients who have slower, hemodynamically well-tolerated rhythms. Although QRS complex duration >160 ms is one of the criteria the device uses to sense VT, differences in sensitivity to VT with QRS complex duration >160 ms or <160 ms were small and did not reach statistical significance in this study.

The ability of the AED to terminate VT with a single 200 joule shock (13 of 14 episodes tested, 93%) compares favorably with the experience reported in previous studies.[10,15] In a study using an AED to treat patients with out-of-hospital cardiac arrest, researchers at the University of Iowa reported a 97% conversion rate for VF.[15] In that study, 8 of 26 (31%) of patients converted to asystole, an arrhythmia not encountered following cardioversion in the present study. The comparatively short time to cardioversion in our study probably favored successful conversion to normal sinus rhythm. Our study permitted only 1 AED shock per arrhythmic episode in each patient. It is possible that a second shock from the AED would have converted the 1 failed episode in this study.

In this study the Lifepak 200 detection algorithm demonstrated 100% sensitivity for rapid ventricular arrhythmias associated with hemodynamic collapse. The device was 100% specific for wide complex tachyarrhythmias and was highly effective in converting both VT and VF to normal sinus rhythm with a single 200 joule electrical countershock.

IN MILD, MODERATE,
AND SEVERE HEART FAILURE
(NYHA Class II, III, and IV)
SQUIBB

ADD CAPOTEN® SOONER*..

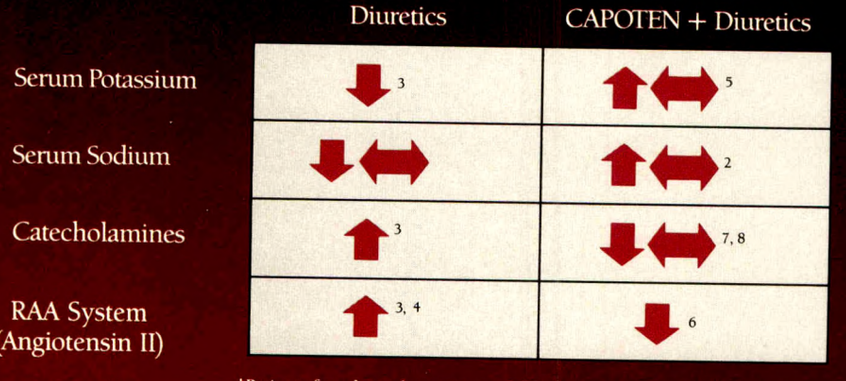
(captopril tablets)

*CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary of prescribing information on last page.

COMPLETE THE JOB YOUR LOOP DIURETIC STARTED

In patients symptomatic on diuretic and digitalis

- Adding CAPOTEN enhances the diuretic effect of furosemide
  - —Disappearance of edema in 55% of a subgroup of patients after adding CAPOTEN to furosemide†[1]
  - —50% reduction in furosemide dose‡[2]
- Helps normalize electrolyte and neurohormone levels



†Patients for whom data were available for two months. Patients were NYHA Class II, III, and IV receiving concomitant diuretic and digitalis therapy.

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia (< 1000/mm³) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count < 1000/mm³) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]). In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function* – Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia* – If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension – Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial of captopril dose in patients on diuretics, especially those recently placed on diu and those on severe dietary salt restriction or dialysis. This possibility can be minin by either discontinuing the diuretic or increasing the salt intake about 1 week pr initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators shou administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihyperte agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may l pecially important in supporting blood pressure in patients receiving captopril alo with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive to captopril, but the overall response is less than additive. Therefore, use agents a ing sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blo agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or pota supplements only for documented hypokalemia, and then with caution, since the lead to a significant increase of serum potassium. Use potassium-containing salt s tutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonste anti-inflammatory agents may reduce the antihypertensive effect of captopril, espe in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urin for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studie doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcin potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C: There are no adequate and well-controlled studies in nant women. Embryocidal effects and craniofacial malformations were observed i bits. Therefore, captopril should be used during pregnancy, or for patients lik become pregnant, only if the potential benefit outweighs the potential risk to the Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution wh ministering captopril to a nursing woman, and, in general, nursing should be interr

Pediatric Use: Safety and effectiveness in children have not been established altl there is limited experience with use of captopril in children from 2 months to 15 y age. Dosage, on a weight basis, was comparable to that used in adults. CAPC (captopril) should be used in children only if other measures for controlling bloo sure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials inv approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Re sufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 pa

Hematologic – Neutropenia/agranulocytosis has occurred (see WARNINGS) mia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash, (usually maculopapular, rarely urticarial), often with pr and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depend renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, withou in about 2 of 100 patients. A reversible associated pemphigoid-like lesion photosensitivity, have also been reported. Angioedema of the face, mucous memt of the mouth, or of the extremities in about 1 of 1000 patients – reversible on disc uance of captopril therapy. One case of laryngeal edema has been reported. Flush pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur; see WARNINGS and PRECAUT [Drug Interactions] for discussion of hypotension on initiation of captopril th Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pe myocardial infarction, Raynaud's syndrome, and congestive heart failure each in of 1000 patients.

Dysgeusia – Approximately 2 to 4 (depending on renal status and dose) of 100 p developed a diminution or loss of taste perception; taste impairment is reversib usually self-limited even with continued drug use (2 to 3 months). Gastric irri abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, alopecia, paresthesias reported in about 0.5 to 2% of patients but did not appea creased frequency compared to placebo or other treatments used in controlled tr

Altered Laboratory Findings: Elevations of liver enzymes in a few patients alt no causal relationship has been established. Rarely cholestatic jaundice, and hepatoc injury with or without secondary cholestasis, have been reported. A transient ele of BUN and serum creatinine may occur, especially in volume-depleted or renova hypertension patients. In instances of rapid reduction of longstanding or severe vated blood pressure, the glomerular filtration rate may decrease transiently, also re in transient rises in serum creatinine and BUN. Small increases in serum pot concentration frequently occur, especially in patients with renal impairmer PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume exp with an I.V. infusion of normal saline is the treatment of choice for restoration of pressure. Captopril may be removed from the general circulation by hemodialys

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be tak hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosag be individualized; see DOSAGE AND ADMINISTRATION section of package for detailed information regarding dosage in hypertension and in heart failure. B CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustme recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of mg and 50 mg also available in bottles of 1000), and in UNIMATIC® unit-dose p 100 tablets. (J

Determinants of Survival in Patients with Malignant Ventricular Arrhythmia Associated with Coronary Artery Disease

STEVEN LAMPERT, MD, BERNARD LOWN, MD, THOMAS B. GRABOYS, MD, PHILIP J. PODRID, MD, and CHARLES M. BLATT, MD

The long-term survival data in patients with coronary artery disease and a history of malignant ventricular arrhythmia, defined as noninfarction ventricular fibrillation (VF) or hemodynamically compromising ventricular tachycardia (VT) followed for up to 9 years, were analyzed. In this group of 161 patients there was a total of 57 deaths, of which 35 (63%) were sudden. Life-table analysis demonstrated a 10% sudden death rate for all patients in the first year and a 7% annual rate in the subsequent 4 years. In patients managed noninvasively, the overall mortality rate was 27% over 9 years, or 3% per year. Suppression of ventricular tachycardia on both ambulatory monitoring and exercise testing was associated with improved survival. In patients evaluated by electrophysiologic testing the sudden death rate was 1.4% per year over an average of 5 years. This survival rate was not different compared with the noninvasive group ($p = 0.09$). Measures of left ventricular dysfunction and the frequency of ventricular arrhythmia before and after drug therapy were associated with a risk of sudden cardiac death by univariate analysis. Multivariate regression analysis identified 4 variables as independent predictors of sudden cardiac death: rales ($p = 0.009$), the number of runs of VT during exercise testing while receiving antiarrhythmic drug therapy ($p = 0.0003$), a history of congestive heart failure ($p = 0.0009$) and the number of premature beats on Holter monitoring ($p = 0.01$). These findings support the concept that suppression of repetitive arrhythmia on Holter monitor and exercise testing is a marker for improved survival among patients with malignant ventricular arrhythmia. However, in the coronary population at high risk of sudden cardiac death, ventricular function is the most powerful predictor of survival and, when severely depressed, the control of ventricular arrhythmia does not significantly improve outcome.

(Am J Cardiol 1988;61:791–797)

Preventing sudden cardiac death in patients with coronary artery disease remains a clinical challenge.[1] Advances in this area during the past 2 decades have comprised a diversity of approaches including cardiopulmonary resuscitation, numerous new antiarrhythmic drugs, electrophysiologic identification of the patient at risk, automatic implantable defibrillators and cardioverters, and surgical ablation of the arrhythmic focus. Perhaps the most significant advance relates to a conceptual change, namely, that the patient at risk is identifiable and that sudden death may be preventable.[1]

Current treatment of patients threatened with sudden cardiac death is based on 2 hypotheses. First, sudden death is due to ventricular fibrillation (VF), often heralded by ventricular tachycardia (VT). Second, elimination of repetitive ventricular arrhythmia, whether induced electrophysiologically or occurring spontaneously, protects against these lethal events.[2,3] Through our efforts, as well as those of other investigators, it was demonstrated that the control of complex ventricular ectopic activity based on a noninvasive evaluation or the suppression of their provocation by programmed electrical stimulation is associated with improved survival in high-risk patients.[2,4,5]

A number of relevant questions concerning the management of these patients remain to be answered.

TABLE I Clinical Variables of 161 Patients with Malignant Ventricular Arrhythmia

Clinical Variable	
Age (yr)*	58 ± 11
Male:female ratio	5:1
Myocardial infarction	127 (79%)
Arrhythmia characteristics	
Ventricular fibrillation	86 (53%)
Ventricular tachycardia	75 (47%)
No. of unsuccessful drug trials*	2.5 ± 1.8
Left ventricular function	
Left ventricular ejection fraction*	0.36 ± 0.19
Cardiomegaly	78 (49%)
Clinical congestive heart failure	72 (45%)

* Values are mean ± standard deviation.

Are patients who respond to antiarrhythmic drugs different from those in whom complex ventricular arrhythmias persist despite therapy? What clinical variables, in addition to arrhythmia, predict survival? In subjects with malignant ventricular arrhythmias, what degree of arrhythmia elimination is necessary to ensure protection? This report addresses these questions and updates earlier studies.

Methods

Patients: One hundred sixty-one survivors of either noninfarction VF or sustained VT associated with syncope or presyncope were referred for management and constitute the study group. All patients had coronary artery disease evidenced by cardiac catheterization, a documented myocardial infarction or angina. Clinical investigations were performed at the Brigham and Women's Hospital or the Cardiovascular Laboratories at the Harvard School of Public Health. Eighty-six patients were referred after at least 1 episode of VF, of whom 30 patients (34%) had 2 or more cardiac arrests. The remaining 75 patients had sustained hemodynamically compromising VT with either syncope or presyncope. In 51 patients (68%), the symptomatic tachyarrhythmia occurred more than once. The patients' clinical characteristics are listed in Table I.

Evaluation procedures: The evaluation of these patients has been described in previous studies.[2] Patients were admitted either to a coronary care unit or a cardiac unit with telemetry capabilities. Antiarrhythmic drugs were stopped whereas digoxin and β-adrenergic blocking agents were continued when indicated. In 130 patients (82%) antiarrhythmic drugs were stopped without sequelae; runs of nonsustained VT were untreated during this initial phase. Continuous antiarrhythmic drug therapy to prevent recurrent VF or sustained symptomatic VT was required in 23 patients (14%). The remaining 8 patients (4%) were considered medically unstable and continued receiving antiarrhythmic drugs. The baseline, or control phase of arrhythmia evaluation, included 48 hours of ambulatory monitoring, an exercise tolerance test and a radionuclide ventriculogram. These were carried out after a drug washout period equal to 5 half-lives of any antiarrhythmic drug.

Ambulatory monitoring: Monitor data analysis was performed using a cardiac arrhythmia analyzer (American Optical Corportion) and, more recently, a CAMSCAN 7200 system. Both devices employ a tape playback system that allows 60× or 120× real-time analysis of 24-hour cassettes (the methods have been previously described).[6] Data reduction of ventricular premature beat activity was carried out by qualitative analysis and adhered to the following classification of ventricular premature beats[7]: grade 0, no ventricular premature beats; grade 1, occasional (<30/hr; A, <1/min and B, >1/min); grade 2, frequent ventricular premature beats (>1/min); grade 2, frequent ventricular premature beats (>1/min or 30/hr); grade 3, multiform ventricular premature beats; grade 4, repetitive ventricular premature beats (A, couplets and B, salvos or ventricular tachycardia). Semiautomated data reduction permits quantification of total ventricular premature beats and repetitive forms. Ten percent of all tapes were randomly chosen for quality control.[6]

Exercise stress testing: Testing was performed adhering to a Bruce protocol[8] on a motorized treadmill and has been previously described.[9,10] An electrocardiographic tracing was continuously displayed on an oscilloscope. A permanent continuous record was obtained on a Trendscriber[11] and on a standard electrocardiogram strip chart recorder that inscribed 3 simultaneous leads. Exercise was maximal and symptoms limited, discontinued only when the patient experienced progressive dyspnea, intensifying angina pectoris, or sustained atrial or ventricular tachyarrhythmia. Emergence of ST-segment depression, ventricular premature beats, couplets or episodic ventricular tachycardia did not constitute a reason for terminating the test. Quantification and grading of total ventricular premature beats took place during the control, exercise and recovery periods.[11]

The determination of a methodologic approach for selecting the appropriate antiarrhythmic drug was based on the data acquired during the baseline evaluation. The decision was between noninvasive or electrophysiologic testing. The patient underwent a noninvasive evaluation if monitoring demonstrated grade 2 ventricular premature beats for >50% of the hours and grade 4B arrhythmia for at least 3 hours per day or at least 2 ventricular premature beats per minute provoked by exercise. Electrophysiologic testing was used if this level of arrhythmia was absent or the ventricular arrhythmia was not reproducible from one 24-hour period to the next. Of the 161 patients, 43 (27%) required electrophysiologic testing to guide antiarrhythmic drug therapy, whereas in the remaining 118 patients repeated ambulatory monitoring and exercise testing provided information for drug selection.

Electrophysiologic testing was based on the following protocol. Under fluoroscopic guidance, a 6 Fr hexapolar electrode catheter was inserted percutaneously into the left subclavian vein and positioned at the right ventricular apex. Programmed electrical stimulation

was performed, using up to 3 successive extrastimuli with a pulse width of 5 ms at energies of 2 and 3 times the mid-diastolic threshold, as previously reported.[12] Studies were carried out during both sinus rhythm and ventricular pacing at a cycle length of 500 ms. The endpoint of stimulation was the induction of reproducible nonsustained VT, defined as 3 or more ventricular premature beats (≥ 30 seconds) after the last provoked extrastimulus. To be considered reproducible, the endpoint had to be provoked in 2 of 3 trials at the same coupling cycle and with the same stimulus energy. All patients who required electrophysiologic testing underwent at least 1 baseline study without receiving any antiarrhythmic agent. The purpose of the electrophysiologic study was to induce an arrhythmia against which antiarrhythmic drug effect could be tested.[13]

Antiarrhythmic therapy: The selection of the discharge drug program was based on the results of either the noninvasive or invasive drug evaluations. Both methods used a structured protocol for antiarrhythmic drug selection, which has been previously described.[14-16] The evaluation consisted of 2 phases. Phase 1 covered acute drug testing and phase 2 dealt with short-duration maintenance therapy with a selected antiarrhythmic agent.

In phase 1, a single large oral dose of an antiarrhythmic agent was administered orally after a 30-minute control monitoring period. Thereafter, hourly counts of ventricular ectopic beats were hand tabulated, using programmed trendscription.[11] The patient also was exercised on a bicycle ergometer before the administration of the drug and hourly thereafter. A separate tabulation was made for exercise-induced arrhythmia, comparing the hourly tests after the administration of the drug with the initial bicycle exercise test. Sampling of blood for drug concentration was carried out hourly to assure that a so-called therapeutic blood concentration was achieved. The objective of therapy was elimination of advanced grades of ventricular premature beats (grades 4A and 4B) and reduction by 50% of frequent ventricular premature beats. Acute drug tests were performed daily with different agents, permitting a 24-hour washout period between drugs.

In phase 2, which continued for 48 to 96 hours, the aim was to assess antiarrhythmic drug efficacy and gauge drug tolerance with a dosing program simulating long-term drug maintenance. Drugs that proved effective during phase 1 were used, including agents that could not be tested acutely. Drugs either with a long half-life or with electrophysiologically active metabolites underwent phase 2 testing only. The oral dosing schedule during phase 2 was guided by the pharmacokinetic properties of the selected antiarrhythmic agent. Drug effect was assessed by means of 24-hour Holter monitoring and maximal exercise stress testing. An effective response during the noninvasive assessment required fulfillment of the following criteria: (1) total elimination of grade 4B ventricular premature beats; (2) reduction of >90% in grade 4A ventricular beats; (3) >50% reduction in total number of ventricular premature beats. These criteria had to be met with both 24-hour Holter monitoring and exercise stress testing. When electrophysiologic testing was used, drug effectiveness was defined as the inability to provoke nonsustained VT defined as ≥3 beats.

The drug best tolerated during phase 2 studies was selected for long-term therapy. When a single drug failed to control the arrhythmia, 2 partially effective drugs (based upon either phase 1 or phase 2 testing) were combined and reevaluated. Even if a single agent was effective for patients with recurrent VF, 2 antiarrhythmic drugs were generally used to provide a so-called fail-safe program of drug protection.[16] Each drug had been independently evaluated and the combined therapy was evaluated prior to discharge.

Follow-up: Patients were followed for an average of 31.5 ± 26 months (range 0.13 to 107.5). Follow-up began on the date of hospital discharge and ended on the date of the patient's death, withdrawal because of loss to follow-up (1 patient at 88 months), or termination of the study.

Definitions and data analysis: The type of arrhythmia evaluation and degree of arrhythmia control on the final drug program divided the population into 4 groups. In 61 (52%) of the 118 noninvasively evaluated patients, the ventricular arrhythmia was considered controlled if, during 24 hours of ambulatory monitoring, VT was limited to no more than 2 runs (each lasting less than 6 beats) and exercise testing failed to provoke VT (≥3 cycles). If either ambulatory monitoring or exercise testing failed to meet these conditions, or if the patient was for any reason unable to undergo either evaluation, the patient was considered not controlled (n = 57, 48%). In 21 of the 43 patients evaluated by the invasive method, 3 extrastimuli failed to induce any VT (3 or more beats) while the patient was receiving an antiarrhythmic agent. These patients were considered controlled. In the remaining 22 patients, 10 were discharged after being prescribed medicine that either slowed the VT rate or made the arrhythmia more difficult to induce. In 12 patients, another antiarrhythmic agent was empirically added and not evaluated by electrophysiological testing. For analysis purposes, these 22 patients were considered noncontrolled by electrophysiologic testing.

Sudden cardiac death was defined as death within 1 hour of onset of the terminal event. Patients who were found dead but known to be alive and free of symptoms within the previous 24 hours were considered to have died suddenly. Cardiac fatality included sudden death and death due to progressive circulatory failure.

Continuous data are expressed as mean ± standard deviation. The association between the analyzed variables and sudden cardiac death was determined with univariate statistical methods. Actuarial survival curves for sudden death and cardiac death were constructed using the product-limit method (Kaplan-Meier).[17] Differences in mortality curves for analyzed variables were compared using the Breslow modification of the generalized Wilcoxon test.[18]

Multivariate regression analysis using the Cox proportional hazards linear model with the Breslow modification for tied data was performed to identify variables with significant predictive value for sudden cardiac death.[19] All variables with a univariate predictive value of at least p <0.10 were included in the regression model. When values were missing because either a baseline or final arrhythmia evaluation was not performed, median values (obtained from the univariate analysis) were substituted in the multivariate analysis. Variables were considered predictive of sudden cardiac death when the p value of the chi-square analysis was <0.05.

Results

Survival: Actuarial survival curves for sudden death and cardiac death for the entire study group are presented in Figure 1. There was a total of 57 deaths, of which 56 were due to a cardiac event. Thirty-five of the cardiac deaths (63%) were sudden. The actuarial sudden death rates at 1, 2 and 5 years were 10 ± 2%, 13 ± 2% and 34 ± 6%, respectively.

Determinants of survival: When tested by univariate analysis, many variables were associated with sudden cardiac death (Table II). A number of measures of left ventricular dysfunction as well as frequency of ventricular premature beats during the baseline ambulatory monitoring were closely associated with sudden death. Patients unable to undergo a baseline (drug-free) evaluation were more likely to die suddenly, compared with patients who could safely discontinue antiarrhythmic drugs. The lack of arrhythmia suppression at discharge from the hospital also was associated with sudden death, as was the frequency of ventricular premature beats during the discharge exercise testing and Holter monitoring.

Multivariate regression analysis identified 4 variables as independent predictors of sudden cardiac death in the entire cohort: rales during the initial physical examination (p = 0.009), the number of runs of VT on the discharge exercise test (p = 0.0003), a history of congestive heart failure (p = 0.0009) and the number of hours of frequent (grade 2) ventricular premature beats on the discharge Holter monitor (p = 0.01). All the other univariate factors failed to provide additional independent predictive value. When analysis was limited to the 118 patients whose therapy was based upon the noninvasive evaluation, the same 4 independent predictors of sudden death were identified.

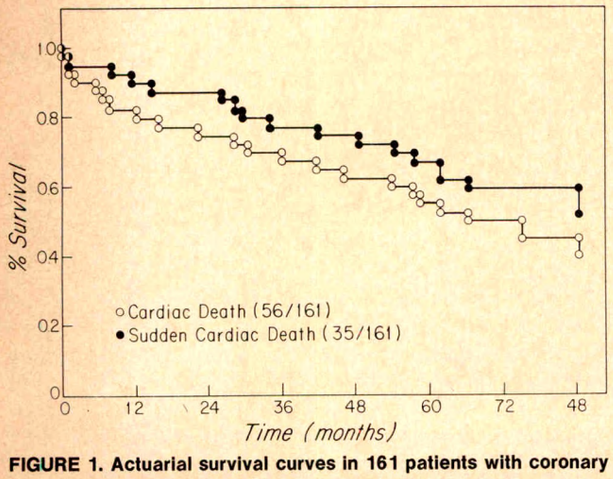

FIGURE 1. Actuarial survival curves in 161 patients with coronary disease and malignant ventricular arrhythmia followed for an average of 31.5 months.

* NS (not significant) when p >0.10; † discontinue therapy = when drugs can be stopped without sustained tachyarrhythmia occurring.
H/O CHF = history of congestive heart failure.

Survival by method of evaluation and arrhythmia control: Patients evaluated by noninvasive methods experienced an overall sudden death rate of 27% during a 9-year (3%/yr) follow-up period as compared with 7% in the group managed by electrophysiologic testing and followed for an average of 5 years (1.4%/yr). The difference in the actuarial survival rate did not reach statistical significance (p = 0.09). There were 3 sudden cardiac deaths in the invasively managed group. Two occurred within 8 months of discharge and 1 at 26 months. The 2 groups were clinically similar with respect to prior history, initial physical examination and left ventricular function. The major difference was in the amount of baseline arrhythmia, with the invasive group being nearly free of frequent or reproducible higher grades of ventricular arrhythmia during both Holter monitoring and exercise testing. Although the mean left ventricular ejection fraction was slightly higher in the group undergoing electrophysiologic testing (41.5 vs 33.8%, p = 0.053), other indexes of left ventricular function were not different.

The percentage of patients with a history of congestive heart failure (43 vs 46%), cardiomegaly by chest x-ray (39 vs 53%) and with an ejection fraction below 40% (51 vs 62%) were not significantly different between the invasive and noninvasive groups.

The actuarial sudden death rates in the controlled (n = 61) and noncontrolled (n = 57) groups, based on the noninvasive evaluation, are shown in Figure 2. The difference in survival between the 2 groups is significant at the $p < 0.02$ level. The largest difference occurred during the first year after discharge, when 19% of patients in the noncontrolled group died suddenly compared with 5% in the controlled group. At 5 years, the sudden death rates were 48 ± 9% and 29 ± 8%, respectively.

Patients evaluated by electrophysiologic testing had excellent survival rates. Survival was not related to the presence or absence of inducible nonsustained VT on the discharge drug program. Patients who were discharged with inducible nonsustained VT had an overall survival of 86% compared with 100% in patients free of inducible arrhythmia (difference not significant).

In the entire cohort of patients, all Lown grades of ventricular arrhythmia were reduced during exercise testing and ambulatory monitoring. The reduction during exercise testing was associated with fewer sudden cardiac deaths (Table III). The median reductions in Lown grades 2, 4A and 4B during ambulatory monitoring were 90, 95 and 100%, respectively. For exercise tolerance testing, the median percentage reductions were 96, 100, and 100% for Lown grades 2, 4A and 4B.

Comparison of the controlled and noncontrolled groups: The baseline clinical characteristics of the controlled and noncontrolled groups are compared and summarized in Table IV. The major difference between the 2 groups was the degree of left ventricular impairment. Clinical signs of left ventricular impairment were found more often in the noncontrolled group. When the 2 groups were classified according to the left ventricular ejection fraction, 33% of the controlled group had left ventricular dysfunction (left ventricular ejection fraction <30%), compared with 51% of the noncontrolled group ($p = 0.08$). Thus, ventricular arrhythmia was suppressed more often in patients without left ventricular impairment. The frequency of ectopic activity or the grade of ventricular arrhythmia during baseline studies was not correlated with the degree of left ventricular impairment in either group.

The interaction between left ventricular function and ventricular arrhythmia suppression was evaluated by stratifying the cohort into 4 groups. The patients were initially stratified as having normal or abnormal left ventricular function based on an ejection fraction above or below 30% and, within each group, dichotomized according to the degree of control of the ventricular arrhythmia. The results are presented in Figure 3. When the left ventricular ejection fraction was >30%, controlling ventricular arrhythmias were associated with improved survival ($p = 0.05$). When

severe left ventricular dysfunction was present, controlling arrhythmia did not affect the sudden death rate.

Discussion

The present study corroborates earlier findings that the control of advanced grades of ventricular premature beats with antiarrhythmic drugs is associated with improved survival in patients with coronary artery disease presenting with life-threatening ventricular arrhythmias. In these 161 patients, prognosis was related to the severity of left ventricular dysfunction and the frequency of VT during antiarrhythmic drug therapy.

In an earlier report from our laboratory, the annual rate of sudden cardiac death in a heterogeneous population was 2.3% when the objective of therapy aimed at the total elimination of VT salvos and R-on-T ventricular premature beats.[2] In the present study, a nearly similar result was achieved with less rigorous control of ventricular ectopic activity in a population with coronary artery disease. The presence of >2 salvos of nonsustained ventricular tachycardia (<6 beats) was associated with a sudden cardiac death rate of approximately 5% per year, compared to 3.4% when all couplets and runs of VT were eliminated. Although elimination of VT salvos remains a valid therapeutic objective,[4] total abolition of arrhythmia in these high-risk patients may not be necessary to optimize prognosis.

The state of the left ventricular function has been identified as an important predictor of survival in a variety of patient populations. Swerdlow and co-workers[5] found that the New York Heart Association functional classification was a strong predictor for sudden death in a group of patients with malignant ventricular arrhythmias evaluated by electrophysiologic testing. In a long-term follow-up study of resuscitated victims of out-of-hospital cardiac arrest, Goldstein et al[20] suggested that the major determinant of survival was left ventricular dysfunction. Bigger and co-workers[21] followed 766 survivors of acute myocardial infarction and demonstrated that a left ventricular ejection fraction of <30% was an independent predictor of survival, with the mortality rate increasing further in the presence of either frequent or high-grade ventricular arrhythmias.[21-23] We also found that the left ventricular function was the strongest predictor of survival in patients with malignant ventricular arrhythmia. When patients were stratified according to left ventricular function, the control of ventricular arrhythmia was most beneficial in patients with an ejection fraction >30.

We learned that estimates of left ventricular function and the amount of ventricular arrhythmia during antiarrhythmic drug therapy were the strongest predictors of survival. The presence of rales at the time of admission had the highest chi-square value of all variables entered into the logistic regression equation. The number of runs of VT during the final exercise tolerance test was the next most important predictor of sudden death. This conclusion is important because exercise tolerance testing is not routinely used to guide antiarrhythmic drug therapy. As a therapeutic approach for the general population, whether ventricular arrhythmia during exercise tolerance testing adds independent prognostic information beyond other exercise parameters has been a controversial issue. Few investigators use this noninvasive procedure to assess antiarrhythmic drug effectiveness in patients with ventricular arrhythmias. Over the past decade we have used this testing method as an integral part of our antiarrhythmic drug evaluation and found that, in 15% of drug trials, exercise testing exposes arrhythmia which was not present on the therapeutic ambulatory monitor. It is possible that differences in survival among different institutions are related to whether exercise testing is used to determine drug effectiveness.

Sufficient evidence has now accrued to support the hypothesis that suppression of ventricular premature beats in patients who have survived sudden cardiac death or symptomatic VT by an effective antiarrhythmic program is associated wtih enhanced long-term survival. It is possible that a positive response to antiarrhythmic therapy merely identifies a subset of patients who have a lower risk of dying suddenly and the therapy does not truly "protect" the patient. If this is the case, then survival in these patients is unrelated to the drug therapy. Our group[24] recently examined the recurrence of clinical arrhythmia after cessation of an effective drug program. Among 24 patients who un-

derwent antiarrhythmic drug withdrawal, there was a 50% recurrence of either cardiac arrest or sustained ventricular tachycardia. This mortality rate, after discontinuing drug therapy, suggests that patients with a history of malignant ventricular arrhythmia are always at risk of recurrence and that antiarrhythmic therapy effectively protects these high-risk patients.

Effect of Behavior State on Caffeine's Ability to Alter Blood Pressure

GWENDOLYN A. PINCOMB, PhD, WILLIAM R. LOVALLO, PhD,
RICHARD B. PASSEY, PhD, and MICHAEL F. WILSON, MD

Caffeine use during exposure to mental stress is an extremely common occurrence. Because both have been shown to alter blood pressure (BP) and its underlying hemodynamic mechanisms, the potential exists for additive or even synergistic effects. Changes in heart rate, BP and noninvasive thoracic impedance measures of left ventricular function were examined in young men (ages 20 to 36) at rest and during a demanding behavioral task performed 40 minutes after predosing with caffeine (3.3 mg/kg, equivalent to 2 to 3 cups of coffee) or placebo in a double-blind crossover design. All subjects were healthy young men without history of cardiovascular disease, regular use of nicotine, recreational or prescription drugs or caffeine intolerance. Caffeine abstinence was required for 12 hours before each test session. Systolic and diastolic BP were elevated by both caffeine and the behavioral task alone ($p < 0.01$ for each); when combined, caffeine's pressor effects were additive to those of the behavioral task. However, caffeine's pressor effect was produced by different mechanisms depending on the behavioral state. Caffeine increased systemic vascular resistance ($p < 0.01$) under resting conditions, but it enhanced cardiac output ($p < 0.01$) during behavioral arousal associated with the task. The combined influence of caffeine and the task increased the number of men in whom peak systolic BP reached hypertensive levels, and also synergistically increased cardiac minute work ($p < 0.01$) and the rate-pressure product estimate of myocardial oxygen demand ($p < 0.05$). Implications of these findings are discussed for longstanding theoretical disputes regarding caffeine, its health consequences, and for methodologic issues in behavioral and clinical studies.

(Am J Cardiol 1988;61:798–802)

Caffeine's effects on cardiovascular regulation in humans, which have been questioned for at least a century,[1] remain a subject of controversy among scientists, physicians and the lay public. Early theoretical disputes concerned whether caffeine elevates blood pressure (BP) by: (1) enhancing vasoconstriction and thus vascular resistance, or (2) producing cardiac stimulation of rate, contractility or both, which then increase cardiac output sufficiently to overcome enhanced vasodilation. No consensus yet exists regarding these mechanisms, because the few previous studies involved a small number of normal volunteers or patients and lacked a placebo-controlled condition.[2–5]

The mechanism of caffeine's pressor effect has important health implications. Caffeine-induced vasoconstriction might accelerate the development of systemic hypertension and its associated vascular, cardiac and renal pathology. Mild cardiac stimulation, if accompanied by vasodilation, might improve circulatory capacity with benefits that outweigh the risks of modestly elevated BP. Thus far prospective studies relating caffeine use to cardiovascular disease and mortality have yielded inconclusive findings.[6–11] A recent study refined the estimates of daily caffeine use by obtaining updated information about coffee con-

sumption at 5-year intervals[12] and reported a significant elevation in relative risk of 2.5 for subsequent coronary artery disease in recent heavy coffee drinkers (≥5 cups daily), even after adjustment for the effects of age, systemic hypertension, current cigarette smoking and baseline serum total cholesterol levels.

In most placebo-controlled designs, acute administration of caffeine or coffee leads to systolic and diastolic BP elevations, and may also slightly decrease heart rate (HR). A few investigators suggest that a rapid development of tolerance during long-term caffeine administration eliminates sustained elevations in BP; and tolerance may at least partially account for discrepant epidemiologic findings.[13] However, the duration of tolerance is apparently brief, since habitual caffeine use does not usually alter the BP response magnitude to caffeine after only a 12-hour abstinence.[14–17]

Caffeine's actions are undoubtedly complex. One hypothesis is that caffeine's effects are modified by psychologic/behavioral stressors, because both affect common organ systems and both may occur simultaneously under natural conditions. Few available studies examined this hypothesis in humans. Caffeine appeared to increase BP, but not HR in early studies concerning caffeine's effects on psychomotor speed and accuracy.[18] The administration of caffeine before performance of a mental arithmetic task did not change HR, but resulted in higher BP,[16,17,19] lower forearm vascular resistance[17,19] and a synergistic increase in forearm blood flow[17,19] during the task. These studies do not fully clarify mechanisms underlying caffeine's effects on BP regulation, but they do confirm the importance of studying caffeine and behavioral interrelations.

An initial study in our laboratory[20] examined the effects of caffeine (3.3 mg/kg, equivalent to 2 to 3 cups of coffee) compared with placebo during controlled resting conditions in 15 healthy young men (ages 20 to 35). We observed that at rest caffeine's pressor effect was predominantly due to a progressive enhancement of vascular resistance, rather than cardiac stimulation. Cardiac output was not altered by caffeine; in fact, HR decreased slightly, and no evidence was seen of an increased ejection acceleration to indicate enhanced myocardial contractility.

The current study compares hemodynamic mechanisms underlying caffeine's pressor effect during resting conditions versus during manipulation of behavioral state using a highly demanding reaction-time task. Previous experience indicates that cardiovascular responses to such tasks are characterized by increased HR, stroke volume, ejection acceleration and cardiac output, accompanied by decreased systemic vascular resistance[21,22] with a net increase in systolic and diastolic BP. The task-related pattern of cardiovascular activity is similar to that seen during mild aerobic exercise or during mental effort such as making rapid mental arithmetic calculations.[23] Yet it is elicited while limiting necessary physical activity to small finger movements, thereby minimizing breathing, speaking and movement artifacts.

Methods

Forty-four healthy young men (ages 20 to 36) volunteered for the study with informed consent. No volunteers reported known cardiovascular disease, regular smoking, recreational or prescription drug use or caffeine intolerance. Each participant completed 2 test sessions scheduled at the same time of day. Prior abstinence was required from food and caffeine (12 hours), alcohol (24 hours) and medications (36 hours). Grapefruit juice (6 ounces) alone for the placebo or with 3.3 mg/kg caffeine (equivalent to 2 to 3 cups of coffee) was given according to a double-blind, within-subject crossover design.

HR and BP were measured by an automated Critikon/Dynamap oscillometric monitor. Measurements of left ventricular function were obtained noninvasively using a Surcom 304B impedance cardiograph and companion 7000 microcomputer. The technique and data documenting its reliability have been described elsewhere.[20]

Procedure: Upon entering the laboratory each participant completed a questionnaire to confirm current good health and compliance with dietary restrictions. Then a predose of placebo or caffeine was given with the instructions to drink it as rapidly as possible. Surface electrocardiographic and aluminum strip impedance electrodes were attached to the skin. A phonocardiographic microphone, held in place by an elastic strap, was placed 2 to 3 cm above the left nipple and just left of midline. A heparinized Teflon® intravenous catheter was inserted in a left forearm vein to permit periodic blood sampling with minimum disruption. A BP cuff was placed on the upper left arm. The complete instrumentation process required 20 minutes and overlapped the first half of the postdrug absorption period.

Participants were then seated in a semirecumbant position and asked to remain awake while quietly reading general interest news or science publications for an additional 20-minute postdrug rest period. Then participants were instructed to begin a 15-minute behavioral task, which involved watching a small red signal light illuminated for 60 trials at unpredictable intervals. Successful performance required maintaining intense concentration and rapid responding by depressing a telegraph key as soon as the signal light appeared. Bonuses of 50 cents were earned for each extremely fast response (<270 ms). Immediate feedback was given for successful responses. A resting recovery period of 20 minutes followed the task.

Dependent variables and sampling procedures: HR and BP were sampled at 2-minute intervals, and their averages were calculated for the following experimental periods: (1) *postdrug resting baseline* was a 10-minute period begun 30 minutes after drug administration; (2) *behavioral task* was a 15-minute period of continuous task performance; and (3) *recovery baseline* was a 5-minute period begun 15 minutes after task completion. Impedance-derived measurements were obtained on 2 to 3 cardiac cycles per minute and then averaged for each of these experimental periods. Immediately after the cardiovascular measurements

were made for baseline and task periods, residual heparin was removed from the intravaneous catheter and 15 cc of blood was drawn for later determination of plasma caffeine, cortisol and norepinephrine concentrations. The catheter was reheparinized to prevent clotting during subsequent periods.

Systemic vascular resistance and 2 indexes of cardiac work were calculated according to standard formulas. Systemic vascular resistance = (mean BP/cardiac output) × 80. Minute work index = (mean BP/cardiac output). Myocardial oxygen demand estimated from the rate-pressure product = (HR × systolic BP).

Assays: Immediately after each blood sample was drawn the plasma was separated and stored on ice until the end of the session. The plasma was then transferred to storage at −70°C until batched assays were performed. Blood for norepinephrine determinations was collected in 15-cc vacutainer tubes preinjected with glutathione, and plasma concentrations were quantified using radioenzymatic assay (UpJohn Cat-A-Kit). Plasma cortisol concentrations were quantified by radioimmunoassay (Travenol Laboratories' Gamma-Coat). Caffeine was isolated from plasma using acetonitrile precipitation and quantified by high-pressure liquid chromatography.[24]

TABLE I Subject Characteristics

	Mean	Range	(± SEM)
Age (yrs)	23	21–36	0.4
Height (in)	71	66–77	0.3
Weight (lb)	166	115–210	2.6
Percent ideal weight	106	85–125	0.1
Caffeine use (mg/day)	424	30–1,937	63

Caffeine use was based on structured recall for coffee, tea, chocolate and medicinal sources; median use was 316 mg daily.
SEM = standard error of the mean.

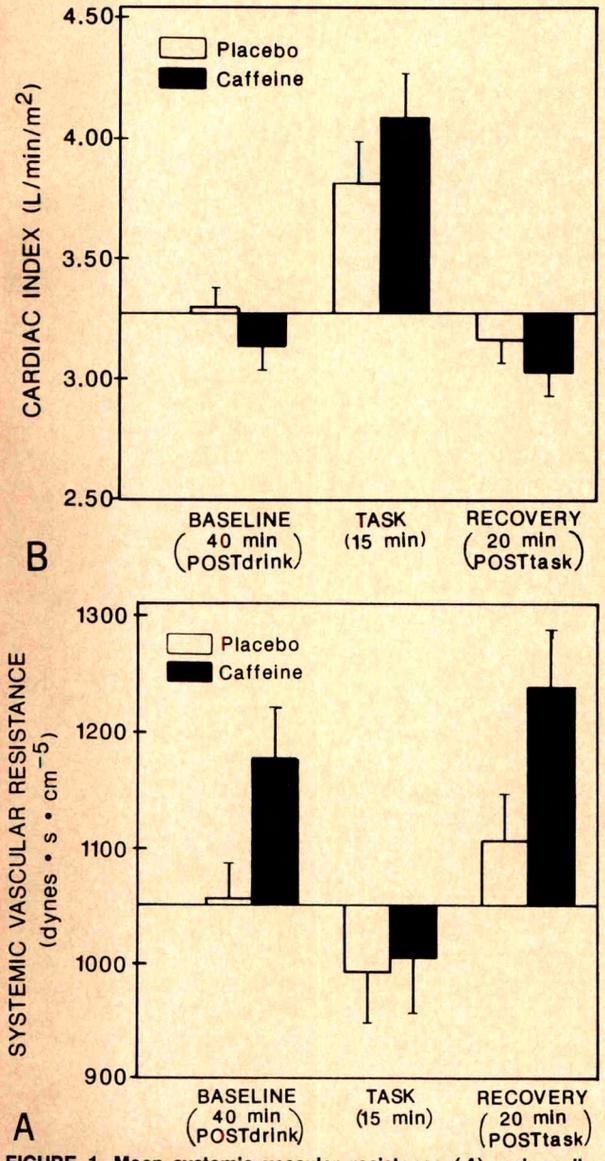

FIGURE 1. Mean systemic vascular resistance (*A*) and cardiac index (*B*), at 40-minute postdrink baseline during 15-minute behavioral task and at 20-minute post-task recovery. Cardiac index is defined as cardiac output divided by body surface area.

Results

The ages, height, weight and self-reported caffeine use for the 41 men included in the final study population are summarized in Table I. Data were omitted for 2 men due to difficulty in obtaining valid impedance measurements, and for another volunteer whose plasma caffeine concentrations were unacceptably elevated on the placebo day (>2.5 μg/ml), indicating either a dosing error or caffeine consumption during the required abstinence period.

Effectiveness of the double-blind drug administration was confirmed by asking the men immediately after each session to predict whether they had received caffeine. Neither correct predictions of caf-

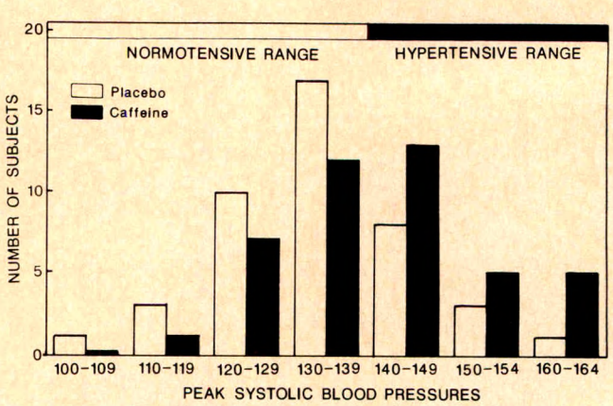

FIGURE 2. Peak systolic blood pressures obtained during the behavioral task on placebo compared with caffeine days. Normotensive versus hypertensive ranges are typically defined using casual measurements obtained after 5 minutes of rest in a seated posture. The peak pressures obtained during the behavioral task could have clinical significance, if they are representative of sustained responses during naturally occurring stressors.

TABLE II Cardiovascular and Endocrine Responses to Caffeine Versus Placebo During Rest and a Behavioral Challenge Task

	Placebo		Caffeine		F Values		
Variables	Rest	Task	Rest	Task	Caffeine (at rest)	Task	CXT

feine drinks (59%) nor of drug-order conditions (49%) were better than chance.

There were no effects of drug order (placebo-caffeine vs caffeine-placebo) or of session day (day 1 vs day 2) on the initial postdrug resting baseline values summarized in Table II. One-way analyses of variance comparing placebo with caffeine days showed that the present results replicate our previous findings. Under resting conditions, caffeine increased systolic BP and diastolic BP by elevating vascular resistance rather than by enhancing cardiac output. Additionally, caffeine increased resting plasma norepinephrine levels.

The effects of caffeine and the task (Table II) were examined using 1-way analyses of variance with repeated measures for 2 drug conditions (placebo vs caffeine) and 2 experimental periods (postdrug baseline vs task). Task-related cardiovascular responses on either day were characterized by increased HR, stroke volume, ejection acceleration and cardiac output accompanied by decreased vascular resistance. This hemodynamic response pattern increased systolic BP via enhanced cardiac stimulation (Figure 1), a pressor mechanism opposite to that seen with caffeine at rest. Performance of the task was also associated with elevated levels of plasma norepinephrine.

Caffeine's effects during the behavioral task were qualitatively different from those observed at rest (Table II). During the task caffeine no longer elevated vascular resistance. Instead caffeine synergistically increased task-related increments in cardiac output (Figure 1), apparently through heart rate, ejection acceleration and stroke volume. The combination of caffeine and the task increased the number of men with *peak* blood pressures reaching hypertensive levels (Figure 2). Further, caffeine increased cardiac work as estimated by 2 commonly used indexes: the minute work index and the rate × pressure product estimate of myocardial oxygen demand. The caffeine-induced increase in norepinephrine concentrations seen at rest during the postdrug baseline was additive with the task-related elevation. While caffeine did not affect cortisol concentrations at rest, it potentiated the task-related increase in plasma cortisol levels. Caffeine did not significantly improve reaction-time performance; the average number of rewards earned was 18 on the placebo day and 19 on the caffeine day ($p > 0.50$).

Most cardiovascular variables returned rapidly to near postdrug resting levels after the task. Because caffeine's effects during the initial rest period were opposite those seen during the task it seemed possible that either pattern (enhanced vascular resistance or cardiac stimulation accompanied by decreased vascular resistance) might dominate during the after-task recovery baseline, or that their opposing action might obviate any persistent effect of caffeine after the task was terminated. We found that caffeine's pressor effect persisted during recovery, predominantly due to rapid reinstatement of an elevated vascular resistance (Figure 1).

Discussion

These findings help clarify disagreements concerning the mechanisms underlying caffeine's pressor effect. It appears that caffeine's pressor effect may be produced either by increased vascular resistance or cardiac output. At least in healthy young men, the elevated vascular resistance appears to predominate during resting conditions, while potentiation of cardiac stimulation predominates during periods of behavioral arousal. The *resting* elevation in vascular resistance is consistent with the current view that many of caffeine's effects at concentrations achieved by dietary use are related to adenosine antagonism.[13] Whether caffeine's potentiation of β-adrenergically mediated responses *to a behavioral challenge* involve additional central or peripheral enhancement of sympathetic ac-

tivity merits further examination. We found that both caffeine and the task increased plasma norepinephrine levels, but the relation is additive rather than interactive. No data were available for plasma epinephrine.

Other investigators[17,19] have suggested that caffeine might actively enhance vasodilation during mental stress based on the observation that caffeine synergistically increased forearm blood flow and decreased forearm vascular resistance during performance of mental arithmetic. However, methodologic difficulties with the forearm blood flow measurements prevented adequate calibration and also limited the extent to which the vasodilation hypothesis could be supported. In the current study we also observed that caffeine synergistically decreased systemic vascular resistance during the behavioral task compared with the pretask baseline. However, the average level of systemic vascular resistance during the task was equivalent on both caffeine and placebo days. Thus, it appears that caffeine did not produce a net enhancement of systemic vasodilation. Instead the previous caffeine-induced elevation in vascular resistance seen at rest was eliminated during the task.

The health consequences of caffeine use may then partially depend on complex interactions with the extent and duration of behavioral/emotional stressors. Caffeine consumption may be increased during periods of chronic stress, such as during heightened occupational demand.[25] Our findings suggest that caffeine may potentially contribute to pressor responses extending into hypertensive ranges and may synergistically enhance cardiac workload during naturally occurring stressors. Particularly in persons with or at risk for the development of cardiovascular diseases, both caffeine's vasoconstrictive effects and its enhancement of stress-related cardiac stimulation may adversely affect the disease processes. Possible circulatory benefits from caffeine's enhancement of cardiac stimulation appear to be limited, because we were unable to find evidence supporting earlier speculation that such effects were accompanied by net vasodilation.

Further, when designing and interpreting future studies it should be recognized that caffeine's effects may be altered by psychologic or behavioral factors, particularly when invasive or obtrusive procedures are used. Earlier studies that reported that caffeine increased cardiac output relied on measurements made during rebreathing procedures or during cardiac catheterization.[2,3,5,26] It seems possible that either the discomfort and disruption of respiratory patterns frequently associated with rebreathing techniques or the anxiety associated with the invasiveness, risks and diagnostic implications of cardiac catheterization may have produced interactions like those seen between caffeine and our behavioral task.

A more general methodologic precaution concerns the effect of dietary caffeine intake on diagnostic tests or research protocols. Interpretation of acute stress studies or ambulatory monitoring data may be affected by interactions between caffeine and the primary conditions being investigated. Such studies may be improved either by restricting caffeine intake or by documenting the amount consumed to permit the use of statistical control procedures.

Lisinopril Versus Lisinopril plus Hydrochlorothiazide in Essential Hypertension

JAWAHAR MEHTA, MD, LARRY M. LOPEZ, PharmD, and ALFRED D. THORMAN, PA-C

The efficacy of a new angiotensin converting enzyme inhibitor, lisinopril, used alone (group A) was compared with lisinopril plus hydrochlorothiazide (group B) in 26 patients with essential hypertension. Therapy with both regimens was equally effective in lowering blood pressure compared to placebo. Mean antihypertensive dose of lisinopril was lower when given in combination with hydrochlorothiazide than when given alone (48 ± 6 vs 68 ± 12 mg daily). Plasma renin activity increased in both groups of patients, but more in group B ($p < 0.05$). Plasma aldosterone concentrations and serum uric acid levels were also higher in the group receiving lisinopril plus hydrochlorothiazide ($p < 0.05$). Serum potassium concentrations were unaffected in either group. The incidence of side effects was similar in groups A and B (44% and 38%, respectively). This study suggests that lisinopril alone or in combination with hydrochlorothiazide effectively lowers blood pressure in patients with essential hypertension without any major side effects.

(Am J Cardiol 1988;61:803–806)

Initial pharmacotherapy for most patients with essential hypertension consists of β-adrenergic blockers or diuretics.[1–3] Because these agents may have unacceptable side effects, initial therapy with other agents, such as calcium antagonists,[4] centrally acting α_2-adrenoceptor agonists[5] and angiotensin converting enzyme (ACE) inhibitors[5,6] has been recently advocated. The ACE inhibitors exert minimal side effects[6,7] and, therefore, are appropriate in a variety of patients. However, ACE inhibitors currently marketed in the U.S. may occasionally cause proteinuria and bone marrow depression.[8,9] Recently, a new ACE inhibitor, lisinopril, was developed.[10] It is a lysine analog of enalaprilat, which itself is the active metabolite of enalapril, an ACE-inhibitor prodrug. In previous studies, lisinopril has been shown to be as potent as enalapril, but with longer duration of action. Its hemodynamic effects appear at 2 to 4 hours after administration and persist for more than 24 hours.[10] This study examines the efficacy of lisinopril alone and in combination with hydrochlorothiazide in patients with essential hypertension.

Methods

Patient selection: Patients recruited for this trial were men over 18 years of age with mild to moderate essential hypertension defined as untreated diastolic blood pressure (BP) of 90 to 114 mm Hg. Patients were excluded if they had a history of a cerebrovascular accident, hypertensive encephalopathy or myocardial infarction within the past year. Patients with a history of drug or ethanol abuse or hypersensitivity to either thiazide diuretics or ACE inhibitors were likewise excluded. Other exclusion criteria included significant renal, hepatic or hematologic disorders and the presence of grade 3 or 4 hypertensive retinopathy.

Protocol: Each qualifying patient was entered into the first of 3 study phases after gradual discontinuation of all existing antihypertensive medications. The first phase involved single-blind administration of placebo for 4 weeks. Every patient was instructed to take medication once daily upon arising in the morning. BP and heart rate were determined during weekly clinic visits before administration of medication. Complete physical and laboratory examinations were performed at the end of withdrawal of antihypertensive therapy and the 4-week placebo period. Each patient with a sitting diastolic BP of 90 to 114 mg Hg was randomized to

TABLE II Adverse Effects of Lisinopril Alone and with Hydrochlorothiazide

Lisinopril Alone (Group A)	Lisinopril + Hydrochlorothiazide (Group B)
Disorientation (1)	Rash (1)
Nocturia (1)	Impotence (1)
Dry throat (1)	Increased uric acid (1)
Frequency (1)	Postural dizziness (1)
Postural dizziness (1)	Lightheadedness (1)
Reduced exercise tolerance (1)	
Increased alkaline phosphatase (1)	

Number in parentheses represents number of patients complaining of adverse effect.

active therapy if the difference between the last 2 diastolic BPs was ≤10 mm Hg.

Randomization to active therapy marked the beginning of the second phase. Patients were randomly assigned to lisinopril alone (group A) or lisinopril plus hydrochlorothiazide (group B). Double-blind medication was administered once daily and dose was titrated upward every 4 weeks to a sitting diastolic BP of <90 mm Hg and a decrease in sitting diastolic BP ≥10 mm Hg. The daily dose of lisinopril in group A was begun at 20 mg and increased to 40 mg and then to 80 mg, if needed. The daily doses of lisinopril and hydrochlorothiazide in group B were begun at 20 and 12.5 mg, respectively, increased to 40 and 25 mg, and then to a maximum of 80 and 50 mg, respectively, as needed. At the end of this phase, if BP goal was not achieved, the patient was removed from the study and returned to previous antihypertensive therapy. If BP goal was realized, however, the patient then entered the third phase of the study, which was a treatment period lasting 12 weeks. The dose of double-blind medication associated with adequate BP reduction in the second phase was continued throughout this phase. As in the previous phase, BP and heart rate were evaluated biweekly in sitting and erect positions. Complete physical and laboratory examinations were performed every 4 weeks, and patients were interviewed during each clinic visit concerning occurrence of side effects. During all phases, compliance was assessed with tablet counts and patients were instructed to continue their usual diet. Medications know to affect BP were not allowed, and other medications taken during this study were tabulated.

Laboratory tests: Laboratory tests included evaluation of hematologic, renal and hepatic functions. Plasma renin activity, plasma aldosterone levels, serum uric acid and potassium levels were also measured. All of these analyses were performed by Smith-Kline/Bioscience Laboratories. Blood was collected from all patients at the end of placebo, titration and treatment phases in supine position after at least 15 minutes of rest between 8 and 9 A.M., before the drug intake. No attempt was made to regulate patients' dietary habits or salt intake, as each patient served as his own control.

Statistical analysis: The study code was unblinded at the end of the treatment phase. Heart rate and BP data were averaged for all groups. Data are presented as mean ± standard error. The effects of the 2 forms of therapy on BP were determined by 1-way repeated measures analysis of variance and the Student *t* test for paired data. Frequency data were analyzed using Fischer's exact test. Laboratory data were evaluated for changes in plasma renin activity, plasma aldosterone concentrations, serum uric acid and potassium concentrations associated with the use of lisinopril alone or in combination with hydrochlorothiazide.

Results

Out of 29 patients initially screened for entry into this trial, 26 qualified. Of these 26, 3 were unable to receive double-blind medication due to adverse events encountered during placebo phase (one had a nonfatal myocardial infarction, one had ventricular arrhythmias and the third developed a rash). One patient was removed from the trial at the end of the titration phase when his BP failed to decrease sufficiently. Table I summarizes the clinical and demographic characteristics of the remaining 22 patients who completed all phases of the study. The 2 groups were comparable, except that group A patients had hypertension of longer duration.

Effects of lisinopril alone and in combination with hydrochlorothiazide on BP and heart rate are presented in Figure 1. BP in both supine and erect positions was significantly reduced with minimal effects on heart rate. Comparisons of these changes failed to achieve statistical significance between the groups even though the daily dose of lisinopril in group B was somewhat less than that in group A (48 ± 6 vs 68 ± 12 mg, $p = 0.15$).

The effects of lisinopril administration alone and in combination with hydrochlorothiazide on selected metabolic parameters (plasma renin activity, plasma aldosterone concentrations, serum potassium and uric acid concentrations) are depicted in Figure 2. Plasma renin activity increased significantly in both groups of patients, but the magnitude of this increase was more pronounced ($p < 0.05$) in group B patients. Aldosterone concentrations were lowered in patients receiving lisinopril alone ($p < 0.05$) but were unchanged in patients receiving both medications. Serum potassium concentrations were unaffected in both groups of patients. When hydrochlorothiazide was combined with lisinopril, uric acid concentration increased signifi-

cantly ($p < 0.01$), but not when lisinopril was given alone.

All adverse effects reported by patients during double-blind titration and treatment phases are listed in Table II. Frequency of these adverse effects did not differ between the study groups, nor did proportions of patients experiencing them (44% group A; 38% group B; difference not significant). Postural dizziness occurred in both groups and in both instances was not accompanied by clinically important changes in BP. Lisinopril did not cause an adverse effect on proteinuria, renal function or other laboratory parameters. It is noteworthy that a small but significant reduction in hematocrit was observed in both groups (46% to 43%, group A; 45% to 42%, group B; $p < 0.01$ for both). All adverse effects encountered were minor in nature and none required discontinuation of therapy in any patient.

Discussion

This study demonstrates that lisinopril alone and in combination with hydrochlorothiazide is effective as initial pharmacotherapy in the management of patients with essential hypertension. Although both therapeutic regimens were equally effective, the dose of lisinopril required to decrease BP was lower when used in combination with hydrochlorothiazide compared with lisinopril alone. It is noteworthy that both regimens caused no significant tachycardia, either in the sitting or standing position.

Comparable BP responses to combination therapy with a low dose of lisinopril plus hydrochlorothiazide and lisinopril alone may be expected, because the 2 drugs act via different mechanisms and may act synergistically. Whereas hydrochlorothiazide is a diuretic and stimulates the renin-angiotensin-aldosterone axis secondary to reduction of plasma volume, lisinopril inhibits the same axis by blocking conversion of angiotensin I to angiotensin II. A cumulative antihypertensive response became apparent when small doses of both drugs were administered concomitantly. Similar cumulative effects between diuretics and other ACE inhibitors have been described previously.[11] Sodium loss associated with thiazide diuretics is increased when the diuretics are combined with the ACE inhibitor enalapril.[11] The resultant loss of fluid volume potentiates the hypotensive effect of the ACE inhibitor.

Lisinopril alone or in combination with hydrochlorothiazide lowered BP quickly (≤4 weeks) and that reduction in BP after titration of dose was maintained throughout the remainder of the study. In spite of rapid and sustained reduction in BP, we did not observe any objective incidence of orthostasis. This was perhaps related to the relatively slow onset of the action of lisinopril with a peak action at 2 to 4 hours.[10] No patient was withdrawn because of the development of side effects, although side effects were frequent and similar in both groups (44% of patients in the lisinopril group, and 38% of patients in the lisinopril plus hydrochlorothiazide group). The somewhat lower frequency of side effects in the latter group may be explained by the use of small amounts of 2 different drugs.

The effects of lisinopril alone or its combination on plasma renin activity, plasma aldosterone levels and serum potassium levels are interesting, although not unexpected (Figure 2). Plasma renin activity increased in both groups, although to a greater extent in the lisinopril plus hydrochlorothiazide group, perhaps because of volume depletion. Plasma renin activity increased during the titration phase and continued to increase into the treatment phase. Plasma aldosterone concentrations were higher in the combination treatment group than in the lisinopril alone group, again a reflection of the varied mechanisms of action of the 2 agents. Serum potassium levels were unchanged in both groups. Similar responses have been observed before.[12] Diuretic-induced hypokalemia occurs as a result of excess delivery of sodium to the distal renal tubule and secondary hyperaldosteronism. Effects of both the reduction in circulating volume and secondary hyperaldosteronism are blunted by the concurrent administration of ACE inhibitor.[11] Serum uric acid concentrations, however, were increased in the group B patients, related most likely to the well known,

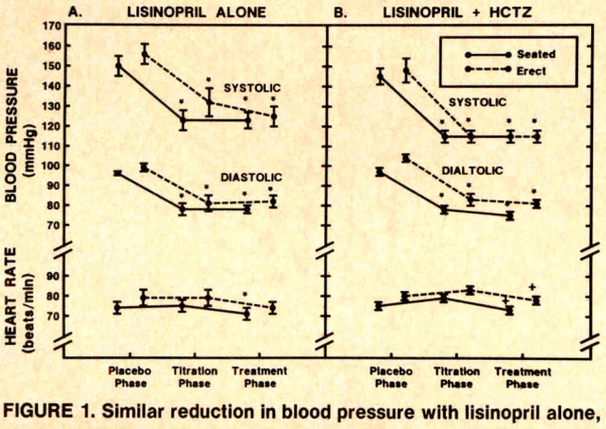

FIGURE 1. Similar reduction in blood pressure with lisinopril alone, *A*, or lisinopril plus hydrochlorothiazide (HCTZ), *B*. There was no evidence of significant orthostasis. Heart rate was minimally changed by both regimens.

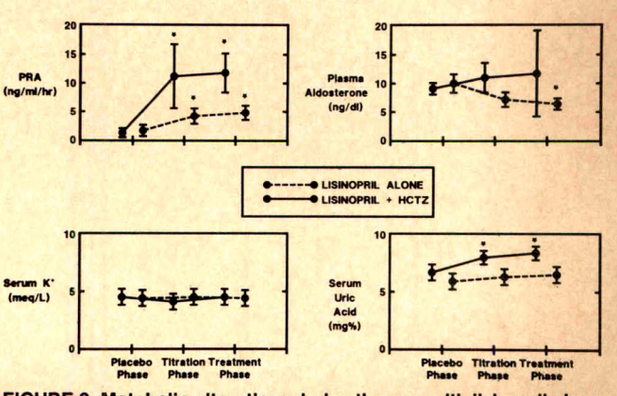

FIGURE 2. Metabolic alterations during therapy with lisinopril alone or combination of lisinopril and hydrochlorothiazide (HCTZ). (See text.) PRA = plasma renin activity.

antiuricosuric effect of thiazide diuretics. Of note is the slight decrease in hematocrit in patients receiving lisinopril alone and in combination with hydrochlorothiazide, but this reduction did not appear to be of clinical significance. Whether this abnormality would be clinically significant when these drugs are used in larger numbers of patients for prolonged periods is not known.

In summary, this study demonstrates a similar efficacy of lisinopril plus hydrochlorothiazide and lisinopril alone. When the combination regimen is used, the dosage of each agent is quite low. In this short-term trial, the incidence of side effects was small and acceptable.

Acknowledgment: The authors are thankful to Janet Wootten for editorial assistance and to Anne Crawford for typing the manuscript.

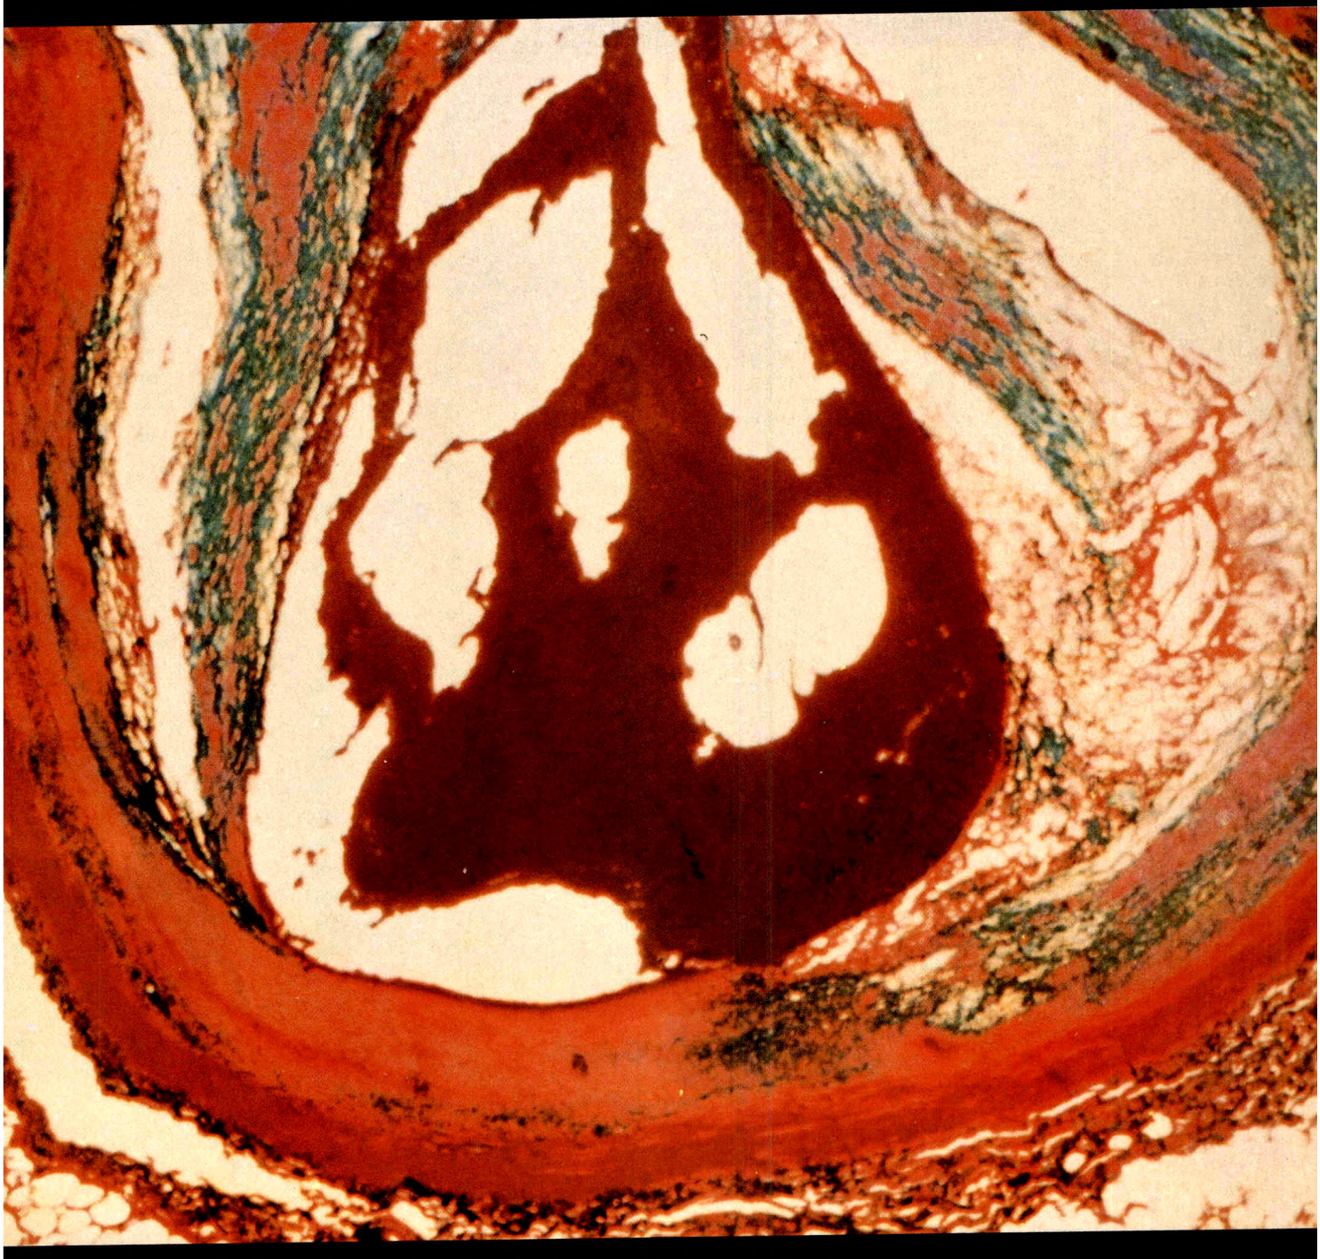
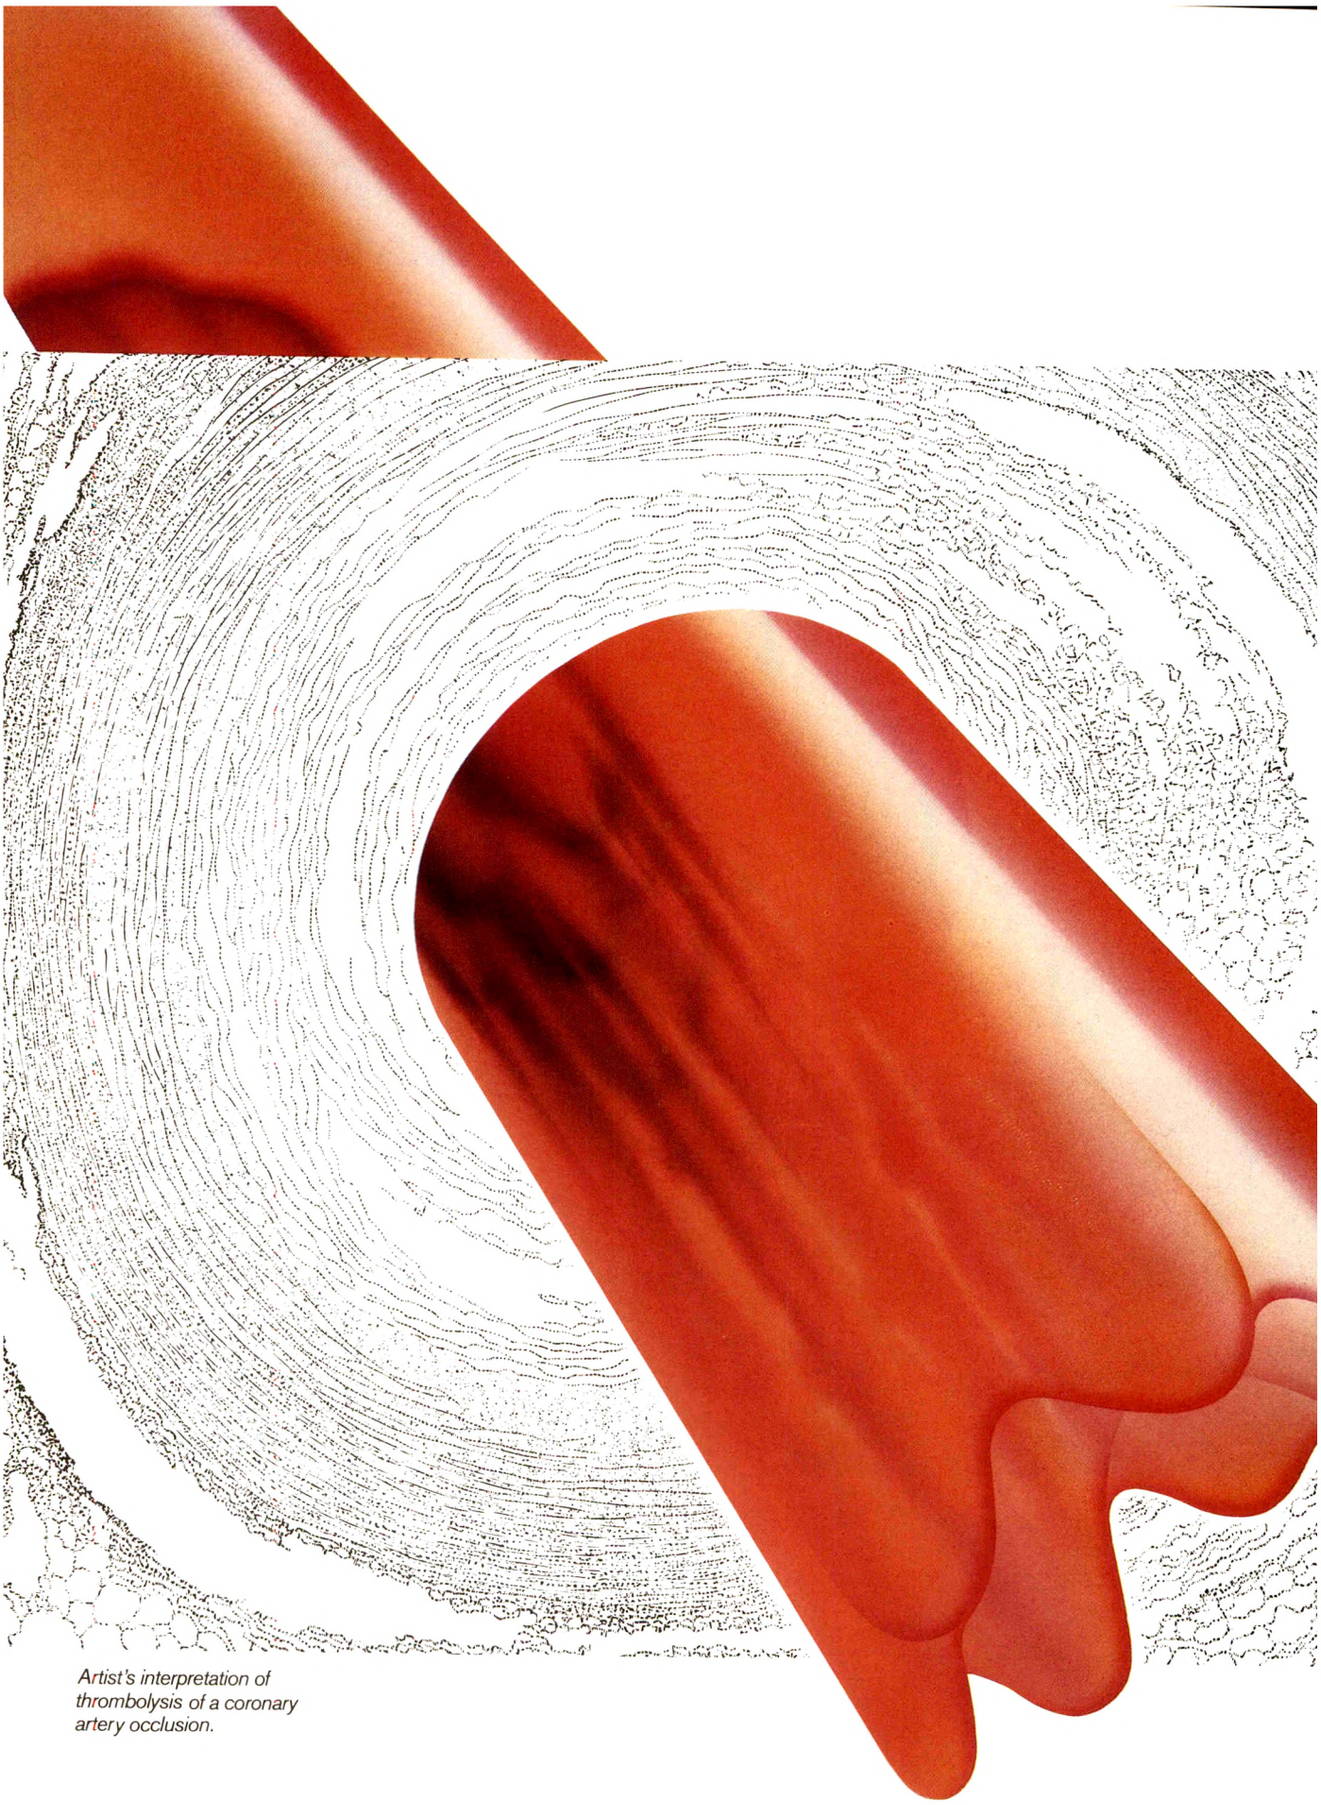
In the first critical hour of acute MI

MORTALITY REDUCED UP TO 47%



Cross section of a cardiac artery showing atheromatous plaque and occluding thrombus.

...and ventricular function improved.



Artist's interpretation of thrombolysis of a coronary artery occlusion.

Now...for acute MI
Intravenous
Streptase®
(Streptokinase)

Mortality reduced, ventricular function improved, unique benefits beyond lysis.

Lower in-hospital mortality with an acceptable level of risk[1]

- Multicenter trial with almost 12,000 randomized acute MI patients reported in *The Lancet*
- 1.5 million units of streptokinase plus conventional therapy vs. conventional therapy alone
- 47% less mortality with IV streptokinase given within one hour of onset of chest pain
- 23% less mortality with IV streptokinase given within three hours
- 17% less mortality with IV streptokinase given within six hours
- Incidence of major and minor complications considered acceptable

Improved cardiac function with few adverse effects[2]

- Randomized, placebo-controlled trial with 172 first-infarction patients, reported in *New England Journal of Medicine*, Oct 1, 1987
- 1.5 million units of streptokinase plus conventional therapy (including anticoagulants) vs. placebo infusion plus conventional therapy within four hours of onset of chest pain
- Coronary artery reperfusion shown by earlier peak of myocardial creatine kinase
- Significant increase in left ventricular ejection fraction and significant reduction in end-systolic volume confirmed by left ventricular angiography
- In this study, the most serious adverse effect was manageable hypotension

Benefits beyond thrombolysis

- Decreases red blood cell aggregation, and plasma and blood viscosity[3-5]
- Reduces blood pressure and total peripheral resistance with corresponding reduction in cardiac afterload for reduced myocardial oxygen demand[6-8]

Timing, dosage, and patient selection criteria

- Earliest treatment gives the best results
- Dosage: 1.5 million international units of streptokinase; duration of infusion up to 60 minutes
- Risk vs. benefits must be considered.

—Contraindications include active internal bleeding; recent (within two months) cerebral vascular accident, intracranial or intraspinal injury; intracranial neoplasm; and severe, uncontrolled hypertension

—*Risk of bleeding:* From pooled data of studies of 8,369 patients, the overall incidence of major bleeding was 1.2%. Nonetheless, physicians should be alert to untoward bleeding events. (Consult Warnings section of Streptase full prescribing information.)

Please see references and brief summary of prescribing information at end of this advertisement.

Intravenous
Streptase®
In the critical hours of acute MI

For acute MI
Intravenous

Streptase®
(Streptokinase)

The only thrombolytic that provides all these important benefits:

Proof of increased survival
- Reduction in mortality documented in a randomized study with almost 12,000 patients[1]

Proof of improved cardiac function
- Angiographic confirmation of improved left ventricular function[2]

Unique actions for greater reductions in cardiac stress
- Extrathrombolytic activity—reduces blood pressure, red blood cell aggregation, and blood and plasma viscosity[3-8]

Speed and simplicity in a one-step regimen
- Convenient, 1-hour constant-rate infusion compared to a 3 hour variable rate infusion with tissue plasminogen activator (r-TPA)

Staff confidence through many years of experience
- 10 years' experience in U.S. hospitals—and 25 years' worldwide—in lytic therapy

A tradition of service and support
- Extensive inservice training, important speakers' programs, and personal service by 650 skilled representatives to meet your hospital's needs

...all this at 90% less cost
- Priced at less than 10% of the reported cost of tissue plasminogen activator (r-TPA)

Bleeding, allergy and fever are the most frequent side effects seen with streptokinase; during treatment of myocardial infarction, hypotension and arrhythmias have been reported. Please see Warnings section of prescribing information before using Streptase®.

STREPTASE®
(Streptokinase)

Brief Summary
Consult full prescribing information before using.

INDICATIONS AND USAGE
Acute Evolving Transmural Myocardial Infarction
Streptase®, Streptokinase, is indicated for use in the management of acute myocardial infarction in adults, for the lysis of intracoronary thrombi, for the improvement of ventricular function, and reduction of mortality when administered by either the intravenous or intracoronary route. Earlier administration of Streptokinase is correlated with greater clinical benefit. See CLINICAL PHARMACOLOGY section of full prescribing information.

CONTRAINDICATIONS
Because thrombolytic therapy increases the risk of bleeding, Streptase®, Streptokinase, is contraindicated in the following situations:
- —Active internal bleeding
- —Recent (within 2 months) cerebrovascular accident, intracranial or intraspinal surgery (see WARNINGS)
- —Intracranial neoplasm
- —Severe uncontrolled hypertension.

Streptokinase should not be administered to patients having experienced severe allergic reaction to the product.

WARNINGS
Bleeding
Streptase®, Streptokinase, will cause lysis of hemostatic fibrin deposits such as those occurring at sites of needle punctures, and bleeding may occur from such sites. In order to minimize the risk of bleeding during treatment with Streptokinase, venipunctures and physical handling of the patient should be performed carefully and as infrequently as possible, and intramuscular injections must be avoided.
Should arterial puncture be necessary during intravenous therapy, upper extremity vessels are preferable. Pressure should be applied for at least 30 minutes, a pressure dressing applied, and the puncture site checked frequently for evidence of bleeding.
In the following conditions the risks of therapy may be increased and should be weighed against the anticipated benefits.
- —Recent (within 10 days) major surgery, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels
- —Recent (within 10 days) serious gastrointestinal bleeding
- —Recent (within 10 days) trauma including cardiopulmonary resuscitation
- —Hypertension: systolic BP ≥ 180 mm Hg and/or diastolic BP ≥ 110 mm Hg
- —High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation
- —Subacute bacterial endocarditis
- —Hemostatic defects including those secondary to severe hepatic or renal disease
- —Pregnancy
- —Cerebrovascular disease
- —Diabetic hemorrhagic retinopathy
- —Septic thrombophlebitis or occluded AV cannula at seriously infected site
- —Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Should serious spontaneous bleeding (not controllable by local pressure) occur, the infusion of Streptase®, Streptokinase, should be terminated immediately and treatment instituted as described under ADVERSE REACTIONS.

Arrhythmias
Rapid lysis of coronary thrombi has been shown to cause reperfusion atrial or ventricular dysrhythmias requiring immediate treatment. Careful monitoring for arrhythmia is recommended during and immediately following administration of Streptase®, Streptokinase, for acute myocardial infarction.

Hypotension
Hypotension, sometimes severe, not secondary to bleeding or anaphylaxis has been observed during intravenous Streptase®, Streptokinase, infusion in 1% to 10% of patients. Patients should be monitored closely and, should symptomatic or alarming hypotension occur, appropriate treatment should be administered. This treatment may include a decrease in the intravenous Streptokinase infusion rate. Smaller hypotensive effects are common and have not required treatment.

Other
Non-cardiogenic pulmonary edema has been reported rarely in patients treated with Streptase®, Streptokinase. The risk of this appears greatest in patients who have large myocardial infarctions and are undergoing thrombolytic therapy by the intracoronary route.
Rarely, polyneuropathy has been temporally related to the use of Streptase®, Streptokinase.
Should pulmonary embolism or recurrent pulmonary embolism occur during Streptase®, Streptokinase, therapy, the originally planned course of treatment should be completed in an attempt to lyse the embolus. While pulmonary embolism may occasionally occur during Streptokinase treatment, the incidence is no greater than when patients are treated with heparin alone.

PRECAUTIONS
General
Because of the increased likelihood of resistance, due to antistreptokinase antibody, Streptase®, Streptokinase, may not be effective if administered between five days and six months of prior Streptokinase administration or streptococcal infections, such as streptococcal pharyngitis, acute rheumatic fever, or acute glomerulonephritis secondary to a streptococcal infection.

Laboratory Tests
Intravenous or Intracoronary Infusion for Myocardial Infarction
Intravenous administration of Streptase®, Streptokinase, will cause marked decreases in plasminogen and fibrinogen and increases in thrombin time (TT), activated partial thromboplastin time (APTT), and prothrombin time (PT). These changes may also occur in some patients with intracoronary administration of Streptokinase.
Intravenous Infusion for Other Indications. Before commencing thrombolytic therapy, it is desirable to obtain an activated partial thromboplastin time (APTT), a prothrombin time (PT), a thrombin time (TT), fibrinogen levels, and a hematocrit and platelet count. If heparin has been given, it should be discontinued and the TT or APTT should be less than twice the normal control value before thrombolytic therapy is started.
During the infusion, decreases in plasminogen and fibrinogen levels and an increase in the level of FDP (the latter two causing a prolongation in the clotting times of coagulation tests) will generally confirm the existence of a lytic state. Therefore, lytic therapy can be confirmed by performing the TT, APTT, PT, or fibrinogen levels approximately 4 hours after initiation of therapy. If heparin is to be (re)instituted following the Streptase®, Streptokinase, infusion, the TT or APTT should be less than twice the normal control value (see manufacturer's prescribing information for proper use of heparin).

Drug Interactions
The interaction of Streptase®, Streptokinase, with other drugs has not been well studied.
Use of Anticoagulants and Antiplatelet Agents. Streptase®, Streptokinase, alone or in combination with antiplatelet agents and anticoagulants, may cause bleeding complications. Therefore, careful monitoring is advised. Concurrent use of antiplatelet agents such as aspirin, dipyridamole, or nonsteroidal antiinflammatory agents is not recommended.
Anticoagulation After Treatment for Myocardial Infarction. The administration of anticoagulant and/or antiplatelet drugs following administration of Streptase®, Streptokinase, appears to increase the risk of bleeding (see ADVERSE REACTIONS). These agents have been used in an attempt to prevent reocclusion of the target vessel. Use of anticoagulants or antiplatelet drugs following administration of Streptokinase has not yet been shown to be of unequivocal clinical benefit. Therefore, the use of anticoagulant and/or antiplatelet regimens should be individualized.
Anticoagulation after IV Treatment for Other Indications. Continuous intravenous infusion of heparin, without a loading dose, has been recommended following termination of Streptase®, Streptokinase, infusion for treatment of pulmonary embolism or deep vein thrombosis to prevent rethrombosis. The effect of Streptokinase on thrombin time (TT) and activated partial thromboplastin time (APTT) will usually diminish within 3 to 4 hours after Streptokinase therapy, and heparin therapy without a loading dose can be initiated when the TT or the APTT is less than twice the normal control value.

Pregnancy
Pregnancy Category C. Animal reproduction studies have not been conducted with Streptase®, Streptokinase. It is also not known whether Streptokinase can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Streptokinase should be given to a pregnant woman only if clearly needed.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
The following adverse reactions have been associated with intravenous therapy and may also occur with intracoronary artery infusion:

Bleeding
The incidence of bleeding (major or minor) varied widely from study to study depending on dosage, patient population and concomitant therapy.
Minor bleeding can be anticipated mainly at invaded or disturbed sites. If such bleeding occurs, local measures should be taken to control the bleeding.
Severe internal bleeding involving gastrointestinal, genitourinary, retroperitoneal, or intracerebral sites has occurred and has resulted in fatalities. In three studies in which anticoagulation was optional following intravenous administration of Streptase®, Streptokinase, for acute myocardial infarction, the incidence of major bleeding ranged from 0.3%-6.2%. In 21 studies in which anticoagulation was compulsory, the incidence of major bleeding ranged from 0-16%. The overall incidence of major bleeding with intravenous infusion is 1%-2%.
Major bleed rates are difficult to determine for other dosages and patient populations because of the different dosing and intervals of infusions. The rates reported appear to be within the ranges reported for intravenous administration in acute myocardial infarction.
Should uncontrollable bleeding occur, Streptokinase infusion should be terminated immediately. Slowing the rate of administration of Streptokinase will not help correct bleeding and may make it worse. If necessary, bleeding can be reversed and blood loss effectively managed with appropriate replacement therapy. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for Streptokinase has not been documented, it may be considered in an emergency situation.

Allergic Reactions
Anaphylactic and anaphylactoid reactions have been observed rarely in patients treated intravenously with Streptase®, Streptokinase. These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling or angioneurotic edema. Other milder allergic effects such as urticaria, itching, flushing, nausea, headache and musculoskeletal pain have also been observed, as have delayed hypersensitivity reactions such as vasculitis and interstitial nephritis. Anaphylactic shock was reported in one study with an incidence rate of 0.1%.
Mild or moderate allergic reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase®, Streptokinase, with adrenergic, antihistamine, and/or corticosteroid agents administered intravenously as required.

Fever
Although Streptase®, Streptokinase, is nonpyrogenic in standard animal tests, recent reports in the literature have noted an incidence of fever ranging from 0 to 21% in patients treated intravenously with Streptokinase. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is preferable.

DOSAGE AND ADMINISTRATION
Acute Evolving Transmural Myocardial Infarction
Administer Streptokinase as soon as possible after onset of symptoms. The greatest benefit in mortality reduction was observed when Streptase®, Streptokinase, was administered within one hour, statistically significant benefits were observed up to six hours and some benefit was observed up to 12 hours without statistical significance (see CLINICAL PHARMACOLOGY in full prescribing information).

Route	Total Dose	Dosage/Duration
Intravenous infusion	1,500,000 IU	1,500,000 IU within 60 min.

HOW SUPPLIED
Streptase®, Streptokinase, is supplied as a lyophilized white powder in 50 mL infusion bottles (1,500,000 IU) or in 6.5 mL vials with a color-coded label corresponding to the amount of purified Streptokinase in each vial as follows:
green— 250,000 IU
blue — 750,000 IU
red — 1,500,000 IU vials and infusion bottles.
Store unopened vials at controlled room temperature (15°-30°C or 59°-86°F). Unused reconstituted drug should be discarded.

The Gold Standard in ultrasound now comes to Cardiology. The ACUSON® 128 Computed Sonography™ System. A complete Cardiovascular system utilizing our unique proprietary technology. A technology beyond phased array that provides the best image quality and the best Doppler all in one unit for both Cardiology and Vascular applications.

Nowhere else can you find all this:

- Gold Standard image quality.
- Fully simultaneous steerable continuous wave and pulsed Doppler at all velocity scales to increase diagnostic accuracy and confidence while reducing exam time.
- Dual frequency cardiac transducers that provide more exam flexibility without changing transducers.
- Optimum vascular imaging with linear format to provide the best field of view.
- Color Doppler Imaging option for both sector and linear applications.
- Guaranteed 99% up-time.

INTRODUCING THE GOLD STANDARD IN ULTRASOUND TO CARDIOLOGY.

THE ACUSON 128 COMPUTED SONOGRAPHY SYSTEM.

Call us to see the best in Cardiovascular imaging. The ACUSON 128 Computed Sonography System. 1-800-4-ACUSON or in California 1-800-5-ACUSON.

in Acute MI

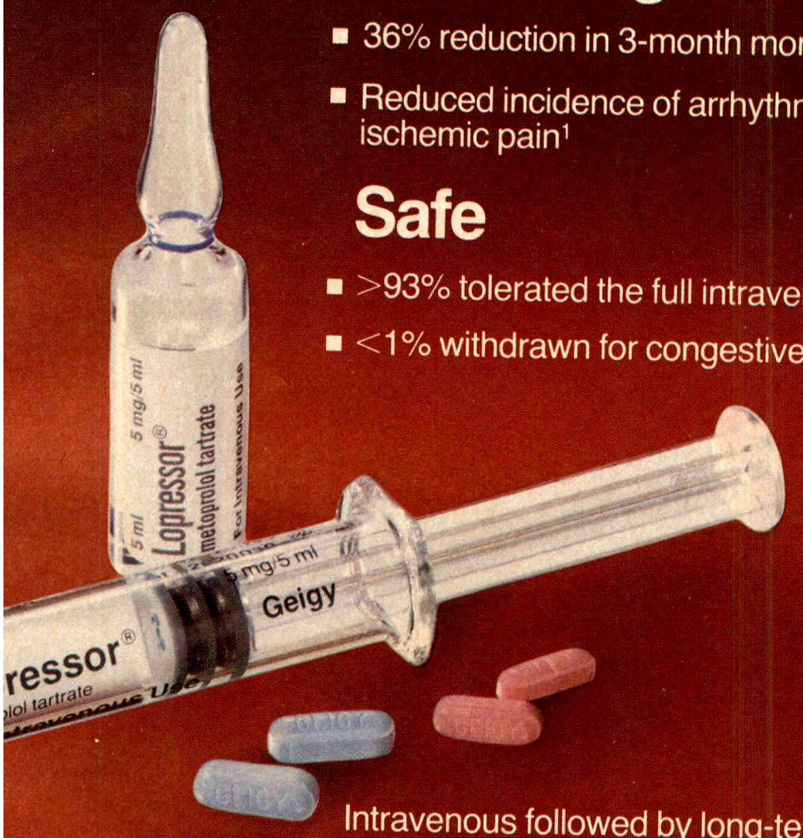
Geigy

Lifesaving

- 36% reduction in 3-month mortality[1]
- Reduced incidence of arrhythmias and ischemic pain[1]

Safe

- >93% tolerated the full intravenous dose[2]
- <1% withdrawn for congestive heart failure[3]



Intravenous followed by long-term oral therapy

Alternatively, oral treatment can begin within 3 to 10 days of the acute event

Lopressor is contraindicated in patients with heart rate <45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥0.24 sec); systolic blood pressure <100 mmHg; or moderate-to-severe cardiac failure.

Please see last page for Brief Summary of Prescribing Information.

Lopressor®

metoprolol tartrate USP

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE

Hypertension
Lopressor tablets are indicated for the treatment of hypertension. They may be used alone or in combination with other antihypertensive agents.

Angina Pectoris
Lopressor is indicated in the long-term treatment of angina pectoris.

Myocardial Infarction
Lopressor ampuls, prefilled syringes, and tablets are indicated in the treatment of hemodynamically stable patients with definite or suspected acute myocardial infarction to reduce cardiovascular mortality. Treatment with intravenous Lopressor can be initiated as soon as the patient's clinical condition allows (see **DOSAGE AND ADMINISTRATION, CONTRAINDICATIONS,** and **WARNINGS**). Alternatively, treatment can begin within 3 to 10 days of the acute event (see **DOSAGE AND ADMINISTRATION**).

CONTRAINDICATIONS

Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).

Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS

Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS

General
Lopressor should be used with caution in patients with impaired hepatic function.

Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.

Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.

Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.

Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.

Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.

Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.

Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

Comparison of the Antihypertensive Effects of Betaxolol to Atenolol

WILLIAM J. MROCZEK, MD, JAMES F. BURRIS, MD, LEO B. HOGAN, MD, DANIEL C. CITRON, MD, ALLAN H. BARKER, MD, and ROBERT H. MCDONALD, MD

A randomized double-blind multicenter study compared a new oral β_1-adrenergic antagonist, betaxolol 10 to 40 mg (n = 71), with atenolol 25 to 100 mg (n = 75). Each drug was administered once daily for 24 weeks in patients with mild to moderate hypertension. Blood pressure (BP) measurements were taken 24 hours after dosing. Each drug produced significant ($p < 0.01$) reductions in mean supine diastolic BP. The mean decrease in supine diastolic BP with betaxolol was significantly greater at weeks 4, 6, 10 and 12 ($p < 0.05$). Throughout the remainder of the trial (weeks 14 to 24), no significant differences in BP reduction were noted between treatment groups. Normotension (supine diastolic BP ≤90 mm Hg) was achieved in 72% of those given betaxolol compared with 52% of those given atenolol ($p < 0.05$). The most common side effects noted were bradycardia, fatigue and headache. The incidence of these and of central nervous system side effects was similar between the betaxolol and atenolol groups. Both agents were well tolerated. At recommended doses, betaxolol once daily may be more effective than atenolol once daily in patients with mild to moderate hypertension.

(Am J Cardiol 1988;61:807–811)

Betaxolol, like atenolol, is cardioselective, lacks partial agonist activity, has little or no membrane stabilizing activity and has no active metabolites.[1–7] Betaxolol has a markedly higher oral bioavailability than atenolol (80 to 89% vs 50 to 60%) and a longer elimination half-life (14 to 22 hours) compared with atenolol (6 to 7 hours).[8–11] Betaxolol has demonstrated effectiveness in reducing blood pressure (BP) when administered once daily in both open and double-blind clinical trials.[12–15] A randomized double-blind multicenter study was conducted to compare the long-term (24 week) efficacy and safety of betaxolol with atenolol taken once daily in patients with mild to moderate essential hypertension.

Methods

Patient population: One hundred forty-six patients with mild to moderate essential hypertension were randomized to receive treatment. Patients with secondary causes of hypertension were excluded from the study. Other reasons for exclusion were severe cardiac arrhythmias, angina pectoris, congestive heart failure, pulmonary disease and insulin-dependent diabetes. Women of child-bearing potential practicing a medically accepted means of contraception were permitted to enter the study.

The protocol was approved by the respective institutional review committee and informed consent was obtained from all patients.

Study design: The study included 4 phases. Phase 1 was an initial 4-week washout period during which all antihypertensive medications were discontinued and patients were given 1 placebo capsule daily at 10 A.M. If the patient's supine diastolic BP was between 95 and 115 mm Hg at the end of the placebo run-in period, he or she was randomized to 1 of 2 treatments and proceeded to the next phase of the trial.

Phase 2 was a 12-week dose-titration period. Patients were seen at 2-week intervals. At 4-week intervals, if supine diastolic BP remained >90 mm Hg, the dosage of betaxolol was increased from 10 to 20 to 40 mg; atenolol was increased from 25 to 50 to 100 mg. Study medications were taken at 10 A.M. The low and high doses in this study were obtained by halving and doubling the usual dose of each agent.

Phase 3 was a 12-week maintenance period during which patients continued to receive their optimal dose

Data are mean ± standard error where appropriate.
BP = blood pressure; KWB-HT = Keith-Wagner-Barker classification limited to hypertensive retinopathy.

TABLE II Reasons for Withdrawal Among the Randomized Patients

	Betaxolol (n = 71)	Atenolol (n = 75)
Side effects	5	3
Intercurrent illness	1	2
Therapeutic failure	2	5
Administrative*	6	5

* Refusal of therapy, lost to follow-up, failure to follow appointment schedule, nonqualifying blood pressure, poor compliance or protocol violation.

of the assigned drug. Phase 4 was a 2-week placebo washout period.

The primary measurements (supine and standing BP and heart rate) were recorded every 2 weeks. At each visit, BP was measured in the morning just before the next dosing after 5 minutes in the supine position and also after 3 minutes in the standing position using a standard mercury sphygmomanometer. An average of 3 recordings was taken and the Korotkoff phase V was used for measuring the diastolic BP. At each visit, patients were queried as to side effects. All patients underwent a full physical examination and a review of their medical histories before entering the trial. Electrocardiogram, chest roentgenogram and ophthalmologic studies were performed during phases 1 and 4. Routine laboratory tests, lipid and lipoprotein analyses and determination of antinuclear antibody titers were performed at scheduled intervals.

TABLE III Supine Systolic and Diastolic Blood Pressure (in mm Hg) at Baseline, End of Titration Phase and End of Treatment

Baseline	Betaxolol (n = 71)	Atenolol (n = 75)
Supine		
systolic	147 ± 2	152 ± 2
diastolic	100 ± 1	101 ± 1
Decrease at end of titration*	**Betaxolol (n = 64)**	**Atenolol (n = 69)**
Supine		
systolic	14 ± 1	13 ± 2
diastolic	14 ± 1	11 ± 1
Decrease at end of treatment*	**Betaxolol (n = 57)**	**Atenolol (n = 60)**
Supine		
systolic	15 ± 1	11 ± 2
diastolic	13 ± 1	11 ± 1

* Data from each patient's last visit in the dose-titration and maintenance phases were used. Values are mean ± standard error. All values for dose titration and maintenance phases represent significant ($p < 0.01$) changes from baseline.

Patients were withdrawn from the study if any of the following occurred: average supine diastolic BP remained ≥105 mm Hg on 2 consecutive visits at the maximum dosage level, serious side effects, symptomatic bradycardia, a standing systolic BP <105 mm Hg, symptomatic orthostatic hypotension or poor compliance.

Statistical analyses: Changes in BP and heart rate at each visit were assessed by an analysis of variance incorporating treatment, center and their respective interaction. All available data from randomized patients at each visit were analyzed for efficacy. Side effects and laboratory parameters were evaluated in all 146 patients randomized to receive treatment. A conventional chi-square test was used for categorical analysis of percentage of patients responding to therapy in each treatment group. In addition, the cumulative percent of responders by treatment was plotted against natural log of dose at the end of titration and at the end of treatment period. The level of significance for all tests was set at $p < 0.05$. All values are expressed as the mean and 1 standard error.

Results

Patient population: One hundred forty-six patients were randomized to receive active therapy: 71 to betaxolol and 75 to atenolol. There were no significant differences in patient demographics between the 2 groups except for age (Table I). In both the betaxolol and atenolol groups, response rates did not differ significantly according to age. There was no difference in previous antihypertensive medications. After randomization, 14 patients receiving betaxolol and 15 patients receiving atenolol were withdrawn before completion of the treatment phase (Table II).

Antihypertensive effects: The time course of the BP-lowering effects of betaxolol and atenolol are

shown in Figure 1. Blood pressures at baseline, end of the titration and maintenance phases are listed in Table III. A significant reduction in BP occurred within 2 weeks from the start of active treatment in both groups and persisted throughout the 24-week treatment period. A comparison between treatment groups at weeks 4, 6, 10 and 12 showed that betaxolol significantly reduced supine diastolic BP to a greater degree compared with atenolol ($p < 0.05$) (Figure 1).

Discontinuation of active treatment and substitution of placebo (phase 4 withdrawal) resulted in an elevation of BP toward pretreatment levels with both drugs. After 2 weeks on placebo, supine diastolic and systolic BP increased by 10 ± 1 mm Hg and 14 ± 2 mm Hg, respectively, in the betaxolol group. Similarly, in the atenolol group, supine diastolic and systolic BP increased by 7 ± 1 mm Hg and 8 ± 2 mm Hg, respectively. For all response variables, the increase did not exceed pretreatment values.

Response rate: A significantly higher percentage of patients receiving betaxolol than those receiving atenolol achieved the targeted supine disastolic BP response (≤90 mm Hg or a reduction of ≥10 mm Hg). Of those patients completing the trial, 83% of the betaxolol group achieved the targeted response compared with 65% of the atenolol group ($p < 0.05$) (Figures 2 and 3). Normotension (supine disastolic BP ≤90 mm Hg) was achieved in 72% of the betaxolol group compared with 52% of the atenolol group ($p < 0.05$).

Heart rate: A significant reduction in heart rate from baseline value occurred in both groups during the first 2 weeks of treatment and persisted throughout the 24-week treatment period. At the end of the titration phase, supine heart rate for the betaxolol group was reduced by 10 ± 1 beats/min ($p < 0.01$) below the baseline value (75 ± 1 beats/min); for atenolol the reduction was 6 ± 1 beats/min ($p < 0.01$) below the baseline value (74 ± 1 beats/min). At the end of the maintenance phase, the supine heart rate was reduced by 11 ± 1 beats/min ($p < 0.01$) with betaxolol, and by 10 ± 1 beats/min ($p < 0.01$) with atenolol.

Side effects: All side effects elicited or volunteered by the patients or observed by the investigators were

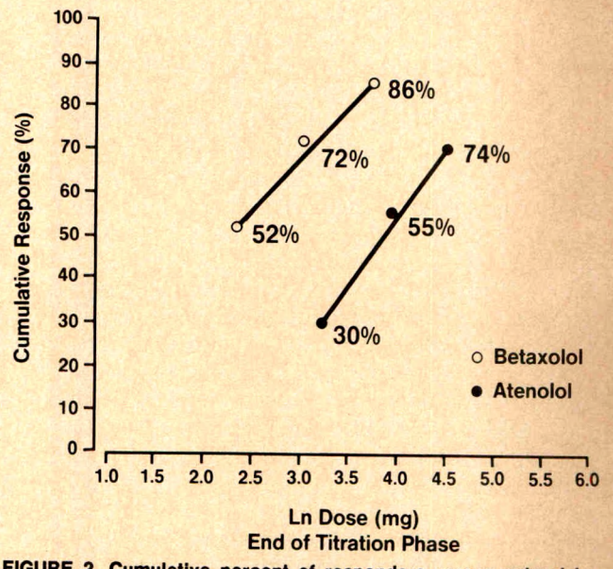

FIGURE 2. Cumulative percent of responders versus natural log (Ln) dose at the end of the titration phase. Response (%) = betaxolol 24.6 × Ln dose (mg) − 3.9; atenolol 31.0 × Ln dose (mg) − 67.8.

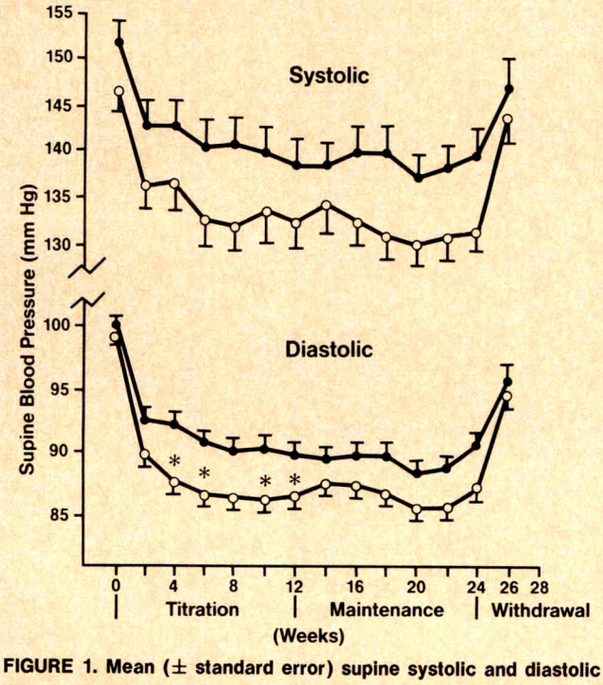

FIGURE 1. Mean (± standard error) supine systolic and diastolic blood pressure during treatment with betaxolol (○) and atenolol (●) in patients with mild to moderate essential hypertension. * $p < 0.05$ for betaxolol versus atenolol.

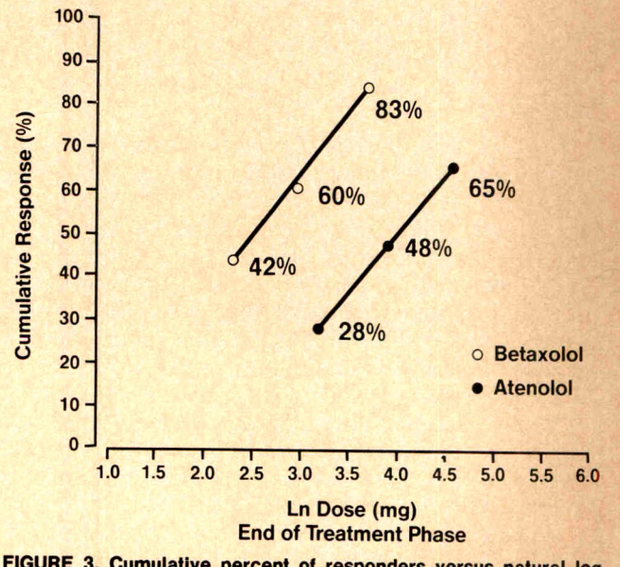

FIGURE 3. Cumulative percent of responders versus natural log (Ln) dose at the end of the treatment phase. Response (%) = betaxolol 24.3 × Ln dose (mg) − 2.9; atenolol 26.4 × Ln dose (mg) − 56.1.

recorded irrespective of their considered relation to treatment. There were no statistically significant differences in the type and incidence of side effects reported between groups. The most common side effects were bradycardia (<50 beats/min) (11 patients in the betaxolol and 9 in the atenolol group), fatigue (5 in the betaxolol and 3 in the atenolol group) and headache (6 in the betaxolol and 4 in the atenolol group).

Central nervous system side effects were similar. Depression occurred in 1 patient given each treatment. There was no difference in the incidence of sleep disturbances or impotence between groups.

Bradycardia occurred with a similar frequency in both treatment groups. Only 1 patient (in the betaxolol group) exhibited symptomatic bradycardia resulting in withdrawal from the study. The associated symptom in this patient was tiredness.

Laboratory abnormalities: There were no clinically significant changes from baseline in routine hematology, blood chemistries or urinalysis for patients treated with either drug. Three patients in the betaxolol group and 4 patients in the atenolol group developed positive antinuclear antibody titer test results, which were not associated with clinical symptoms.

No changes in total cholesterol, high density lipoprotein and low density lipoprotein were observed. There was a slight but not significant increase (10% from baseline) in serum triglycerides in the betaxolol group and a statistically significant ($p < 0.01$) increase (53% from baseline) in the atenolol group. The difference between treatment groups was not significant at either baseline or the end of the study. The baseline values were within normal limits for both groups.

Other clinical abnormalities: Several changes were observed in chest roentgenogram, electrocardiogram and ophthalmologic findings, but the relation to treatment was doubtful or uncertain. Ophthalmologic signs or ocular symptoms were noted in 3 patients in the atenolol group and 2 patients in the betaxolol group. No other clinical abnormalities were observed in any of these patients.

Discussion

The objective of this study was to compare the antihypertensive effects of betaxolol and atenolol 24 hours after administration. Both agents lowered BP over the dose ranges studied throughout the trial. At the end of the study, the percentage of patients responding was 83% for betaxolol and 65% for atenolol. The average dose among betaxolol responders was 20 mg and among atenolol responders was 52 mg; among all patients completing the study, the average dose at final treatment visit was 21 mg for betaxolol while for atenolol the average dose was 62 mg.

A consistently lower supine disastolic BP was observed with betaxolol at each treatment week of the trial. The observed results may be explained by the pharmacokinetic profile of the 2 drugs. The half-life of betaxolol (14 to 22 hours) should produce pharmacologic effects of a duration equal to or greater than its half-life. In contrast, while several studies[16–20] confirm that atenolol can provide BP control over a 24-hour dosing interval, its shorter half-life (6 to 7 hours) may cause the antihypertensive effect to diminish toward the end of a 24-hour period. This observation is supported by Warrington et al.[21] In their study, healthy volunteers received intravenous betaxolol, atenolol and propranolol. Hemodynamic indexes of β-adrenergic blocking effects were similar in magnitude at 2 and 4 hours after dosing, but at 24 hours, the pharmacologic effects of betaxolol were more pronounced than those of the other drugs studied. In another investigation, comparing single oral doses of betaxolol (40 mg), atenolol (200 mg) and propranolol (160 mg), the 24 hour β-blocking effects were reduced from the peak effects by 50% and 63% for atenolol and propranolol, respectively, whereas the β blockade for betaxolol diminished by only 9% over the 24-hour period.[22]

The side-effect profiles for betaxolol and atenolol were similar and consistent with those reported with other β-adrenergic antagonists. In particular, central nervous system side effects were low and similar between the 2 treatment groups. Although 3 patients in the betaxolol group and 4 in the atenolol group developed new and persistent positive antinuclear antibody titers during the study, these were not associated with symptoms. Further, in a recent study of diabetic hypertensive patients with elevated antinuclear antibody titers, subsequent antihypertensive treatment with betaxolol resulted in a decrease in these titers.[23]

It is desirable in the treatment of hypertension to achieve normotension (supine disastolic BP $\leq$90 mm Hg) and thereby influence the morbidity and mortality of the disease. Over the dose ranges studied, normotension was achieved in 72% of the patients who completed the trial with betaxolol. Also of interest was the rate of response to the initial dose of betaxolol. Of those patients completing the study, 50% achieved normotension or at least a 10 mm Hg reduction in supine disastolic BP with a single 10 mg dose of betaxolol.

In conclusion, this trial demonstrated that betaxolol may be more effective than atenolol when administered once daily to patients with mild to moderate hypertension when blood pressure is measured 24 hours after administration.

Comparative Study of Primary Tissue Failure Between Porcine (Hancock and Carpentier-Edwards) and Bovine Pericardial (Ionescu-Shiley) Bioprostheses in the Aortic Position at Five- to Nine-Year Follow-Up

IGNACIO GALLO, MD, FRANCISCO NISTAL, MD, EMILIO ARBE, MS, and EDURNE ARTIÑANO, MD

Retrospective follow-up data on 458 consecutive patients who received a Hancock, Carpentier-Edwards (C-E) or Ionescu-Shiley (I-S) bioprosthesis in the aortic valve position between April 1978 and December 1981 are reviewed. A total of 461 valves (184 Hancock, 131 C-E and 146 I-S) were available for study of the incidence of primary tissue valve failure after 5 to 9 years of follow-up. Cumulative follow-up was 1,016 patient-years for patients with Hancock valve, 688 for the C-E and 767 for the I-S group. Of the 397 prostheses at risk (154 Hancock, 120 C-E and 123 I-S), 36 instances of primary tissue valve failure occurred (12 Hancock, 7 C-E and 17 I-S). On an actuarial basis, the calculated probability of freedom from primary tissue valve failure was 88 ± 4% for the Hancock group, 87 ± 6% for the C-E and 51 ± 17% for the I-S at 9 years. The linear incidence of tissue valve failure was 1.2 failing valves per 100 patient-years for the Hancock group, 1 for the C-E and 2.2 for the I-S. In a cohort of patients older than 40 years of age at the time of valve replacement, the rate of freedom from primary failure was 98 ± 1%, 87 ± 9% and 44 ± 22% for the Hancock, C-E and I-S groups, respectively, at 9 years. Comparison of actuarial curves disclosed a meaningful difference between the pericardial valve and the Hancock and C-E porcine bioprostheses at 9-year follow-up. These data should have some bearing of practical import not only when comparing different types of bioprostheses, but especially when recommending the appropriate valve replacement for the individual patient.

(Am J Cardiol 1988;61:812–816)

Primary tissue failure is the main disadvantage in the long-term evolution of bioprosthetic cardiac[1-20] valves and the reason why many surgeons prefer mechanical valves in patients with a life expectancy >10 years.[4,5] The net 10-year results comparing the incidence of complications in patients receiving biologic or mechanical prosthetic heart valves, however, showed no significant difference between the 2 types of valves.[21,22] We evaluated the incidence of documented primary tissue failure among unselected patients included in 3 groups who underwent operation during the same period of time, by the same surgical team and who received either a porcine or bovine pericardial glutaraldehyde-preserved bioprosthesis in aortic position.

Methods

Patients: Between April 1978 and December 1981 a total of 458 patients, retrospectively reviewed, received in our institution a glutaraldehyde-preserved porcine (Hancock or Carpentier-Edwards [C-E]) or a bovine pericardial (Ionescu-Shiley [I-S]) bioprosthesis as valve substitute in aortic position. This analysis included a total of 461 valves (184 Hancock, 131 C-E and

146 I-S) available for study of the incidence of primary tissue valve failure after 5 to 9 years of follow-up. No special selection or randomization was used to select the type of bioprosthesis to be implanted for each individual patient; only the surgeon's preference was a determinant in this respect. We excluded from this study all patients who were not discharged from hospital, and patients with valve failure caused by infection and paravalvular leaks. This study was limited to the 399 prostheses selected according to the stated criteria and controlled until April 1987. Table I lists the total number of valves placed and those selected for the study.

Operative techniques were standardized, and included cold ischemic arrest with topical hypothermia for myocardial protection, moderate systemic hypothermia and uninterrupted aortic crossclamping. Rinsing and perioperative handling of valves was similar in all cases, because all valves were implanted during the same time frame and by the same surgical team.

Primary tissue valve failure was established either at reoperation or autopsy by detection of valve regurgitation or stenosis due to construction failures, cuspal tears, perforation, calcific deposits or stiffening of the leaflets in the absence of a previous active infective process. Mechanical failures due to faults in construction were included. The endpoint for the definition of primary tissue failure was not only reoperation but also death with confirmation of valve failure by autopsy examination or previous positive diagnosis of dysfunction made clinically and hemodynamically. Living patients with hemodynamic or clinical diagnosis of valve dysfunction are not included because primary tissue valve failure has not been confirmed.

All surviving patients were routinely evaluated at this hospital. Those who failed to report to the hospital were contacted by letter. Follow-up was conducted until April 1987. Survival rates and the incidence of tissue valve failure are determined by actuarial analysis (Kaplan-Meier) and by linearized occurrence rates

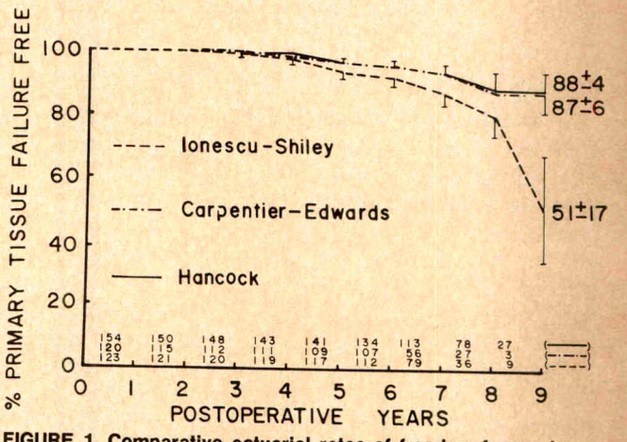

FIGURE 1. Comparative actuarial rates of freedom from primary tissue valve failure in Hancock, Carpentier-Edwards and Ionescu-Shiley bioprostheses at 9-year follow-up. The number of valves at risk per postoperative year is shown. Data are given as ± standard error.

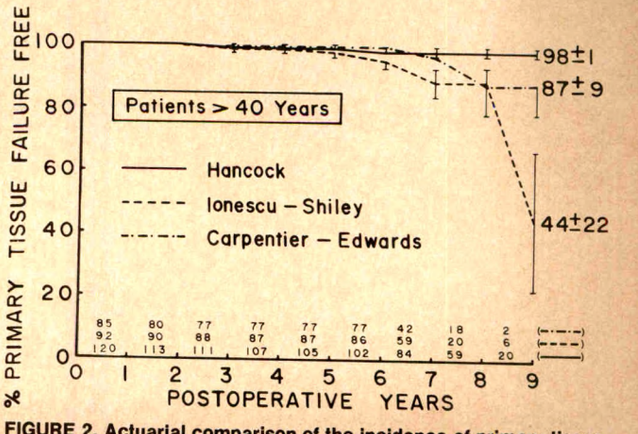

FIGURE 2. Actuarial comparison of the incidence of primary tissue valve failure in patients older than 40 years.

TABLE II Implantation Valve Sizes

and are given as ± 1 standard error of the mean. The comparison between different actuarial curves was performed using normal distribution. Differences were considered meaningful when the significance level was <0.05.

Explanted valves were examined, described and photographed macroscopically, processed by standard techniques for light microscopy and stained by hematoxylin/eosin.

Results

There were 397 valves at risk of primary tissue degeneration (154 Hancock, 120 C-E and 123 I-S). No differences in age, sex and other risk factors of primary tissue failure were observed according to the type of prosthesis.

Cumulative follow-up was 1,016 patient-years for patients with Hancock valves, 688 for the C-E group and 767 for the I-S.

Of the 397 prostheses at risk, 36 instances of valve degeneration, according to the previously expressed criteria, occurred in 36 patients followed for as long as 9 years. Twelve of the failed valves were Hancock (8% or 12 of 154), 7 C-E (6% or 7 of 120) and 17 I-S pericardial (14% or 17 of 123). Mean duration of the valves before being explanted was 68 ± 19 months (range 34 to 95), 63 ± 16 (47 to 93) and 68 ± 21 (36 to 104) for the Hancock, C-E and I-S valves, respectively, without significant differences. Linearized rates of primary valve failure were 1.2 ± 0.3 failing valves per 100 patient-years for the Hancock series, 1 ± 0.4 for the C-E and 2.2 ± 0.5 for the I-S. Mean age of patients whose valves degenerated afterwards was, at the time of implantation, 32 ± 11 years (range 20 to 55) for the Hancock group, 33 ± 10 (range 17 to 46) for the C-E and 41 ± 14 (range 15 to 62) for the I-S. Mean age of patients with failing valves was higher in the I-S series than in the porcine group, with a marginally significant difference ($0.05 < p < 0.1$). Distribution of bioprosthetic failures depending on valve size is listed in Table II.

On an actuarial basis the calculated probability of freedom from primary tissue valve failure was 88 ± 4%, 87 ± 6% and 51 ± 17% at 9 years of follow-up for the Hancock, C-E and I-S groups, respectively (Figure 1). A significant difference ($p < 0.05$) was observed in the last point of the curves between the porcine and pericardial prostheses, although both porcine series have a consistently higher rate of freedom from primary tissue valve failure starting at the fifth postoperative year. Freedom from degeneration was compared using actuarial analysis in a cohort of patients older than 40 years at the time of surgery (Figure 2). For the Hancock prostheses, the rate of freedom from primary tissue failure was 98 ± 1% at 9 years, 87 ± 9% for the C-E and 44 ± 22% for the I-S ($p < 0.01$). No statistically significant difference in the failure rates between C-E and Hancock porcine recipients was observed in this age group. Actuarial analysis of the incidence of primary tissue failure in patients younger or older than 40 years at the time of valve implantation showed a clear-cut difference among porcine valve recipients (Figure 3), with significantly higher failure rates in younger patients since the fifth postoperative year. However, patients with bovine bioprostheses showed no clear difference in failure rates depending on the age at the time of operation (Figure 4). The comparison of actuarial curves from different valve size cohorts yielded no

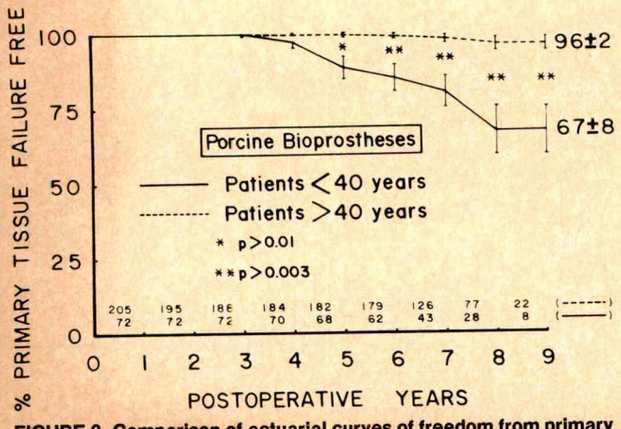

FIGURE 3. Comparison of actuarial curves of freedom from primary tissue valve failure in patients younger or older than 40 years with a porcine bioprosthesis.

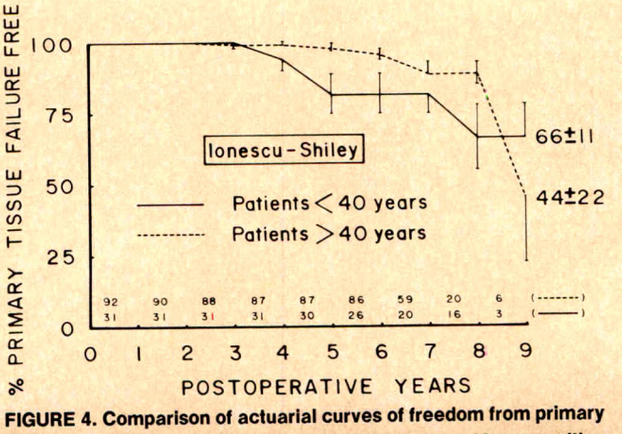

FIGURE 4. Comparison of actuarial curves of freedom from primary tissue valve failure in patients younger or older than 40 years with a bovine pericardial bioprosthesis.

significant difference of failure rates in either type of bioprosthesis.

The cause of valve failure in the pericardial group was tear and calcification in all cases. Calcification, from plaques to florid granulations, caused immobilization of leaflets and, when incompetent, cuspal tears were related with calcifications. Porcine bioprosthetic dysfunction was also associated with cuspal calcium deposits and calcium related tears.

Discussion

Tissue valve replacements for diseased heart valves have, as major advantages over mechanical prostheses, a low risk of thromboembolism, usually without anticoagulation, and therefore with a lower incidence of postoperative hemorrhagic accidents. Although limited durability is a problem with all current bioprostheses, this complication is often slow in onset, and therefore most patients with primary tissue valve failure may successfully undergo reoperation.

Dysfunction of the glutaraldehyde-preserved porcine xenografts, due to tissue degradation, has been extensively reported both in adult patients[1-6] and children.[7-14] In addition, the structural and ultrastructural study of surgically removed porcine bioprostheses has improved our knowledge of the pathogenesis of primary tissue failure and the recognition of several risk factors.[15-20] Primary tissue valve failure of the bovine pericardial xenografts has been reported in isolated cases,[23-39] and in some of them this valve failure was not caused by tissue degeneration or calcium.[35-39]

Comparison of the long-term results of different techniques of valve replacement is difficult because of the many factors that vary between surgical teams, such as patient population and surgical techniques. We have summarized a 9-year concomitant comparison of the incidence of tissue valve degeneration in a group of patients who underwent aortic valve replacement within the same institution, by the same surgical team, over a limited period of time, using porcine and bovine pericardial valves. This retrospective, nonrandomized study shows some advantages in terms of durability of the porcine valves. Preoperative data show no statistically significant differences in age and sex. Valve size distribution is very similar for both porcine series, the average being smaller in the pericardial group. Mean and cumulative follow-up times are very close in all groups and do not differ. Hospital and late deaths are not significantly different but its comparison and that of other events like thromboembolism, or reoperation rate for causes other than primary valve failure, does not constitute the purpose of this study.

Durability still remains as the major problem of tissue valves and a permanent concern for surgeons. Primary tissue valve failure of the Hancock porcine bioprosthesis has been extensively reported.[1-20] However, little information is available on the C-E and I-S durability in the intermediate and long-term period and, although many reports on porcine or pericardial bioprostheses describe the use of both types of valves, no specific comparison between them has been accomplished so far.[28]

Age of the patients at operation acts, in our own[1] and others[3,4,8,12] experience, as a factor that predisposes to primary tissue failure. The present results show that although this tendency is clearly demonstrated among porcine valve recipients, bovine pericardial valves display a completely different behavior in this respect. This phenomenon suggests that, even though younger age has a determinant effect on the appearance of primary tissue failure in porcine bioprostheses, other factors and specifically the intrinsic tendency of the bovine pericardial tissue to calcify may play a role in the latter group. These findings agree well with what has been previously observed both in patients[28-31] and experimental animals.[40] Mean age of patients with failing valves in this series was higher in the I-S group (41 ± 14 years) than in the Hancock (32 ± 11) or C-E (33 ± 10), with a marginally significant difference ($0.05 < p < 0.1$).

No risk factors for calcium (e.g., pregnancy, renal insufficiency) were found in any patient of either group with a failing valve. However, examination of actuarial curves shows no statistically significant difference, although the porcine series displays a consistently lower rate of freedom from primary tissue failure starting at the fifth postoperative year. One should be cautious when interpreting these results, but the origin of the bioprosthetic tissue (porcine aortic valve or bovine pericardium) has been recently considered a significant factor influencing the appearance of tissue degeneration in valves implanted in patients[28-31] and experimental animals.[40]

Noninvasive Assessment of Mitral Stenosis Before and After Percutaneous Balloon Mitral Valvuloplasty

PATRICIA C. COME, MD, MARILYN F. RILEY, BS, RDMS, DANIEL J. DIVER, MD, JAMES P. MORGAN, MD, PhD, ROBERT D. SAFIAN, MD, and RAYMOND G. McKAY, MD

Thirty-seven patients with symptomatic mitral stenosis underwent balloon dilatation of the mitral valve. Significant increases ($p < 0.001$) were noted in both catheterization- and Doppler-determined valve area (0.9 ± 0.3 to 1.8 ± 0.8 and 0.9 ± 0.2 to 1.7 ± 0.5 cm^2). However, catheterization and Doppler areas before and after valvuloplasty correlated less well ($r = 0.51$, $p < 0.002$ and $r = 0.47$, $p < 0.005$, respectively) than the catheterization-Doppler area correlation in a previous study of 59 consecutive patients with varying degrees of mitral stenosis ($r = 0.84$, $p < 0.001$). Mitral valve area increases were independent of valve thickness estimated using 2-dimensional echocardiography. Flail mitral leaflet movement was not observed and the degree of mitral regurgitation qualitatively assessed using pulsed Doppler mapping techniques increased by >1 of 4 grades in only 1 patient. The lateral mitral valve orifice diameter increased more than the anteroposterior diameter, suggesting commissural splitting as the mechanism of successful valvuloplasty. Increases (all $p < 0.0001$) were noted in mitral valve EF slope (7 ± 5 to 18 ± 10 mm/s), excursion (11 ± 5 to 13 ± 4 mm), S20S interval (0.07 ± 0.02 to 0.08 ± 0.02 s) and cardiac output (4.2 ± 1.3 to 5.3 ± 2.0 liters/min). There were significant decreases (all $p < 0.001$) in left atrial diameter (5.4 ± 1.0 to 5.1 ± 1.0 cm), mean catheterization gradient (15 ± 5 to 8 ± 4 mm Hg) and mean Doppler gradient (10 ± 4 to 6 ± 3 mm Hg).

Thus, while Doppler study can accurately predict catheterization mitral valve area in patients referred for assessment of mitral stenosis, the correlation coefficients are lower in balloon valvuloplasty patients preselected for severe mitral stenosis and in patients after balloon valvuloplasty. Other noninvasive parameters, previously shown to be inaccurate predictors of baseline valve area, do reflect increases after valvuloplasty. Valvuloplasty can successfully increase valve area even in patients with severe mitral valve thickening and causes little change in the degree of mitral regurgitation.

(Am J Cardiol 1988;61:817–825)

The development of successful percutaneous balloon mitral valvuloplasty[1–5] will undoubtedly increase the number of patients with rheumatic heart disease undergoing invasive diagnostic testing and therapeutic intervention. Imaging and Doppler echocardiography have been shown to be reliable noninvasive techniques for detecting rheumatic deformity of the mitral valve and for quantitating the severity of associated mitral stenosis and regurgitation.[6–16] The uses and limitations of echocardiography in defining the results of balloon valve dilatation, however, have not been fully defined. Accordingly, this study, including the 15 patients undergoing valvuloplasty at the Beth Israel Hospital in whom valvuloplasty techniques and initial findings have previously been reported,[3] was designed with 2 major objectives: to evaluate the accuracy of noninvasive techniques in determining the results of balloon valvuloplasty in patients with mitral stenosis and to determine the changes in valve appearance, mitral regurgitation, left atrial size and integrity of the interatrial septum following percutaneous mitral valve dilatation.

From the Charles A. Dana Research Institute and the Harvard-Thorndike Laboratory of Beth Israel Hospital, Department of Medicine (Cardiovascular Division), Beth Israel Hospital and Harvard Medical School, Boston, Massachusetts. This study was presented in part at the annual meeting of the American Heart Association, November 1987. Manuscript received September 29, 1987; revised manuscript received and accepted December 10, 1987.

Methods

Patients: Between October 1985 and March 1987, 37 patients underwent balloon dilatation of the mitral valve for mitral stenosis at the Beth Israel Hospital. One of these patients, referred from another hospital for aortic valvuloplasty, was found by echocardiography to also have significant mitral stenosis. After severe stenosis of both valves was confirmed by hemodynamic measurements made immediately before valvuloplasty, both valves were dilated. Six additional patients considered for balloon valvuloplasty were rejected on the basis of echocardiographic study. In 3, imaging echocardiography detected thrombus in the appendage (2 patients) or the body (1 patient) of the left atrium, confirmed subsequently at operation. Based on echocardiographic studies, it was felt that 3 other patients, with prior catheterization diagnoses of severe mitral stenosis, had either no rheumatic mitral valve disease (2 patients) or insignificant mitral stenosis (1 patient with mitral valve area >1.5 cm^2). Repeat diagnostic catheterizations, with pulmonary capillary wedge pressures confirmed by the finding of wedge-position oxygen saturations equivalent to systemic arterial oxygen saturations, confirmed the echocardiographic findings. One of the 3 patients was found to have pulmonary venous obstruction localized to the right lower lobe.

The patients undergoing balloon valvuloplasty included 11 men and 26 women (mean age 55 ± 14 years). All had symptoms of pulmonary venous congestion, most commonly dyspnea on exertion. Noninvasive evaluation by imaging and Doppler echocardiography and echo-phonocardiography preceded valvuloplasty by 1 or 2 days. Repeat noninvasive evaluation was performed 2 to 4 days (all patients), 6 weeks (17) and 6 months (8) after valvuloplasty. Normal sinus rhythm, paced rhythm and atrial fibrillation were present in 22, 1 and 14 patients, respectively.

Phonocardiography: The aortic second sound to mitral valve opening interval was measured from echo-phonocardiograms obtained on an Irex System II. Valve opening was determined by the presence of an opening snap coinciding with the E point of the mitral valve echogram or from the E point alone when an opening snap could not be recorded.

M-mode and two-dimensional echocardiographic studies: M-mode echocardiograms were obtained using Irex System II, ATL Mark 600, or Hewlett-Packard 77020A echocardiographs. Two-dimensional and Doppler echocardiographic studies were performed with the ATL or Hewlett-Packard equipment. Mitral valve excursion was measured (in mm) as the maximal amplitude of the anterior diastolic movement of the anterior mitral leaflet.[17] The mitral valve EF slope was measured in mm/s. Maximal systolic left atrial diameter was measured using the leading edge to leading edge technique[17] from cursor-derived M-mode echocardiograms, with the sound beam oriented perpendicular to the long axis of the left atrium and left ventricle. If the cursor could not be oriented perpendicularly through the left atrium, systolic diameter was measured directly off the 2-dimensional screen. The left atrium, including the appendage, was carefully scanned for echogenic densities suggestive of thrombus.[18] Both M-mode and 2-dimensional echocardiograms were assessed for abnormalities of mitral valve movement typical of rheumatic deformity.[7,9-11] The degree of thickening of the valve and chordae tendineae was estimated from the 2-dimensional scans. Findings suggestive of a flail mitral leaflet, including high-frequency systolic fluttering or projection of a leaflet into the left atrium, were evaluated.[7] Attempts were made to visualize the mitral valve orifice in short axis.[9-11] To do so, the 2-dimensional transducer was placed in the second or third left intercostal space and angled to provide a parasternal long axis view. It was then rotated and angled inferiorly to provide a short axis view at the level of the papillary muscles. With slow superior transducer angulation, the mitral valve orifice at the tips of the mitral leaflets, where the area is generally smallest, was visualized. Transducer orientation was maximized to provide, when possible, true transverse rather than oblique views of the mitral orifice. The anteroposterior and lateral diameters of the mitral valve orifice were measured in the 30 patients in whom definition of anterior, posterior and lateral borders was possible both before and after valvuloplasty. In some patients, the edges of the mitral valve orifice could not be adequately visualized throughout all 360° of its circumference to permit optimal planimetry for determination of areas. In others, with severe pulmonary hypertension and resultant sizeable right heart dilation, the sound beam could not be directed perpendicularly through the left ventricle or mitral orifice. In addition, among those patients with marked chordal thickening, it was apparent that the limitation of leaflet separation might not be the only contributor to mitral inflow obstruction. Finally, prior echocardiographic studies had demonstrated that Doppler assessment of mitral valve area provides a reliable means of assessing the severity of mitral stenosis relative to catheterization[6,13,16,19] and may be the preferable technique in patients after surgical commissurotomy.[19] For these reasons, mitral valve areas were not planimetered from 2-dimensional short axis images.

Doppler echocardiographic studies: The magnitude of mitral regurgitation and stenosis was assessed using pulsed Doppler echocardiography. The left atrium was interrogated for regurgitation using parasternal long axis and apical 4- and 2-chamber views.[15,16] Trace to mild regurgitation was diagnosed if regurgitation could be recorded only at leaflet level or within the first third of the left atrium; moderate regurgitation was diagnosed if the signals extended to one-third to two-thirds of the length of the left atrium, generally over at least two-thirds of its width; and severe regurgitation was diagnosed when signals were obtained from even wider areas of the atrium.

For evaluation of mitral stenosis, the pulsed Doppler transducer was positioned at the apex to obtain 4- or 2-chamber apical views and the sample volume was placed on the ventricular side of the mitral valve. Using both audio and visual output, transducer position

and angulation were altered to record mitral inflow signals of highest velocity and narrowest spectral bandwidth (characteristics suggesting orientation of the sound beam in line with blood flow). Hard-copy recordings were made and digitized with a graphics tablet (GTCO) and microcomputer (IBM PC) using custom-written software (Datastat). Digitization consisted of tracing the velocity curves; from these velocity points for calculation of instantaneous pressures were obtained every 4 ms, permitting calculation of the mean pressure gradient. The pressure half-time was also calculated from the hard-copy recordings and mitral valve area (MVA) was estimated from the formula: MVA (cm^2) = 220/pressure half-time (ms).[13] The values reported for mean gradients and valve areas represent the average of values obtained from 10 beats. Special care was necessary to analyze the tracings from patients with atrial flutter[6] because increases in flow velocity are frequently seen after flutter waves on the ECG. If the slope of velocity decay was to be drawn to include velocity peaks caused by atrial contraction, underestimation of mitral valve area would have resulted. In such patients, therefore, only the initial slope was used to calculate valve area (Figure 1). In patients with atrial fibrillation or normal sinus rhythm, the downslope of the flow velocity signal was generally linear throughout diastole or until atrial contraction, respectively.

Color Doppler imaging was performed in 2 patients using a Toshiba SSH-65A phased array scanner. After mitral regurgitant area was visually assessed, both the width of the diastolic mitral inflow signal and the presence or absence of aliasing and of marked color variegation, typical of turbulent flow, were assessed before and after valvuloplasty.

Atrial septal defect flow was determined using pulsed Doppler, contrast echocardiography, or both.[13,20–22] For pulsed Doppler echocardiography, the sample volume was placed on the right atrial side of the interatrial septum, in the subcostal and parasternal right ventricular inflow tract views. Shunt flow from the left atrium to the right atrium was recognized by the presence of a continuous flow disturbance, usually maximal during late systole and late diastole, and directed toward the right atrium.[13,20] Contrast echocardiography was performed after the injection of agitated saline mixed with the patient's own blood into an antecubital vein. Imaging was performed during quiet respiration and during and after release of a Valsalva maneuver. A communication between right and left atria was diagnosed if there was a subsequent negative contrast effect in the right atrium or a positive contrast appearance in the left heart, or both.[21,22] All echocardiographic recordings were made by the senior technologist or the laboratory director. The measurements were made by a senior echocardiographer, unaware of results of any prior hemodynamic assessment.

Cardiac catheterization and valvuloplasty: Left and right heart catheterizations using a 7 Fr pigtail catheter and a 7 Fr balloon flotation catheter, respectively, were performed via the left femoral artery and left femoral vein. During right heart catheterization, a diagnostic oxygen saturation series was obtained. After placement of left and right heart catheters, measurements were made of systemic arterial, left ventricular, pulmonary capillary wedge and pulmonary arterial pressures. Pulmonary arterial and left ventricular oxygen saturations were determined. The pulmonary arterial catheter was then advanced to the pulmonary capillary wedge position, under hemodynamic monitoring. The presence of the catheter in the wedge position was confirmed by aspiration of blood with oxygen saturation equivalent to that of systemic arterial blood. Oxygen consumption was measured using a metabolic rate meter (Waters Instrument), and cardiac output was calculated using the Fick technique.

In the patients undergoing valvuloplasty, transseptal catheterization was performed following baseline hemodynamic measurements. After dilatation of the interatrial septum, balloon dilatation of the mitral valve was carried out using techniques described previously.[3] The balloon was inflated for 10 to 15 seconds; saline and a radiographic contrast agent (Angiovist) were used. Repeated inflations were performed until a waist in the balloon, created by the mitral valve, disappeared. Maximal balloon sizes were 23 mm (1 patient) and 25 mm (21 patients). Simultaneous inflations of 18 mm and 20 mm balloons were performed in 15 patients. Immediately after balloon valvuloplasty, all hemodynamic recordings and oximetric analyses were repeated. Mitral valve gradients were calculated from recordings of simultaneous pulmonary capillary wedge or left atrial and left ventricular pressures. The mitral valve areas before and after valvuloplasty were calculated according to the Gorlin formula. Left ven-

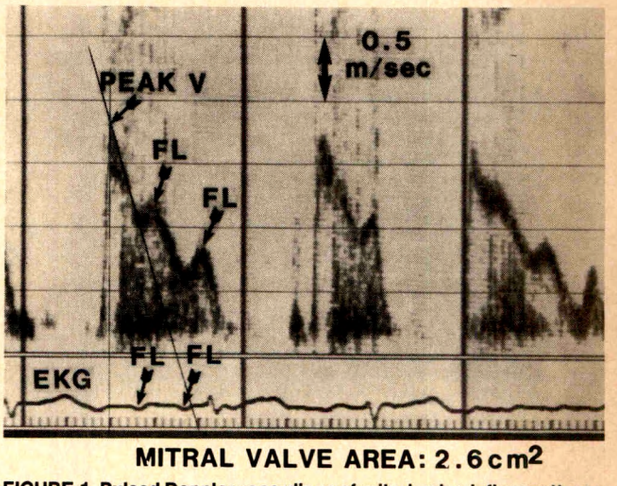

FIGURE 1. Pulsed Doppler recordings of mitral valve inflow patterns in a patient with atrial flutter (FL) indicate the increases in flow velocity (V) produced by atrial contractions. Reliable noninvasive estimation of mitral valve area was possible using the initial rapid diastolic slope. The atrial contributions to flow velocity are clearly seen in this patient, whereas in others it may be more difficult to separate the initial slope from intermittent flutter waves. An underestimation of valve area would occur if the slope of velocity decay was drawn to include the V peaks due to atrial contractions.

triculography was performed in only 9 patients both before and after valve dilatation. High pulmonary venous pressures or concomitant renal disease, or both, precluded the safe use of 2 doses of contrast in many of the other patients.

Twenty of the 37 patients undergoing valvuloplasty had had a diagnostic catheterization 1 to 3 months before valvuloplasty, generally at an outside referral hospital. This afforded the opportunity to assess the reproducibility of catheterization estimates of mitral valve areas. In all cases, cardiac outputs had been assessed using Fick or thermodilution techniques.

Statistical evaluation: Mean and standard deviation were determined for all variables. Correlations between variables were determined by the correlation coefficient and linearity was assessed by linear regression. Paired *t* testing determined the statistical significance of changes in parameters of valve function after valvuloplasty and also compared results of first and second prevalvuloplasty assessments of mitral valve area in patients having 2 catheterizations before valvuloplasty.

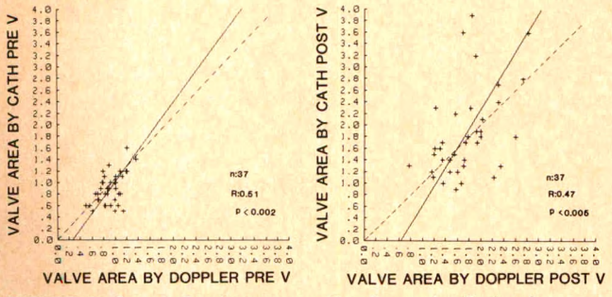

FIGURE 2. Correlation between estimations of mitral valve area made by Doppler pressure half-time techniques and catheterization assessments of mitral valve area before (*left*) and after (*right*) mitral valve valvuloplasty (V) in the group of 37 patients undergoing valvuloplasty for significant, symptomatic mitral stenosis.

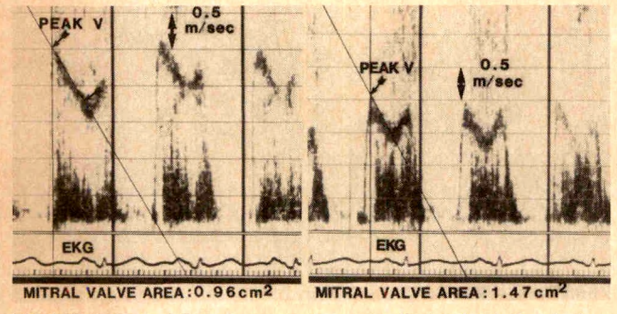

FIGURE 3. Pulsed Doppler recordings of mitral valve inflow before (*left*) and after (*right*) mitral valve dilation. Peak velocity (V) decreased from 2.55 to 2.1 m/s, mean gradient decreased from 16.5 to 9 mm Hg and Doppler-estimated mitral valve area increased from 0.96 to 1.47 cm². By catheterization, mitral valve area changed from 0.9 to 1.5 cm². The *unlabeled black arrows* indicate the velocity at pressure half-time. The *dark vertical lines* represent 1-second markers. EKG = electrocardiogram.

Results

Mild, mild to moderate and moderate to severe valvular thickening was noted on 2-dimensional echocardiography in 14, 5 and 18 patients, respectively. Moderate or severe subvalvular thickening, thought to represent dense fibrosis and fusion of chordae tendineae, was observed in 2 patients. In the 37 patients undergoing mitral valvuloplasty, prevalvuloplasty measurements of mitral valve area by Doppler and catheterization techniques were 0.9 ± 0.2 and 0.9 ± 0.3 cm^2, respectively ($r = 0.51$, $p < 0.002$) (Figure 2). After valvuloplasty, mitral valve areas—assessed by catheterization and Doppler techniques—increased in each patient, with group means increasing from 0.9 ± 0.3 to 1.8 ± 0.8 cm^2 and from 0.9 ± 0.2 to 1.7 ± 0.5 cm^2 (both $p < 0.001$). An example of the transmitral flow patterns before and after valvuloplasty in 1 patient is shown in Figure 3. The correlation coefficient for the relation between Doppler and catheterization area measurement following valvuloplasty was 0.47 ($p < 0.005$) (Figure 2). The mean absolute increases in catheterization or Doppler valve areas for the 14 patients with mild mitral thickening were not different from those in the 18 patients with moderate or severe thickening (1.1 ± 0.7 vs 1.0 ± 0.6 cm^2 by catheterization and 0.9 ± 0.6 vs 0.8 ± 0.4 cm^2 by Doppler, both p = not significant). The 2 patients with marked subvalvular thickening had catheterization-documented area increases of 0.6 and 1.2 cm^2.

No patient developed echocardiographic findings of a flail mitral valve. The diastolic short axis anteroposterior and lateral valve diameters increased significantly from 7.6 ± 1.8 to 9.8 ± 2.3 mm ($p < 0.001$) and from 12.6 ± 2.7 to 20.9 ± 3.5 mm ($p < 0.0001$), respectively (Figure 4). The absolute increase in lateral diameter, however, was significantly greater ($p < 0.0001$).

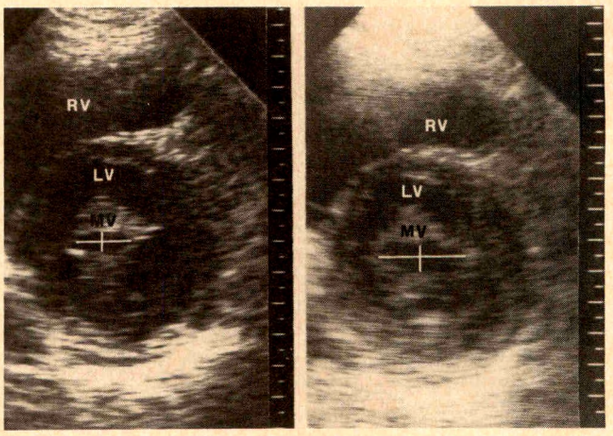

FIGURE 4. Short axis views of the diastolic mitral valve (MV) orifice before (*left*) and after (*right*) valvuloplasty. The anteroposterior diameter increased from 0.8 to 0.9 cm and the lateral diameter increased from 1.7 to 2.5 cm. Catheterization assessment of the mitral valve area revealed an increase from 0.9 to 3.6 cm². *Markings* on the right side of the pictures indicate 1 cm (longer horizontal markings) and 0.5 cm (shorter horizontal markings). LV = left ventricle; RV = right ventricle.

Mitral regurgitation was detected by pulsed Doppler echocardiography in 24 of the 37 patients before balloon valvuloplasty and in 24 patients after it (Figure 5). An increase of >1 grade of regurgitation was noted in only 1 patient. Ventriculography performed both before and after valvuloplasty in only 9 patients revealed an increase in mitral regurgitation of >1 grade in 2 patients. Seven patients had either no regurgitation on either study (5 patients) or no change from a prevalvuloplasty pattern of mild mitral regurgitation (2).

No patient had an evident atrial septal defect before valvuloplasty. However, an interatrial communication was detected after valvuloplasty in 12 patients by contrast, Doppler echocardiography, or both (Figure 6) and in 9 patients by oximetry (mean Qp/Qs = 1.6, range 1.1 to 2.3). Echocardiographic and oximetric diagnoses of the presence or absence of an atrial septal defect were concurrent in 30 patients. One shunt (Qp/Qs = 1.2) was not detected by noninvasive study and in another patient noninvasive evaluation of the integrity of the interatrial septum was inadvertently omitted from study. Five patients with echocardiographic findings of a left-to-right shunt had no diagnostic oxygen step-up (i.e., <2 volumes %) in the right heart.

Following valvuloplasty, there were increases (all p <0.0001) in EF slope (7.4 ± 4.9 to 18.3 ± 10.2 mm), valve excursion (10.7 ± 4.9 to 12.9 ± 4.3 mm/s), and aortic second sound to opening snap interval (0.07 ± 0.02 to 0.08 ± 0.02 s) (Figure 7). Decreases or no change were seen in 5 of 37, 10 of 37 and 10 of 35 patients, respectively. There were decreases (all p <0.0001) in left atrial diameter (5.4 ± 1.0 to 5.1 ± 1.0 cm), mean catheterization gradient (15 ± 5 to 8 ± 4 mm Hg) and mean Doppler gradient (10 ± 4 to 6 ± 3 mm Hg). Increases or no change in values were seen in 8 of 37, 6 of 37 and 6 of 37 patients, respectively. Cardiac output increased (4.2 ± 1.3 to 5.3 ± 2.0 liters/min, p <0.0001) in 33 of 37 patients.

In the 23 patients undergoing valvuloplasty who had had 2 prevalvuloplasty measurements of valve area by catheterization, there was a significant corre-

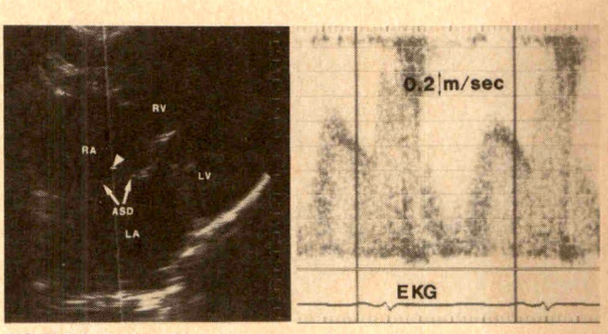

FIGURE 6. Pulsed Doppler interrogation of the interatrial septum in the subcostal 4-chamber view (*left*) demonstrates a continuous flow disturbance (*right*) directed toward the transducer and characteristic of left-to-right shunt flow through an atrial septal defect (ASD) created by transseptal catheterization and dilatation of the interatrial septum for passage of dilatation catheters. EKG = electrocardiogram; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

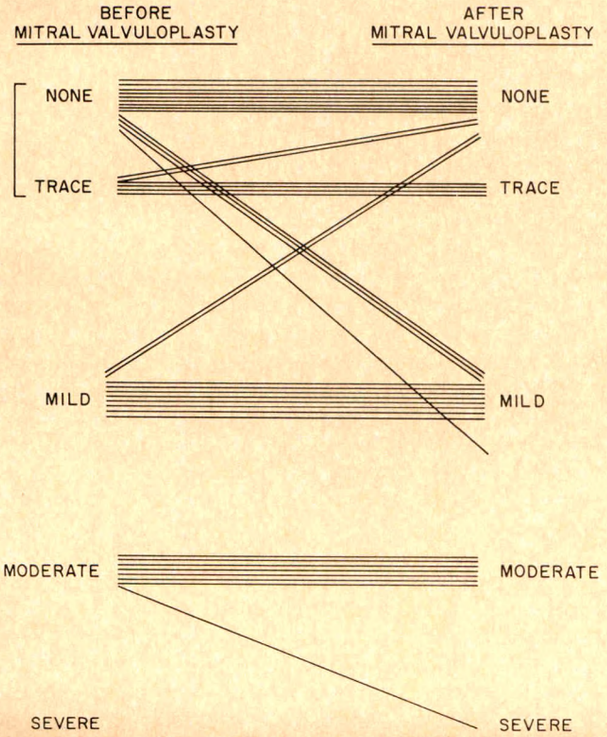

FIGURE 5. Grade of mitral regurgitation before (*left*) and after (*right*) mitral valvuloplasty.

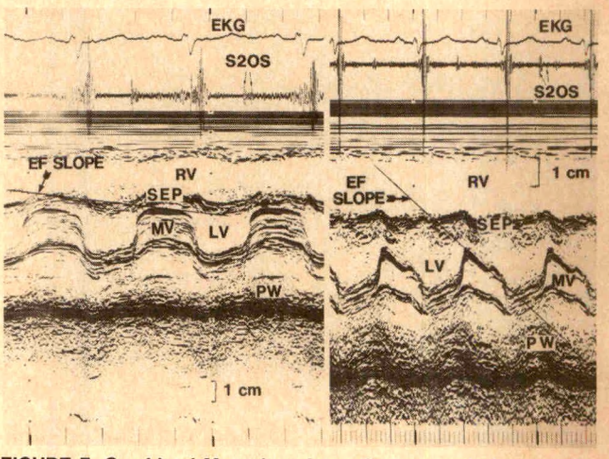

FIGURE 7. Combined M-mode echocardiogram and phonocardiogram in a patient before (*left*) and after (*right*) valvuloplasty. The catheterization- and Doppler-estimated mitral valve area increased from 1.4 to 2.4 and from 1.4 to 2.3 cm², respectively. The excursion of the anterior mitral valve (MV) leaflet did not change but the EF slope increased from 10 to 40 mm/s. The aortic second sound to opening snap (S2OS) increased from 0.04 to 0.07 seconds. The paper speeds in the 2 recordings differ; the distance between the vertical calibration dots denotes 1 second. EKG = electrocardiogram; LV = left ventricle; PW = posterior wall; RV = right ventricle.

lation between the first and the second measurements ($r = 0.74$, $p < 0.001$) (Figure 8).

Analysis by color Doppler (Figure 9) revealed a narrow diastolic mitral inflow jet before valvuloplasty, with a variegated color pattern indicating turbulent flow and aliasing reflecting high flow velocity. After valvuloplasty, the flow jet through the less stenotic valve was wider and had a fairly homogeneous color spectrum, indicating lower blood flow velocity and a lesser degree of turbulence (Figure 9).

In the 17 patients restudied by echocardiography 6 weeks after valvuloplasty, the mean mitral valve area assessed by pressure half-time techniques was unchanged from that on the first study carried out after valvuloplasty (1.6 ± 0.4 vs 1.6 ± 0.4 cm^2, p = not significant). Valve areas in 8 patients restudied by Doppler 6 months after valvuloplasty also were unchanged from the first postvalvuloplasty study (1.5 ± 0.3 vs 1.6 ± 0.3 cm^2, difference not significant).

Discussion

Because of its initial success and low complication rate,[2-5] balloon mitral valve dilatation will likely become widely used for the treatment of symptomatic patients with mitral stenosis. Because diagnostic catheterization is costly and has a definite, albeit small, associated morbidity and mortality, there is a need for noninvasive techniques permitting accurate quantitation of the severity of mitral stenosis and assessment of short- and long-term results of valve dilatation.

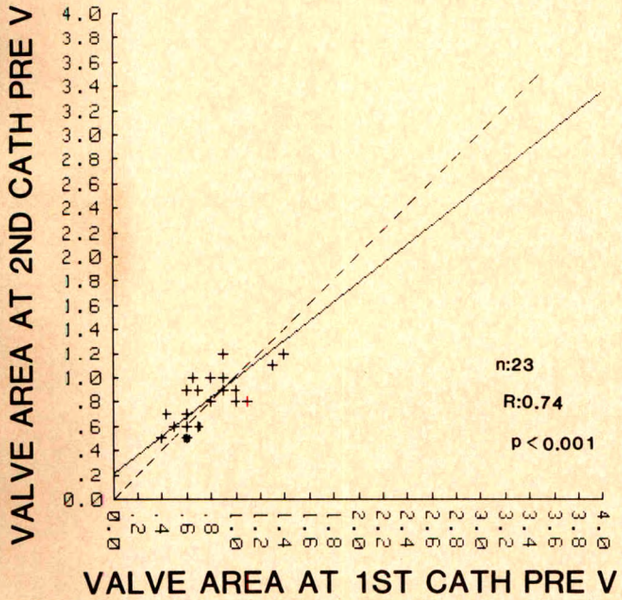

FIGURE 8. Correlation between 2 prevalvuloplasty values for catheterization mitral valve areas in the 23 patients in whom a diagnostic catheterization preceded the catheterization performed for purpose of valvuloplasty (V) by less than 3 months. Excluded from the figure are those patients referred with a catheterization diagnosis of severe mitral stenosis but found to have mild mitral stenosis.

A previous study from our institution of 59 consecutive patients with rheumatic mitral valve disease[8] indicated a close correlation ($r = 0.84$, $p < 0.001$) between noninvasive and catheterization determinations of mitral valve area and confirmed findings of several previous smaller studies in which Doppler echocardiography was shown to reliably quantitate the severity of mitral stenosis.[6,13,14,19] The accuracy of Doppler studies should enable catheterization for diagnostic purposes to be largely eliminated. Most patients, except those with suspected coronary arterial pathology or aortic valve disease (not adequately defined by noninvasive techniques), could undergo a single cardiac catheterization procedure, with standby for valvuloplasty if the noninvasive findings were supported. The savings in cost from the elimination of 1 catheterization and the associated in-patient days would be considerable. In addition, the total morbidity and mortality associated with catheterization would be reduced. In 1 of our patients, mitral valvuloplasty was delayed for weeks due to femoral vein thrombosis following diagnostic catheterization. Another patient, not included in our series, had persistent femoral venous thrombosis after diagnostic catheterization, making valvuloplasty impossible.

The importance of actual calculations of mitral area has been emphasized in the previous study from our institution of 59 consecutive patients with rheumatic mitral valve diseases.[8] Although significant correlations were found between catheterization mitral valve area and other noninvasive parameters, including EF slope ($r = 0.36$, $p < 0.01$), valve excursion ($r = 0.47$, $p < 0.001$), aortic second sound to opening snap interval ($r = 0.46$, $p < 0.001$) and mean mitral gradient ($r = -0.54$, $p < 0.001$), the wide scatter of data points, reflected by the low r values, does not permit their use as indicators of stenosis severity.[8] Because those measurements depend upon multiple factors in addition to valve area, such findings were not surprising. The mean diastolic gradient, for example, also depends upon forward cardiac output, mitral regurgitation, duration of diastole and the contribution of atrial systole. The aortic second sound to opening snap interval is also dependent on left atrial pressure at the mitral valve opening, heart rate, mitral valve stiffness, rate of left ventricular relaxation and the pressure at which the aortic valve closes.[23] The EF slope also depends on cardiac output, transducer angulation, coexisting ventricular disease, heart rhythm and the structural characteristics of the valve itself.[7] Finally, the recorded anterior leaflet excursion varies depending upon which portion of the leaflet is transected by the sound beam.[7]

It is of interest that the degree of valve thickening in our valvuloplasty patients did not correlate with the success of dilatation. Our experience supplements both case reports[24,25] of successful dilatation of heavily calcified mitral valves and an in vitro study in which balloon-induced increases in valve area were unrelated to the extent of calcific deposits on a roentgenographic study.[26] These findings suggest that attempted

percutaneous mitral valve dilatation need not be restricted to those patients with only mild valve fibrosis. They, however, contrast with findings suggesting reduced efficacy of surgical commissurotomy in patients with highly fibrotic and calcific mitral valve disease[27-31] and with studies from other institutions suggesting lesser short- and long-term efficacy of percutaneous valve dilation in patients with severe leaflet fibrosis and calcification.[32-34] The predictive role of echocardiography in identifying optimal patients for valvuloplasty requires further study.

Another major role for noninvasive testing in centers performing percutaneous valvuloplasty will be confirmation of the presence and severity of mitral stenosis in patients referred for valvuloplasty. In this regard, our echo findings of either no rheumatic disease or of mild mitral stenosis (valve area >1.5 cm^2), confirmed by repeat catheterization in our laboratory, in 3 patients referred with catheterization diagnoses of severe mitral stenosis are disturbing in that they suggest that some patients may be undergoing unindicated, aggressive therapy, including valvuloplasty and mitral valve replacement.

Another role of echocardiography reflects its ability to define intracardiac pathology in addition to mitral stenosis. The presence and severity of aortic stenosis

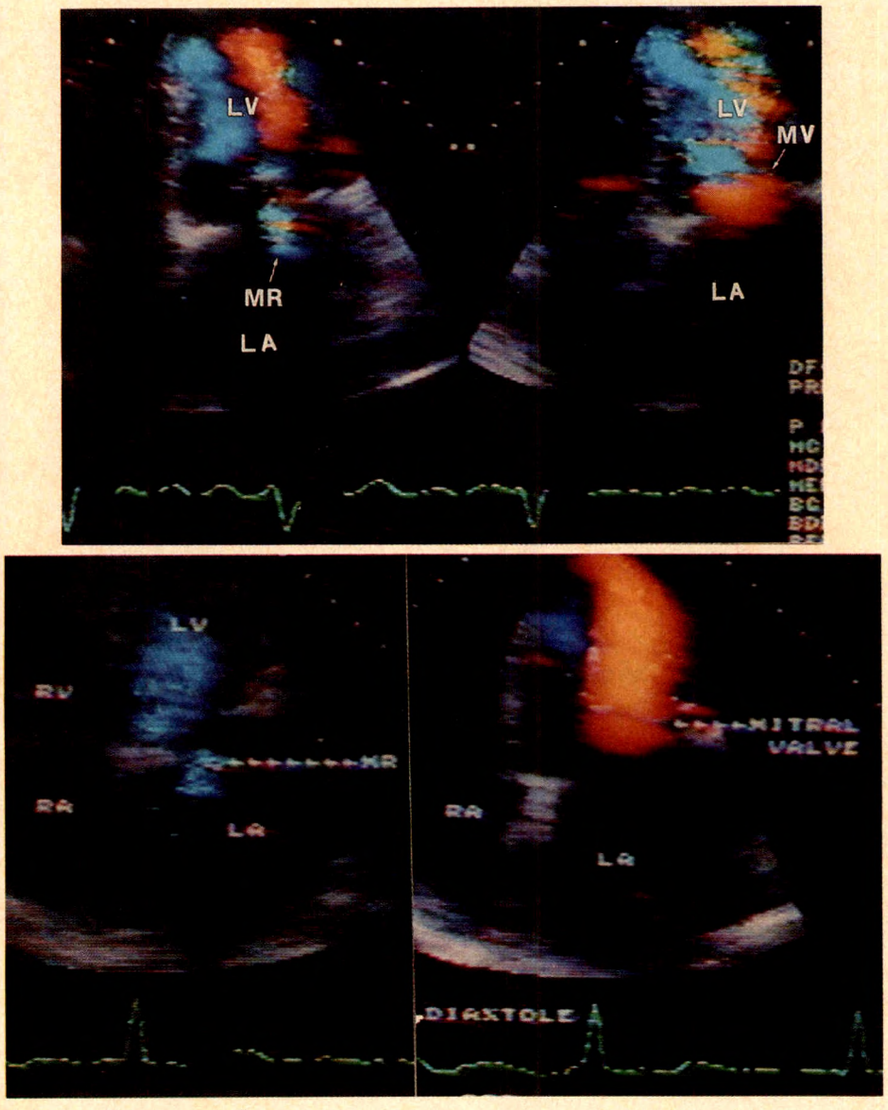

FIGURE 9. Color-coded pulsed Doppler recordings obtained with transducer placement at the left ventricular apex before valvuloplasty in systole (*upper left*) and diastole (*upper right*) and after valvuloplasty in systole (*lower left*) and diastole (*lower right*). The magnitude of mitral regurgitation (MR) in the left atrium during systole appears unchanged. Before valvuloplasty, the mitral valve inflow jet had a variegated color pattern (indicating turbulent flow) and aliasing (pointing to high flow velocity). After valvuloplasty, the width of the inflow signal at the level of the mitral valve orifice is far wider and the signal has a fairly homogeneous color spectrum, indicating both lower flow velocity and a lesser degree of turbulence.

can be quite accurately defined using the continuity equation.[35,36] In addition, the presence and relative magnitude of aortic insufficiency and mitral regurgitation and the status of left ventricular systolic performance can be evaluated. While color Doppler echocardiography may be preferable to routine pulsed Doppler echocardiography in estimating the severity of regurgitation, especially if regurgitant jets are eccentric, careful pulsed mapping of the entire left atrium in several planes (as performed in our study) permits detection and gross quantitation of regurgitant severity and, most importantly, allows comparison with prevalvuloplasty assessments. The number of patients undergoing both pre- and postvalvuloplasty ventriculography was small. However, the limited results from our institution suggest that sizable increases in mitral regurgitation are uncommon. In the present study, Doppler estimates of severity of regurgitation were very similar to the ventriculographic assessments. Full noninvasive definition of other pathology is particularly important in patients with high baseline pulmonary capillary wedge pressures, in whom the use of hyperosmolar contrast agents for ventriculography or aortography, or both, may precipitate pulmonary edema, and in patients with renal dysfunction. Echocardiography can also be used to detect left atrial thrombi within the body or appendage of the left atrium.[18] Their presence, as in the 3 patients denied valvuloplasty, is considered a relative contraindication to valvuloplasty using the transseptal approach.

Finally, echocardiography promises to be a useful technique for defining both the short- and long-term results of percutaneous mitral valve dilatation. Chordal and leaflet tears were not apparent in our study, as assessed by abnormalities of leaflet movement, and the greater increase in lateral rather than in anteroposterior dimension of the diastolic valve orifice was compatible with pathologic findings indicating that successful valvuloplasty involves splitting of previously fused commissures.[3,26,27] Doppler mapping of mitral regurgitant jets provides evidence that successful dilatation may usually be accomplished without appreciable increases in mitral regurgitation. Contrast and 2-dimensional echocardiography are sensitive techniques for detection of left-to-right shunting through the hole created in the interatrial septum for passage of the dilatation catheter. Serial studies should permit analysis of whether these defects close over time, and, in appropriate patients such as those without pulmonary or aortic regurgitation, may permit serial quantitation of the Qp/Qs ratio over time. Because right ventricular and, therefore, pulmonary arterial systolic pressure (in the absence of pulmonary stenosis) can be estimated from flow velocities in tricuspid regurgitant jets, Doppler echocardiography may additionally permit study of the rate of regression of pulmonary hypertension in patients after successful dilation.

Obviously, the most important parameter to be evaluated is that of mitral valve area. In our study mitral valve area measured by both catheterization and Doppler techniques increased in each patient after valvuloplasty, indicating the ability of echocardiography to detect a reduction of the severity of mitral stenosis. It is disappointing, however, that the coefficients of correlation for the relation between Doppler mitral valve areas and catheterization mitral valve areas were lower than that of 0.84 noted in our larger, unselected series of 59 patients previously reported.[8] In the group before valvuloplasty, the r value of only 0.51 may reflect the fact that the range of valve areas was very small, with each patient having severe mitral stenosis.

Reasons for the discrepancy between catheterization and Doppler assessments of mitral valve area after valvuloplasty probably include the following: lower accuracy of catheterization-planimetered gradients when gradients are small; inaccuracies in using the Fick cardiac output in the Gorlin determination of mitral valve area in patients with mitral regurgitation or left-to-right shunts across the created atrial septal defects; and decreased accuracy of Doppler calculation of mitral valve area in the setting of relatively large mitral areas, probably related to the steep rates of velocity fall-off. Wilkins[38] and Reid et al[39] noted very poor correlations between Doppler and catheterization determinations of mitral valve area when measurements were made immediately after or within the first 24 hours after balloon valvuloplasty. Thomas et al[40] suggested that alterations after valvuloplasty in left atrial pressure and compliance may adversely affect this correlation. Their studies, performed within the first 24 hours after valvuloplasty, reported pressure half-time measurements based on an average of only 1 to 3 beats. The greater accuracy of postvalvuloplasty pressure half-time valve areas relative to catheterization in our study could reflect a longer delay (48 to 96 hours) between valvuloplasty and echocardiographic evaluation, or the fact that our reported Doppler areas represent mean areas calculated from 10 different beats in normal sinus rhythm or in atrial fibrillation. The longer delay time may be of importance, since Reid et al[39] demonstrated a much closer correlation between catheterization and Doppler areas 3 months after valvuloplasty.[39] The lack of planimetered mitral valve areas in our study is an obvious weakness and further work will be necessary to determine if the planimetry technique or the pressure half-time assessment provides more accurate determination of mitral valve area in short- and long-term follow-up. The limitations of catheterization techniques in area determination also must be emphasized. In the presence of mitral regurgitation, the Gorlin formula will underestimate valve area if Fick determinations of cardiac output are used. Although angiographic stroke volume would be preferable, it would be of limited use in mitral stenosis patients who also have aortic insufficiency or in whom high wedge pressures may contraindicate the use of relatively large amounts of contrast.

Finally, significant directional changes in left atrial size, mitral valve gradient, EF slope, mitral valve excursion and second sound to opening snap interval accompany successful valvuloplasty. In patients in whom valve area calculations via planimetry and Doppler techniques are not feasible, serial changes in

a combination of these parameters may permit a gross means of follow-up to supplement history, physical examination and routine roentgenographic and electrocardiographic evaluations.

Angina Pectoris and Coronary Artery Disease in Severe Aortic Regurgitation

PHILIPPE TIMMERMANS, MD, JOS L. WILLEMS, MD, JAN PIESSENS, MD, and HILAIRE DE GEEST, MD

A consecutive series of 198 patients (148 men and 50 women, mean age 51 years, range 18 to 76) with pure, isolated, severe aortic regurgitation was retrospectively studied to determine the prevalence of angiographically significant coronary artery disease (CAD) and its relation to angina pectoris and coronary risk factors. Significant CAD (coronary diameter stenoses >50%) was found in 28 patients (14%). Typical angina was present in 18% and atypical chest pain in 16%. Angina alone had a sensitivity of 57% to detect significant CAD. The predictive accuracy of a positive history of angina was 46% and that of a negative test 93%. By using multivariate logistic regression, a risk score could be calculated that increased the sensitivity to 74% at equal specificity. Almost 40% of the total population had a risk score of <−2.9 (only 1 patient in this group had CAD). It is concluded that coronary arteriography can safely be omitted in many patients with severe aortic regurgitation if they have no symptoms of myocardial ischemia or risk factors known to increase its incidence.

(Am J Cardiol 1988;61:826–829)

Patients with severe aortic regurgitation (AR) often have a history of chest pain compatible with angina pectoris. It sometimes is even one of the first symptoms. However, there is significant controversy in the reported prevalence of angina pectoris and associated coronary artery disease (CAD).[1–5] As a result, disagreement exists with respect to the diagnostic workup of these patients. Some investigators recommend coronary arteriography only for patients with angina pectoris[1–3] whereas others advocate this examination for all cases irrespective of complaints.[4,5] Such conclusions were based on studies with relatively small sample sizes and assessed via univariate analysis only. The present study reviews clinical and cardiac catheterization findings in 198 cases seen in our institution.

Methods

Patients: All cardiac catheterizations performed between January 1972 and August 1986 were retrospectively reviewed starting from a computerized data base.[6] A total of 198 patients (148 men and 50 women; mean age 51 years, range 18 to 76) were selected because they fulfilled the criteria for severe AR without any concomitant valvular disease. AR was graded from the aortic angiogram on a scale from 1 to 4. Trivial or grade-1 AR was defined as a puff of dye entering the left ventricle during diastole. For grade 2, significantly more dye regurgitation was required, without complete filling of the left ventricle. Complete filling was needed for grade 3. Grade 4 consisted of complete opacification in the first diastole after injection, with contrast material remaining in the left ventricle for several beats. Only cases with AR of grade 3 (n = 83) and 4 (n = 115) were included in the present study. All patients with a peak-to-peak systolic gradient across the aortic valve of >10 mm Hg were excluded. Over the last decade, coronary arteriography is routinely performed in our institution during cardiac catheterization of patients with valvular heart disease and >30 years of age. In patients <30 years of age it is performed only when manifest chest discomfort compatible with angina pectoris is present.

Cardiac catheterization: Right- and left-sided cardiac catheterization, left ventriculography, aortography and selective coronary angiography were performed in all 198 patients. Left ventriculography was performed in the right anterior oblique projection and aortography in the left anterior oblique projection. Se-

From the Departments of Cardiology and Medical Informatics, University Hospital Gasthuisberg, Leuven, Belgium. Manuscript received August 17, 1987; revised manuscript received and accepted November 23, 1987.

lective coronary arteriography was carried out in multiple projections using the Sones technique. Since April 1975 all coronary angiograms are standardly coded in our institution by means of a CAD-reporting system.[7] Significant CAD was defined as >50% diameter reduction of a major coronary artery or its side branches.

Clinical findings: The medical records pertaining to all cases were reviewed to determine the presence and characteristics of angina pectoris, atypical chest pain, dyspnea, palpitations, fatigue, vertigo or syncope. The following variables were also recorded on data collection forms: smoking habits, family history of CAD, personal history of hypertension, diabetes or myocardial infarction, body weight, height, serum cholesterol, hematocrit and use of diuretics or digitalis. The Canadian classification was used to grade angina pectoris and the New York Heart Association (NYHA) to grade the functional status. For arterial hypertension a diastolic pressure of >90 mm Hg was required. Typical angina pectoris was defined as substernal discomfort or left precordial pain precipitated by exertion, emotional stress or exposure to cold, which was promptly relieved by rest or nitrates. Cases with nocturnal angina and typical angina at rest were also included. Patients with atypical chest pain, however, were not considered as having angina pectoris.

Statistical analysis: Bivariate analysis was used in frequency distributions and cross-tabulations of all variables made first for the total group and then, separately, for both sexes and for patients with and without significant CAD. Differences were tested using the chi-square analysis (with Yates correction) and Fisher exact test for categorical variables and the Student *t* test for quantitative variables using the SAS statistical package.[8]

For multivariate analysis, stepwise logistic regression was used to derive a prediction model with parameters significantly related to CAD. A multivariate risk score was calculated to stratify patients into either CAD or non-CAD. Standard methods were applied to derive sensitivity, specificity and the predictive values of a positive and negative test result.[9]

Results

Bivariate analysis results: Thirty-five patients (18%) had typical angina pectoris (29 class I or II and 6 class III or IV) and 32 (16%) had atypical chest pain. Dyspnea on exertion was present in 111 patients (56%) and palpitations in 50 (25%). Dyspnea was grade III or IV in 32.

Significant CAD (coronary diameter stenoses > 50%) was present in 28 patients (14%; 17 men and 11 women). In the so-called non-CAD group, 19 patients had minor narrowing of 1 or more coronary arteries and 151 patients (76%) presented with complete normal arteries (n = 170). The patients with CAD were significantly older (mean age 58 versus 50 years; p <0.005). The youngest case with CAD was a 27-year-old female with familial hypercholesterolemia and presenting with significant 2-vessel disease. In the CAD group, 14 patients had 1-vessel disease, 5 had 2-vessel disease and 8 had 3-vessel disease. One patient had significant left main disease.

TABLE I Clinical Characteristics of Patients with Aortic Regurgitation With and Without Significant Coronary Artery Disease

Variable	CAD Absent (n = 170)	CAD Present (n = 28)	p Value
Mean age (yrs)	50 ± 12	58 ± 11	0.005
Mean total cholesterol (mg/dl)	221 ± 64	247 ± 63	0.042
History of SH	22 (13%)	15 (54%)	0.001
Family history of CAD	47 (28%)	11 (39%)	NS
Diabetes mellitus	6 (4%)	1 (4%)	NS
Total cholesterol >240 mg/dl	47 (28%)	14 (52%)	0.02
Use of diuretics	61 (37%)	16 (59%)	0.03
Cigarette smokers	58 (34%)	9 (32%)	NS
Ex-cigarette smokers	35 (21%)	10 (36%)	NS

CAD = coronary artery disease; NS = not significant; SH = systemic hypertension.

TABLE II Performance of a Multiple Logistic Risk Score for Prediction of Significant Coronary Artery Disease in Patients With Severe Aortic Regurgitation

	Multiple Logistic Risk Score*			
CAD	<−2.92	<−2.00	>−1.35	>−0.65
Absent	76/162	124/162	19/162	9/162
	47%	77%	12%	6%
Present	1/27	3/27	20/27	16/27
	4%	11%	74%	59%
Predictive value	76/77	124/127	19/39	16/25
	99%	98%	49%	64%

* Risk score coefficient = −7.82 + 0.082 age (years) + 0.329 (sex: male = 1; female = 2) + 1.669 angina (yes = 1; no = 0) + 1.089 (sex × hypertension) + 1.607 (smoking × cholesterol >240 mg/dl).

A distribution of some clinical characteristics is given in Table I. The CAD group was not only older (p <0.005) but also had more hypertension (p <0.01) and total cholesterol (p <0.04). Patients with CAD had more frequently a positive family history of CAD, although this difference was not significant. There were more ex-cigarette smokers in the CAD group, but this also was not statistically significant.

Relation between angina pectoris and coronary artery disease: Of the 28 patients with CAD, 16 proved to have typical angina pectoris, which resulted in a sensitivity of 57% for this symptom. However, 19 patients from the 170 without significant CAD also had typical angina, giving a specificity of 89%. From these data a positive predictive value of 46% (16 of 35) can be derived for angina. The absence of angina (the predictive value of a negative test) correctly predicted absent CAD in 93% (151 of 163).

Multivariate analysis: By means of multiple logistic regression a risk score could be calculated based on angina pectoris, age, sex, smoking habits, history of hypertension and serum cholesterol to predict the presence and absence of significant CAD (Table II).

TABLE III Prevalence of Angina Pectoris and Significant Coronary Artery Disease in Patients With Angiographically Proven Severe Aortic Regurgitation

Reference	No.	CAD	Angina Pectoris
Basta et al, 1975[1]	20	—	10 (50%)
Graboys and Cohn, 1977[2]	29	4* (14%)	18 (62%)
Hakki et al, 1980[4]	31	11 (36%)	8 (26%)
Pathak et al, 1986[5]	78	29 (37%)	36 (46%)
Current study	198	28 (14%)	35 (18%)

* CAD defined as coronary diameter stenoses ≥75%; in all other studies 50% narrowing was used.

Due to missing values in some variables the analysis could only be performed for 189 cases, 27 with CAD and 162 without it.

A risk score of <−2.9 was 99% predictive for the absence of significant disease; i.e. it was correct in 76 out of 77 cases (Table II). When the threshold of the risk score was lowered to −2.4, the negative predictive value still remained very high (98%; 124 of 127 cases). However, at this level 3 patients with significant CAD also were labelled as having no CAD. A risk score >−0.65 was 59% (16 of 27) sensitive to predict the presence of CAD. This threshold resulted in 6% (9 of 162) of false positive cases. Lowering the threshold to −1.35 increased the sensitivity to 74%, but at the cost of a decrease in specificity to 88%.

Discussion

Patients with severe AR often have a history of chest pain compatible with angina pectoris. Angina may be due to a lower coronary perfusion pressure during diastole and to an increase in wall tension secondary to increased left ventricular volume load.[1,2] Obviously, significant coronary artery narrowing also is one of the main reasons for angina pectoris in these patients. There is wide variation in the reported prevalence of angina and significant CAD in AR.[1-5,10,11] Angina pectoris has been reported from 3%[12] up to 78%.[11] In studies reporting consecutive cardiac catheterization cases, similarly as in the present study, the prevalence of angina varied between 26 and 62% (Table III). The prevalence of significant, angiographically proved CAD has been reported to be within a range of 13 and 37%. Of the 11 patients (mean age 48 years) with pure AR reported by Pichard and associates,[13] none had significant coronary narrowing by arteriography. Of the 17 patients (mean age 42 years) studied by Clark et al,[14] 3 (18%) had significant CAD. In the present study the prevalence of angina and significant CAD was 18 and 14%, respectively. The wide variation in these prevalence figures depends on the group of patients studied and on the definitions that were applied. The highest prevalence figures were reported by Richardson et al[11] with patients who had received valve replacement and myocardial revascularization. In most studies the number of patients was rather small.

Some investigators have included atypical chest pain in the angina class.[5] In the present study this symptom was present in 16%. Inclusion of such patients would almost have doubled the prevalence rate of angina pectoris. Some authors have used as criterion for significant CAD a luminal narrowing of 75%[1] whereas another used 60%.[3] However, in most studies 50% was used as threshold to define angiographically significant CAD. There is general agreement that such narrowing significantly disturbs the coronary circulation in these patients when myocardial oxygen demand is increased.

In the present study, the largest on severe AR reported so far, 151 patients (76%) had angiographically complete normal coronary arteries. A minor degree of CAD was present in 47 patients (24%). However, significant coronary artery stenosis (>50%) was found in only 28 (14%). This was very similar to the prevalence rate reported by Graboys and Cohn,[2] but 2.5 times less than the prevalence reported by Hakki et al[4] and Pathak et al.[5] In the latter studies, only patients >40 years were included. The mean age in these studies was 55 ± 8 and 57 ± 6 years, respectively, whereas in the present study it was 51 ± 11.

Age was significantly related to coronary artery narrowing, not only in our bivariate analysis but also in the multivariate analysis. The patients with significant CAD also had more frequently an elevated serum cholesterol, they smoked more and had more often a history of hypertension. When these variables were used in addition to angina, a multivariate risk score could be calculated that significantly increased the power to predict the presence or absence of CAD. In the 127 patients with a risk score <−2 no CAD was present in 124, resulting in a negative predictive value of 98%. The absence of angina had a negative predictive value of 93%. At 74%, the sensitivity of the multivariate risk score also proved to be significantly greater, as opposed to 57% with almost equal specificity (88 versus 89%) for angina pectoris alone.

Clinical implications: There is general agreement that coronary arteriography should be performed in every patient with severe AR and angina pectoris evaluated with cardiac catheterization. However, there is disagreement as to whether coronary arteriography should be performed routinely in patients with no symptoms of angina pectoris. Some advocate this procedure for all patients over the age of 40, or even 30,[4,5] whereas others are opposed to such measures.[2,3,15,16] Our data are in more agreement with the latter. Based on the findings from the present study it may be concluded that coronary arteriography can safely be omitted before valve replacement in many patients (up to 40%) with severe AR who have no symptoms of ischemic heart disease and who lack risk factors known to increase its incidence.

Relation Between Serum Nifedipine Concentration and Hemodynamic Effects in Nonobstructive Hypertrophic Cardiomyopathy

SANDRO BETOCCHI, MD, ROBERT O. BONOW, MD, RICHARD O. CANNON, III, MD, LAWRENCE J. LESKO, PhD, HAROLD G. OSTROW, MS, RITA M. WATSON, MD, and DOUGLAS R. ROSING, MD

The relation between nifedipine concentration and hemodynamic effects after sublingual administration of 10 or 20 mg was examined in 13 patients with nonobstructive hypertrophic cardiomyopathy (HC). Serum nifedipine concentrations were determined by gas chromatography and were not related to dose. Peripheral vascular resistance decreased as a function of nifedipine concentration ($r = -0.63$, $p < 0.001$); this was associated with a concentration-related increase in heart rate ($r = 0.56$, $p < 0.001$) and in cardiac index ($r = 0.50$, $p < 0.001$). However, evidence for a pure vasodilator effect of nifedipine was inconsistent, in that the change in stroke volume index with nifedipine was not significant. Although stroke volume index increased at nifedipine concentrations between 60 and 120 ng/ml (38 ± 6 to 42 ± 4 ml/m^2, $p < 0.01$), it decreased at concentrations >120 ng/ml (40 ± 3 to 38 ± 4 ml/m^2, $p < 0.01$). Moreover, pulmonary artery wedge pressure increased at nifedipine concentrations >120 ng/ml (11 ± 2 to 16 ± 4 mm Hg, $p < 0.001$), suggesting either depressed left ventricular (LV) systolic function or reduced LV filling. To investigate these possible mechanisms, LV systolic and diastolic function was studied during catheterization with a nonimaging scintillation probe in 6 of the 13 patients. In these subjects, heart rate was held constant by atrial pacing. Nifedipine, at concentrations ≤120 ng/ml did not alter end-diastolic volume, but increased LV stroke volume and ejection fraction; concentrations >120 ng/ml were associated with increased end-diastolic and end-systolic volumes, reduced ejection fraction and end-systolic pressure-volume ratio. No beneficial effects on LV diastolic function were observed at these higher concentrations, as the time constant of isovolumic relaxation increased (32 ± 13 to 60 ± 11 ms, $p < 0.01$). These results indicate that the hemodynamic effects of nifedipine are related closely to nifedipine concentration in patients with nonobstructive HC. Peripheral vasodilating effects are evident over a wide range of nifedipine levels. At low and medium concentrations, these effects result in augmentation of LV ejection performance; however, negative inotropic effects predominate at high concentrations.

(Am J Cardiol 1988;61:830–835)

Verapamil therapy is effective in many symptomatic patients with hypertrophic cardiomyopathy (HC).[1–4] Intravenous verapamil reduces left ventricular (LV) outflow tract gradients[2] and both intravenous and oral verapamil enhance LV relaxation and diastolic filling.[5–10] Nifedipine has also been studied in patients with HC and has been shown to enhance LV relaxation and filling.[11,12] However, such effects have not been observed consistently.[13] In addition, the potent peripheral vasodilating effects of nifedipine may increase outflow gradients in patients with obstructive HC,[13] resulting in net deleterious, rather than advantageous, hemodynamic effects. This compounding influence of increased outflow gradients with nifedipine treatment would not be encountered in patients with nonobstructive HC.

Previous data obtained in patients with coronary artery disease and in normal subjects indicate that a given dose of nifedipine is associated with a wide variability in patient responses[14] and in nifedipine plasma concentrations.[15] The relation between plasma concentration and hemodynamic effects of nifedipine has not been investigated in patients with nonobstructive HC. In the current study we hypothesized that differ-

ent concentrations of the drug might explain the otherwise discordant hemodynamic results of previous studies.

Methods

Patient selection: Thirteen patients with nonobstructive HC participated in this study. There were 7 men and 6 women, ages 18 to 67 years (mean 39). The diagnosis of HC was based on M-mode and 2-dimensional echocardiographic demonstration of a hypertrophied nondilated left ventricle in the absence of another cardiac or systemic disease capable of causing LV hypertrophy.[16] No patient had concomitant coronary artery disease. All patients were symptomatic; 4 were in New York Heart Association functional class II, 8 were in functional class III and 1 was in functional class IV.

After admission, all cardiac medications were discontinued for at least 5 drug half-lives before cardiac catheterization. Each patient gave informed consent before participation in the study according to a protocol approved by the Institutional Clinical Research Subpanel of the National Heart, Lung, and Blood Institute.

Hemodynamic measurements: Patients underwent diagnostic right- and left-sided heart catheterization. A Swan-Ganz thermodilution catheter (Edwards Laboratories, Inc.) was used to measure right heart pressures and cardiac output. For each cardiac output determination at least 3 measurements were averaged. LV pressure was measured with a micromanometer catheter (Millar Instruments, Inc.) in 7 patients, or through a fluid-filled pig-tail catheter (end-hole only, no side holes) in the remaining patients, using the retrograde femoral technique. Systemic blood pressure was monitored by means of a brachial artery catheter. Any patient with an LV outflow gradient >30 mm Hg under resting conditions was excluded from this study. However, patients with provocable outflow gradients (by Valsalva maneuver, amyl nitrite inhalation or isoproterenol infusion) were not excluded.

Control studies included measurements of heart rate, LV pressure, brachial artery pressure, pulmonary wedge pressure and cardiac output. From these determinations, cardiac index, stroke volume index and peripheral vascular resistance index were derived.

Radionuclide measurements: In 6 patients studied with micromanometer catheters, relative changes in LV volume were investigated using an electrocardiographic-gated nonimaging scintillation probe after in vivo labeling of red blood cells with 15 to 20 mCi of technetium-99m. The technical characteristics of the probe and the methodology of data acquisition for these studies have been described in detail elsewhere.[6,13,17] From these data, we constructed LV time activity curves, representing the relation between LV volume and time during the average cardiac cycle. On each curve we computed ejection fraction, peak filling rate and time to peak filling rate.[8] Peak filling rate was measured in counts per second, normalized for the number of counts at end-diastole and expressed as end-diastolic volume/second. Time to peak filling rate was measured relative to end-systole. In addition to these primary measurements, during sequential radionuclide data acquisitions after nifedipine, we measured the percent change in end-diastolic volume and end-systolic volume relative to control end-diastolic counts. These latter measurements were also used to assess the directional changes after nifedipine in the end-diastolic and the end-systolic pressure-volume relations. LV relaxation was assessed by digitizing the LV pressure curve and computing the time constant (T) of the decrease in LV pressure, as previously described.[6,13] Biexponential fitting was also used in all patients and T1 (time constant of LV pressure decrease during the first 40 ms after peak negative dP/dt) and T2 (relative to the second 40 ms) were measured.

It was anticipated that nifedipine administration would increase heart rate, thereby complicating the interpretation of the radionuclide data after nifedipine. We therefore obtained control radionuclide measurements under basal conditions and during sequential atrial pacing at heart rates 10 to 30 beats/min faster than the baseline heart rate in order to facilitate interpretation of the subsequent nifedipine data.

Nifedipine administration: After control data were obtained, nifedipine was administered sublingually. Patients were instructed to break the nifedipine capsule(s) in their mouths and not swallow for several minutes. Nine patients received 20 mg of nifedipine initially, while 4 patients received 10 mg. The initial nifedipine dose was determined individually on the basis of the patient's blood pressure, heart rate and intracardiac pressures. Hemodynamic measurements were repeated at 10, 20 and 30 minutes after administration. A second dose of 10 mg was given to all but 1 patient, and hemodynamic parameters were determined every 10 minutes for the next 30 minutes. In 1 patient the second dose was not administered because his systolic blood pressure decreased below 100 mm Hg after the initial dose of 10 mg of nifedipine. In 6 patients studied simultaneously with the nonimaging scintillation probe, repeat radionuclide measurements were obtained 20 minutes after each dose of nifedipine.

Nifedipine concentration assay: Blood samples were obtained at the time of each hemodynamic measurement. The samples were collected in glass tubes wrapped in aluminum foil, placed on ice and centri-

fuged at the end of the study. The plasma was collected by aspiration and frozen at −20°C until assayed for nifedipine. All sample handling was performed while protecting the specimens from light because of the known instability of nifedipine in plasma exposed to light. Plasma nifedipine concentrations were measured by gas liquid chromatography with electron capture detection.[18] This assay is specific for nifedipine and has a sensitivity of 10 ng/ml with an intra- and interday variation of <12%.

Data analysis: The difference among mean values of nifedipine concentration in the study was tested by means of Duncan's multiple range test.[19] The Student's *t* test for unpaired samples[19] was used to determine whether different doses were associated with different concentrations. To assess the nifedipine concentration-effect relation we used linear regression analysis.[19]

To assess whether an "optimal" nifedipine concentration could be identified nifedipine concentrations were arbitrarily divided as follows: low (≤60 ng/ml), medium (61 to 120 ng/ml) and high (>120 ng/ml) nifedipine concentrations. Hemodynamic parameters measured in each concentration range were compared to the corresponding control value by the paired *t* test.[19] All measurements are expressed as the mean ± 1 standard deviation.

Results

Nifedipine concentration: Figure 1 shows the time course of nifedipine concentration in patients receiving 10 or 20 mg as a first dose. No differences were observed between nifedipine concentration values measured in patients receiving 20 mg and 10 mg at any time during the study. Mean values of nifedipine concentration, independent of initial dosing, increased over the first 20 minutes, then plateaued (Table I). A high (>120 ng/ml) nifedipine concentration was reached in 5 patients (17 observations).

Hemodynamic data: Nifedipine administration resulted in a significant decrease in peripheral vascular resistance and increase in heart rate and cardiac index (Table II), and the magnitude of changes in these variables correlated significantly with plasma drug level. The percent change in peripheral vascular resistance index decreased ($r = 0.63$, $p < 0.001$) as a function of nifedipine concentration (Figure 2), and the percentage change in heart rate and cardiac index increased with increasing drug concentrations ($r = 0.56$ and 0.50, $p < 0.001$ for both).

In contrast, stroke volume index had directional changes dependent on nifedipine concentration (Figure 3); it increased 17% (38 ± 6 to 42 ± 4 ml/m², $p < 0.01$) with nifedipine concentrations between 60 and 120 ng/ml, but decreased relative to control by 5% (40 ± 3 to 38 ± 4 ml/m², $p < 0.01$) at concentrations >120 ng/ml. The change in mean pulmonary artery wedge pressure correlated with nifedipine concentration ($r = 0.56$, $p < 0.001$), and a significant increase in pulmonary wedge pressure was observed at high nifedipine concentrations (Table II and Figure 4). Only 2 patients had an abnormal (>15 mm Hg) pulmonary artery

wedge pressure at baseline; therefore, no attempts were made to analyze separately the effects of nifedipine in patients with normal versus elevated pulmonary artery wedge pressures. No patient developed an LV outflow tract gradient ≥30 mm Hg during nifedipine administration.

Radionuclide data: We assessed the influence of nifedipine concentration on LV systolic and diastolic function by analyzing data obtained at high (>120 ng/ml) and low or medium nifedipine concentrations (≤120 ng/ml). The lower nifedipine concentration group consisted of 6 determinations, whereas the high concentration group was made up of 5 radionuclide studies. Mean nifedipine concentrations were 68 ± 36 and 172 ± 14 ng/ml, respectively. These results are listed in Table III. At low and medium nifedipine concentration, end-diastolic volume did not change, whereas end-systolic volume decreased significantly. As a consequence, ejection fraction increased. Peak filling rate increased and time to peak filling rate shortened significantly. In contrast, the time constant of isovolumic relaxation did not improve, and its late component (T2) was significantly slowed. At high nifedipine concentration a significant increase in both end-diastolic and end-systolic volumes was observed, associated with a decrease in ejection fraction. The end-systolic pressure volume ratio also decreased significantly, with a shift downward and rightward in the end-systolic pressure-volume relation. The elevated end-diastolic volume was associated with increased end-diastolic pressure. Isovolumic relaxation was impaired as both the time constant T and its late component T2 increased at high nifedipine concentrations.

T2	34 ± 11	47 ± 15	<0.01	32 ± 13	60 ± 11	<0.01
Nifedipine concentration (ng/ml)		68 ± 36			172 ± 14	

C = control; EDV = end-diastolic volume; LV = left ventricular; N = nifedipine; NS = difference not significant.

An improvement in the diastolic pressure-counts relation (as assessed by downward-rightward shift of the diastolic portion of the curve) was observed in only 1 patient at high and in 1 patient at low nifedipine concentrations. In this latter patient at a nifedipine concentration of 20 ng/ml, a consistent improvement of peak filling rate and shortening of time to peak filling rate was observed.

Discussion

Nifedipine concentration: Nifedipine concentration increased over the first 20 minutes after its sublingual administration, but then plateaued for the remainder of the study (Table I). There was a wide range of concentrations achieved for a given dose, and the mean blood levels did not differ between those patients who received 10 mg as their initial dose and those who received 20 mg (Figure 1). These results correspond to observations made during previous investigations, using sublingual,[20,21] intravenous[15,21] or oral administration[15,21] of nifedipine.

Relation between nifedipine concentration and hemodynamic effect: In our patients with nonobstructive HC, the anticipated decrease in peripheral vascular resistance after nifedipine administration was linearly related to drug concentration (Figure 2), as was the reflex increase in heart rate. A similar concentration-dependent decrease in peripheral vascular resistance has already been demonstrated in dogs[22] and in hypertensive patients.[20,23,24] Evidence against a pure peripheral vasodilating effect, however, was apparent in the stroke volume response to nifedipine (Figure 3); although stroke volume index increased significantly at low and medium range nifedipine concentrations (60 to 120 ng/ml) it decreased significantly at high concentrations (>120 ng/ml). In addition, mean pulmonary artery wedge pressure increased at high nifedipine concentrations (Figure 4).

The differential effects on stroke volume index, as well as our radionuclide data, suggest that 2 distinctly opposite hemodynamic patterns result at different plasma concentrations of nifedipine. At low or medium nifedipine concentration the increase in stroke volume can be explained by the radionuclide data: end-systolic volume decreased whereas end-diastolic volume was unchanged. Therefore, ejection fraction increased. This is probably due to afterload reduction rather than to increased contractility, as the end-systolic pressure-volume ratio did not change. The end-diastolic pressure-volume relation was also not altered.

In this concentration range, an increase in peak filling rate and a shortening in time to peak filling rate were observed. In the absence of changes in the time constant of LV relaxation or in LV distensibility characteristics, we interpret the increase in peak filling rate as purely a reflection of augmented ejection fraction.

In contrast, a negative inotropic effect was observed at high nifedipine concentration, as shown by the decreases in ejection fraction in stroke volume index, and in the end-systolic pressure-volume ratio. This response at high drug concentrations may be explained by the primary effect of nifedipine to reduce contractility,[25] which in the intact animal and in man is usually counterbalanced by marked afterload reduction and a reflex increase in sympathetic activity.[20] At elevated nifedipine blood levels, however, the primary negative inotropic effect becomes clinically evident. At these high concentrations, LV compliance was unchanged such that the increased LV end-diastolic volume was associated with elevated LV end-diastolic and pulmonary artery wedge pressures.

These data suggest that high nifedipine blood levels may be potentially detrimental in patients with HC, as the negative inotropic effect is associated with reduced stroke volume and increased pulmonary artery wedge pressure without demonstrable effects on LV diastolic function. In contrast, "optimal" nifedipine concentrations seem to be those ≤120 ng/ml. The practical applications of these observations are limited, as a given dose of nifedipine is associated with totally unpredictable blood levels, as observed in this and other studies[20,21] with sublingual administration, and in previous investigations using oral or intravenous administra-

tion.[14,21] These unpredictable results necessitate caution in the use of nifedipine in patients with nonobstructive HC.

A Comparative Study of Thallium-201 Single-Photon Emission Computed Tomography and Electrocardiography in Duchenne and Other Types of Muscular Dystrophy

SHUHEI YAMAMOTO, MD, HIDEO MATSUSHIMA, MD, AKIO SUZUKI, MD, IWAO SOTOBATA, MD, TOSHIKATSU INDO, MD, and YUKIHIKO MATSUOKA, MD

Single-photon emission computed tomography (SPECT) using thallium-201 was compared with 12-lead electrocardiography (ECG) in patients with Duchenne (29), facioscapulohumeral (7), limb-girdle (6) and myotonic (5) dystrophies, by dividing the left ventricular (LV) wall into 5 segments. SPECT showed thallium defects (37 patients, mostly in the posteroapical wall), malrotation (23), apical aneurysm (5) and dilatation (7). ECG showed abnormal QRS (36 patients), particularly as a posterolateral pattern (13). Both methods of assessment were normal in only 7 patients. The Duchenne type frequently showed both a thallium defect (particularly in the posteroapical wall) and an abnormal QRS (predominantly in the posterolateral wall); the 3 other types showed abnormalities over the 5 LV wall segments in both tests. The percent of agreement between the 2 tests was 64, 66, 70, 72 and 72 for the lateral, apical, anteroseptal, posterior and inferior walls, respectively. The 2 tests were discordant in 31% of the LV wall, with SPECT (+) but ECG (−) in 21% (mostly in the apicoinferior wall) and SPECT (−) but ECG (+) in 10% (mostly in the lateral wall). Some patients showed large SPECT hypoperfusion despite minimal electrocardiographic changes. ECG thus appeared to underestimate LV fibrosis and to reflect posteroapical rather than posterolateral dystrophy in its posterolateral QRS pattern. In this disease, extensive SPECT hypoperfusion was also shown, irrespective of clinical subtype and skeletal involvement.

(Am J Cardiol 1988;61:836–843)

In the clinically advanced stage of muscular dystrophy, left ventricular (LV) involvement (myocardial dystrophy) is inevitable and the electrocardiograms are often abnormal.[1-5] In addition, a specific electrocardiographic pattern is observed in X-linked muscular dystrophy of the Duchenne type, i.e., anteromedial shift of the QRS wave.[3,4] Among several hypotheses proposed for its pathogenesis,[1-7] that of posterolateral wall fibrosis is widely accepted, being also supported by data from methodologies other than electrocardiography (ECG).[3,4,6,7] However, few papers have reported the sensitivity of ECG in assessing myocardial dystrophy. Thus, ECG seems to have been accepted a priori as a satisfactory method to screen LV involvement in this disease. Although LV myocardial infarction has been evaluated via single-photon emission computed tomography (SPECT) with thallium-201,[8,9] there have been no reports, to our knowledge, of the application of SPECT to the evaluation of a large series of patients with muscular dystrophy. Therefore, we studied 47 patients with several types of muscular dystrophy by SPECT, regardless of their ECG findings.

This study addressed the following questions: (1) What are the characteristics of the SPECT image in each type of muscular dystrophy? (2) How does SPECT correlate with ECG? More specifically, do patients with the typical posterolateral electrocardiographic

pattern show SPECT hypoperfusion confined to that wall? (3) How do these results correlate with skeletal involvement? Does the latter predict the former?

Methods

Patient selection: The entry criterion for this study was a firm diagnosis of muscular dystrophy with either Duchenne, myotonic, limb-girdle or facioscapulohumeral type, based on clinical characteristics, serum creatine kinase levels, electromyograms and muscle biopsy. The exclusion criteria included previous heart surgery or the presence of congenital or valvular heart disease, other systemic diseases in addition to muscular dystrophy, use of drugs that would affect the electrocardiogram, LV or right ventricular hypertrophy, complete bundle branch block or fascicular block on the electrocardiogram. Forty-seven patients were randomly selected from our clinic: 43 men and 4 women (ages 9 to 62 years) with Duchenne (29 patients), facioscapulohumeral (7), myotonic (6) or limb-girdle (5) type. Informed written consent was obtained from each patient before the study. SPECT and ECG were performed on the same day.

Single-photon emission computed tomography: Five minutes after intravenous injection of thallium-201 (2 mCi), SPECT was performed, using a Toshiba GCA-70-TOKU gamma camera and a Toshiba GMS-55A computer. The camera consisted of dual-headed detectors (35 × 50 cm^2) equipped with low-energy, all purpose, parallel-hole collimators with a spatial resolution of 17 mm (full width half maximum), as described elsewhere.[10] Briefly, data were acquired with 128/128 matrix format by 6° sampling steps and 20-second imaging time over the 360° arc in 10 minutes. Then trans-, long- and short-axial tomograms (3, 3 and 6, respectively) were reconstructed on a 16-mm width slice by a filtered back projection algorithm (Shepp & Logan filter), photon attenuation correction (Chang), spatial smoothing and background processing (Goris).

Left ventricular fibrosis: In each image we assessed the anteroseptal, apical, lateral, posterior and inferior LV walls by circumferential profile analysis,[11] using 15 healthy men as volunteers. We defined LV walls with subnormal profile counts (mean − 2 standard deviations) as hypoperfused.

Morphology: The LV boundary was defined as 50% of the maximal count with a region of interest drawn around each LV image.

Regarding malrotation (Figure 1), 2 angles were identified: 1 between the LV axis and the sagittal plane projected on the transaxial image and 1 between the former and the horizontal plane. By comparison with data from 108 normal adults (mean ± 2 standard deviations) obtained by the same method, the LV axis was assumed to be oriented counterclockwise or clockwise if the former angle was <20° or >55°, respectively, and horizontally or vertically if the latter angle was <20° or >65°, respectively.

In hypertrophy and dilatation, the LV cavity to LV wall ratio was obtained (short-axial images). LV wall was then defined as hypertrophic, normal, dilated or ballooning if the ratio was <0.5, 0.5 to 1.0, 1.1 to 2.0, or >2.0, respectively. The right ventricle was defined as hypertrophic if it was clearly visualized in the transaxial image.

An LV aneurysm was assumed to be present if the LV cavity widened toward a particular wall.

Standard 12-lead electrocardiography: The morphology and amplitudes of the QRS wave were determined in each electrocardiographic lead. Based on normal data from children and adults,[12–14] electrocardiographic criteria for each LV wall lesion were as follows (QRS criteria, suspected wall): (1) abnormally deep Q or decreased R in leads V_1, V_2 and V_3 (anterior wall, i.e., anteroseptal and apical walls combined); (2) decreased R in leads V_5 and V_6 or abnormally deep Q in leads V_5, V_6, I, aVL (lateral wall); (3) tall R or increased R/S ratio in leads V_1 and V_2 (posterior wall); and (4) abnormal Q in leads II, III, aVF (inferior wall). The combination of (2) and (3) was defined as the "distinctive" electrocardiographic pattern.[3] Rhythm disturbances, repolarization abnormalities, electrical axis deviation and ventricular or supraventricular premature activities were also assessed.

Musculoskeletal involvement (clinical stage): A gradation from mildest (1) to severest (8) was used on the basis of a detailed clinical examination.[15]

Statistics: In SPECT versus ECG, the incidences of SPECT hypoperfusion and abnormal QRS were compared in each LV wall, using Fisher's exact test. In LV malrotation versus ECG, 2 groups, those with and without such malrotations in the SPECT images, were compared for their incidences of abnormal QRS in each LV wall, using Fisher's exact test. In skeletal versus LV involvement, 2 sets of paired data for each patient were examined, the clinical stage versus the number of hypoperfused walls (SPECT) and the clinical stage versus the number of walls with abnormal QRS (ECG), both using Spearman's rank correlation test. A p value of <0.05 was considered significant in all cases.

Results

Table I lists the results and Tables II to IV are its summaries.

Single-photon emission computed tomography: SPECT hypoperfusion was shown in 40% of 235 LV walls and in 79% of the 47 patients. Although hypoper-

* LV dilatation (see Methods): +2 = ballooning; +1 = moderate; 0 = absent.

AP = apical; AS = anteroseptal; CC = counterclockwise rotation; DMD = Duchenne muscular dystrophy; ECG = standard 12-lead electrocardiography; FSH = facioscapulohumeral muscular dystrophy; H = horizontal heart; I = inferior; L = lateral; LG = limb-girdle muscular dystrophy; LV = left ventricle; MT = myotonic dystrophy; N = normal result; P = posterior; SPECT = (thallium-201) single-photon emission computed tomography; V = vertical heart.

fusion was most frequent in the posterior wall, it showed a wide distribution pattern in that 19 different patterns were identified among the 47 patients. SPECT showed LV malrotations in 49% of the patients, including vertical heart (12), counterclockwise rotation (8), horizontal heart (2) and horizontal heart with counterclockwise rotation (1). SPECT also showed LV aneurysm (5), dilatation (5) and ballooning (2), but hypertrophy was not found.

Electrocardiography: Abnormal QRS was shown in 30% of the LV walls and in 77% of the patients. It was most frequent in the lateral wall, followed by the posterior wall. In contrast to SPECT, the electrocardiogram was specific in its pattern. Among the 7 patterns into which the abnormal QRS was classified, that of posterolateral wall injury was the most frequent, being seen in 13 patients. Moreover, 10 of these 13 patients consisted mostly of Duchenne type (patients 2, 7, 8, 12, 16, 17, 23, 24, 25 and 28), whereas the 3 others consisted of myotonic type (patients 37 and 40, siblings) and limb-girdle type (patient 43). ECG showed first degree atrioventricular block (3 patients), ventricular (2) and

* + and − denote hypoperfusion and normal perfusion, respectively (see Methods); † + and − denote QRS-wave abnormality and normal QRS waves, respectively (see Methods).
NS = not significant. Other abbreviations as in Table I.

patients showed SPECT hypoperfusion extending over the 3 LV segments despite only mild ST changes in the precordial leads (patient 26). Of the 13 patients with the posterolateral wall pattern, only 1 showed SPECT hypoperfusion confined to that wall (patient 25), whereas 8 showed, with or without lateral wall hypoperfusion, apical hypoperfusion as well (patients 7, 12, 16, 17 23, 28, 40 and 43) and the remaining 4 showed posterior (patients 2 and 24), anteroseptoposterior (patient 8) and posterolateroinferior (patient 37) hypoperfusion.

Among the 4 clinical types, the Duchenne type was most frequently characterized by both SPECT and ECG abnormalities. This group showed abnormal QRS complexes predominantly in the posterior and lateral walls as the distinctive ECG pattern, with

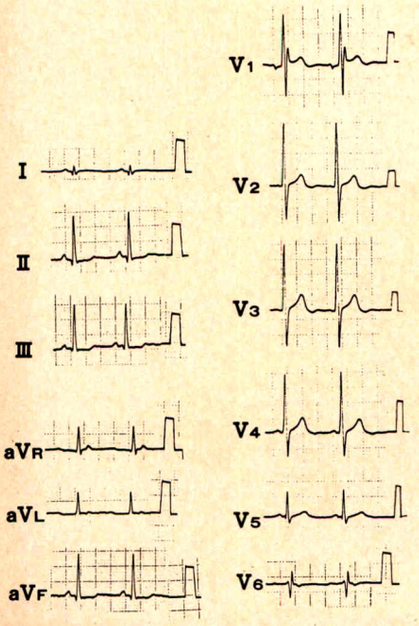

FIGURE 2. Standard 12-lead electrocardiogram (patient 28) shows posterolateral wall pattern, i.e., increased R (≥1.0 mV) and R/S ratio (≥1.0) in V_1 and V_2 and diminished R (≤1.0 mV) in V_5 and V_6. All calibrations are 1.0 mV.

SPECT hypoperfusion most frequently seen in the posterior wall, followed by the apical wall and occasionally the lateral wall. In the non-Duchenne types, SPECT and QRS abnormalities were both scattered over the 5 LV segments. The overall combined results of SPECT hypoperfusion and abnormal QRS in the 5 LV walls were (−) in 49% and (+) in 20% (Table IV), which gave an overall agreement of 69%. The percent agreement in each wall ranged from 64 to 72%. In the apical, lateral and posterior walls, the incidence of SPECT hypoperfusion correlated significantly with that of abnormal QRS. The 2 tests were discordant in 31% of LV walls, with SPECT (+) but ECG (−) in 21%, particularly in the apical wall, and vice versa in 10%, especially in the lateral wall. The anteroseptal and inferior walls did not show correlation between the SPECT and ECG results. The complication of LV malrotation did not influence the abnormal QRS, meaning that in no wall did the percent agreement of SPECT with ECG show significant difference between patients with and without LV malrotation (23 and 24 patients, respectively). None of the electrocardiographic findings except abnormal QRS was indicative of the distribution of SPECT hypoperfusion.

Systemic versus left ventricular involvement: The number of walls with SPECT hypoperfusion or with abnormal QRS complexes was 2.02 ± 1.51 or 1.49 ± 1.12, respectively (mean ± standard deviation). Neither result showed significant correlation with the clinical stage, which ranged from mildest (grade 1) to severest (grade 8) (4.85 ± 2.39, mean ± standard deviation). Patients 30 and 45 showed slight skeletal involvement (clinical stage <3) despite extensive hypoperfusion and LV dilatation in their SPECT images.

Two case presentations: Patient 28 (Figures 2 and 3) had had no symptoms of LV failure and had taken no cardiovascular drugs. His electrocardiogram was suggestive of a posterolateral lesion. In contrast, his SPECT showed posterior and anteroapical lesions—the latter being larger and evolving into an aneurysm—plus vertical heart status. The lateral wall showed normal perfusion. These SPECT results were confirmed by tomographic echocardiography as posterior and apical wall dyskinesia and vertical orientation of the anatomical LV axis. Thus, the posterolateral

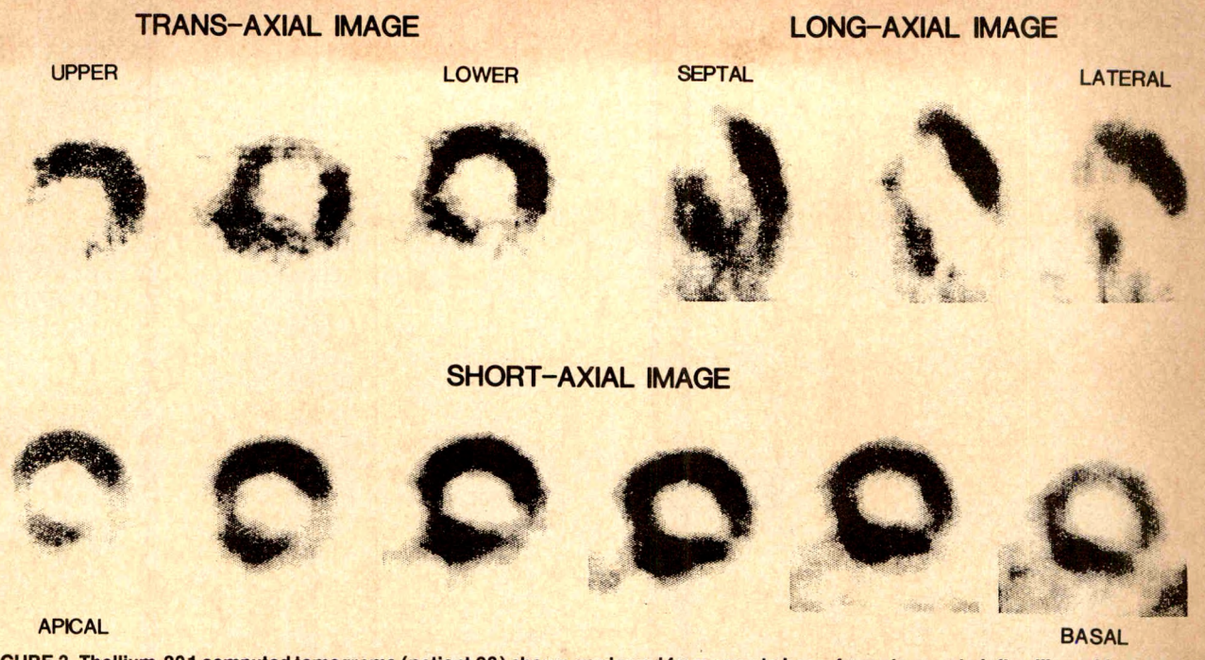

FIGURE 3. Thallium-201 computed tomograms (patient 28) shown as viewed from apex to base, from sternum to left axilla and from apex to base, respectively, in the trans- (3 images in the *left upper row*), long- (3 images in the *right upper row*) and short-axial (6 images in the *lower row*) images. In contrast to the electrocardiogram, the thallium scintigram showed solitary perfusion defect in the anteroapical wall and in the posterior wall (the former was larger than the latter). The LV cavity widened toward the apex. The angle between the LV long axis and the horizontal plane, which is projected on the long-axial image, was 70°. Reproduced with permission from Kaku Igaku.[18]

ECG pattern of the Duchenne type is not necessarily accompanied by SPECT hypoperfusion confined to that wall.

Patient 13 (Figures 4 and 5) had an electrocardiogram suggestive of posterolateral and anterior injuries, but was asymptomatic. His SPECT showed diffuse LV hypoperfusion, LV ballooning and marked lung uptake of thallium. In terms of these SPECT results, his prognosis for survival appeared doubtful. Six months after the study, he developed refractory heart failure and died 2 months thereafter. Thus, it is apparent that ECG may underestimate myocardial dystrophy that is demonstrable by SPECT.

Discussion

With sensitivity of 87% and specificity of 93%,[9] thallium-201 SPECT is an established method of assessing LV infarction. In a canine model, it accurately estimated by circumferential profile analysis the extent of infarcts that weighed from 7 to 40 g.[16] In muscular dystrophy, LV fibrosis has been assessed with various noninvasive methods[1-5,6] because left ventriculography is not justifiable in most patients. Reports on thallium imaging, however, are few.[7,17,18] In our present SPECT study, quantitative diagnosis of LV hypoperfusion as well as gross LV morphology were easily carried out although the diagnosis was also obvious by inspection in most cases.

Pathophysiology of thallium defect in muscular dystrophy: According to recent electron microscopic[19-21] and biochemical[22-25] studies, the plasma membrane is believed to be primarily affected in muscular dystrophy, i.e., before the gross pathologic changes occur. The myocardium may thus show reduced thallium uptake as a result of altered sarcolemmic permeability to the ion, even if the myocardium is structurally normal. In addition, the autopsy of Duchenne types often reveals loss of myocardial cells responsible for thallium uptake.[1-4] Thus, localized loss of the uptake implies severe dystrophy or fibrosis, although SPECT cannot diagnose a diffuse lesion or a small lesion beyond its spatial resolution. Thallium hypoperfusion was reportedly seen in 27% of boys with Duchenne dystrophy in planar imaging.[7] In contrast, our SPECT study showed hypoperfusion in 90% of Duchenne boys and in 61% of the 3 other types combined. It is known that, because of photon attenuation, the diagnostic reliability of planar imaging in LV infarction is lowest in the posteroinferior wall,[9] where dystrophy is likely to be most frequent. More importantly, SPECT is relatively free of unwanted contributions from overlapping tissues. Because SPECT is thought to detect multiple dystrophic lesions difficult to assess with planar imaging, we believe our study was valid in demonstrating frequent LV involvement in muscular dystrophy, as shown by reduced thallium uptake. The SPECT image also frequently demonstrated concurrent abnormal LV morphology (dilatation and aneurysm) and LV malrotations accompanying chest deformities.

Pathogenesis of abnormal QRS in muscular dystrophy: Several mechanisms have been proposed for the abnormal QRS: (1) reduced electromotive forces due to LV fibrosis,[1-4] (2) chest deformity,[1] (3) right ven-

tricular or septal hypertrophy,[1-2] (4) coexisting coronary artery disease,[26] (5) chest muscle atrophy,[1] (6) genetic predilection[5] and (7) impaired electrical conduction.[27] Our study basically supports hypothesis (1) because the results of our ECGs and SPECTs agreed in 69% of the LV walls and most Duchenne boys had SPECT and ECG abnormalities in the posterior wall, which is the commonly involved site.[4] However, if 2 fibrous zones of equal size happen to be located oppositely, then a cancellation effect should make the electrocardiogram appear normal. Our patients occasionally exhibited multiple perfusion defects despite minimal ECG abnormalities, and both the anteroseptal and inferior walls showed no correlations between the 2 tests. Thus, as a logical extension of hypothesis (1), an electrocardiogram that appears normal despite SPECT hypoperfusion can be ascribed to a cancellation effect of the reciprocally reduced electromotive forces in the opposite walls. Consequently, the more profound the LV dystrophy, the more often ECG may underestimate LV fibrosis. In addition, our patients often showed hypoperfusion in the posteroapical wall despite the posterolateral electrocardiographic pattern. This was consistent with the report that an abnormal Q in leads I, aVL, V_5 and V_6 reflects apical rather than lateral scar in LV infarction.[28] Thus, the ECG pattern in muscular dystrophy may also mean posteroapical rather than posterolateral dystrophy. Hypothesis (2) is unlikely because ECG and SPECT showed no significant difference in incidence between groups with and without LV malrotations. However, an abnormal Q can be seen with a heart that is normal except for LV malrotation.[29] Because 49% of our patients had LV malrotations, probably due to kyphoscoliosis, ECG in muscular dystrophy may be complicated by both LV fibrosis and LV malrotation(s). A discussion of hypotheses (3) through (7) is beyond the scope of our paper. (We excluded such confounding electrocardiograms.) Nevertheless, based on our results, hypotheses (3) and (4)

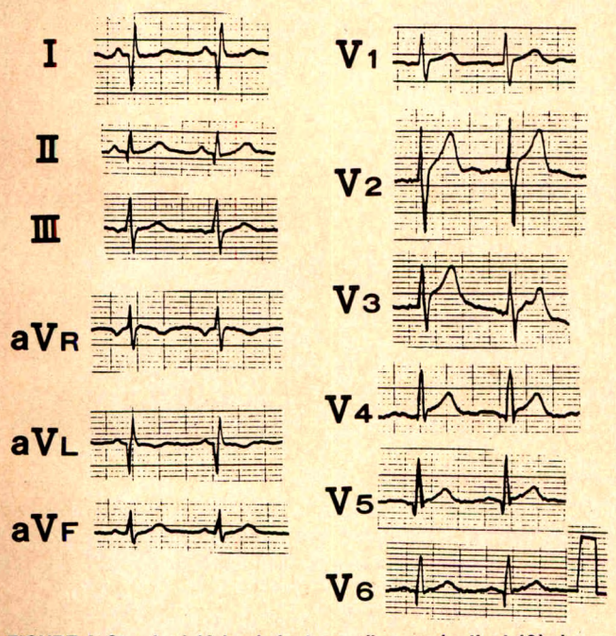

FIGURE 4. Standard 12-lead electrocardiogram (patient 13) shows low voltage in all leads. This is suggestive of both posterolateral wall injury—in terms of abnormally deep Q in leads I and aVL, increased R/S ratio (>1.0) in lead V_1 and diminished R in leads V_5 and V_6 (<1.0 mV)—and anterior wall injury—in terms of decreased R wave amplitude from V_2 to V_3. All calibrations are 1.0 mV.

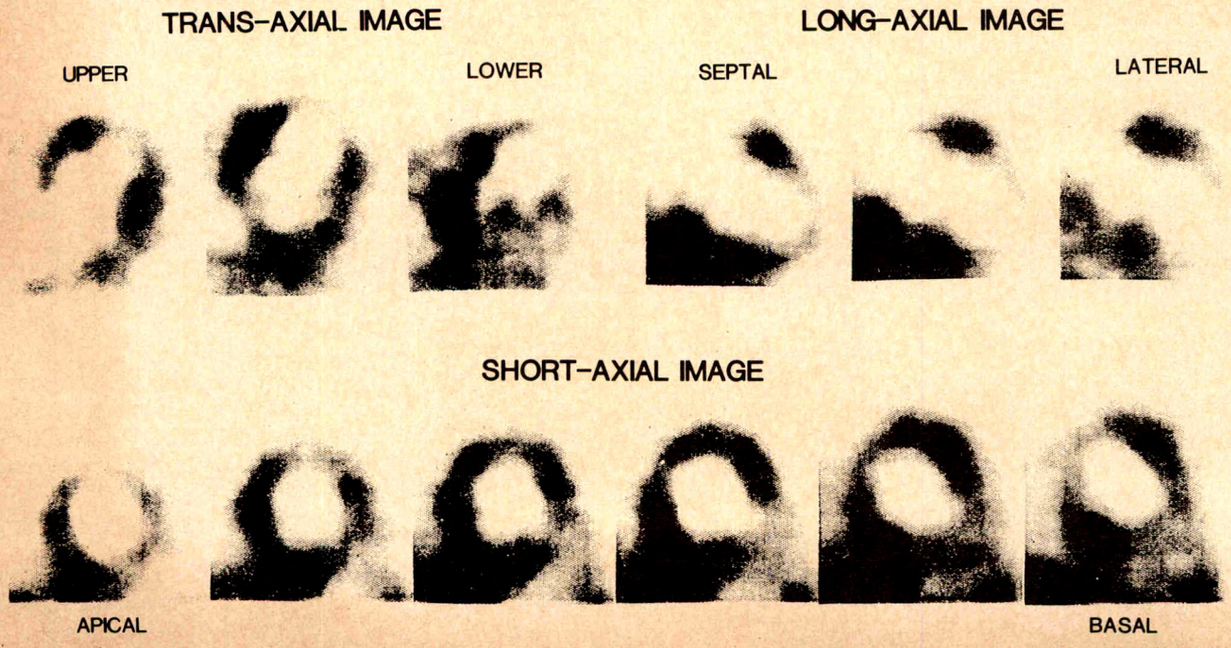

FIGURE 5. Thallium-201 computed tomograms (patient 13) showed diffuse loss of thallium uptake over all the LV walls, especially at the apical wall. The LV cavity was dilated and lung uptake of thallium was marked. Reproduced with permission from Kaku Igaku.[18]

seem unlikely because our SPECT images showed neither right ventricular nor septal hypertrophy and our electrocardiograms did not reveal an infarction pattern, i.e., a deep Q plus inverted T-wave.

In summary, the pathogenesis of an abnormal QRS in muscular dystrophy appears to involve: (1) as a primary effect, a reduced electromotive force in the dystrophic wall; (2) its cancellation effect in multiple lesions; (3) possible LV malrotation; (4) an age-factor[12,13] (in boys with Duchenne dystrophy). Thus ECG may have limited value in assessing the extent of LV dystrophy because it does not provide sufficient information on (2) and (3).

This study conventionally reported LV dystrophy as an "all or none" process in each wall, following the analytical methods of previous investigators.[1-7] Although we believe that SPECT had higher sensitivity for detection of the disease than ECG, further follow-up of our patients with both tests should be helpful in determining whether ECG underestimates or SPECT overestimates LV dystrophy.

The clinical stage showed correlation with neither SPECT nor ECG. This study showed individual variability for skeletal versus LV dystrophy and also revealed LV fibrosis in all 4 clinical types, as demonstrated by SPECT. Consequently, LV fibrosis may be a critical problem in this disease, irrespective of skeletal involvement and clinical subtype, and SPECT should be especially helpful in screening for this potentially fatal complication.

Doppler Ultrasound Evaluation of Valvar Pulmonary Stenosis from Multiple Transducer Positions in Children Requiring Pulmonary Valvuloplasty

ELMAN G. FRANTZ, MD, and NORMAN H. SILVERMAN, MD

The modified Bernoulli equation has been used to determine the peak pressure difference across stenotic pulmonary valves. The direction of the poststenotic jet may be eccentric in relation to the axis of the pulmonary artery. Consequently, the maximal velocity obtained from the parasternal transducer position may inaccurately estimate peak pressure difference. Thus, Doppler-derived estimates of pressure difference from the parasternal, subcostal, apical, and suprasternal notch transducer positions were compared with peak-to-peak pulmonary artery to right ventricle catheter withdrawal pressure differences in 24 patients admitted for pulmonary valvuloplasty. Suprasternal, subcostal or apical transducer positions produced higher maximal velocities than the parasternal transducer position in 12 of 24 patients when the studies were performed before cardiac catheterization and in 8 of 12 patients when performed during cardiac catheterization. The Doppler-derived estimates using the highest maximal velocity predicted catheterization pressure difference accurately when the measurements were not performed simultaneously ($y = 1.05x - 3.3$, $r = 0.86$, standard error of the estimate $\pm$ 18.7 mm Hg) and the correlation was closer when the measurements were performed simultaneously ($y = 1.09x - 2.7$, $r = 0.97$, standard error of the estimate $\pm$ 9.4 mm Hg). The transducer position that yielded the highest maximal velocity in an individual patient was the same before and after valvuloplasty. In all groups, the correlation with pressure at cardiac catheterization was improved by using the highest maximal velocity rather than the parasternal maximal velocity.

(Am J Cardiol 1988;61:844–849)

The application of the modified Bernoulli equation to estimate pressure differences across stenotic orifices requires axial alignment of the jet and the Doppler ultrasound beam.[1–3] This technique has become increasingly important for determining which children require valvuloplasty. Positioning the transducer in the left parasternal area and directing the ultrasound beam through the main axis of the pulmonary artery is the accepted approach to measure normal blood flow velocity in the main pulmonary artery[4–6] and to measure poststenotic maximal velocity in valvar pulmonic stenosis.[7,8] In valvar pulmonic stenosis, the direction of the poststenotic jet may deviate significantly from the ultrasound axis obtained from the parasternal transducer position, thereby adversely affecting the accuracy of the Doppler-derived estimate of pressure difference. The use of an alternative transducer position such as the subcostal, suprasternal notch or apical approach might result in a closer ultrasound beam alignment with the jet, allowing a more accurate estimate of pressure difference. With the advent of percutaneous balloon valvuloplasty for valvar pulmonic stenosis, appropriate timing of valvuloplasty can be aided by accurate Doppler-derived estimates of severity. The objective of this study was to determine whether the use of multiple transducer positions would improve the accuracy of estimation of pressure difference in children considered for balloon pulmonary valvuloplasty both before and after the procedure.

Methods

Patients: We identified 74 cases of isolated valvar pulmonic stenosis from January 1984 to October 1986. The patients' ages ranged from 1 day to 16 years. Forty-eight patients had undergone catheterization and continuous wave ultrasound studies. In the 24 patients who form the basis of this report, pulmonary artery velocity was recorded by Doppler ultrasound from more than 1 transducer position. Their ages ranged from 10 days to 13 years (mean 34 months ± 43 months standard deviation) and the median age at the time of study was 20 months.

Continuous wave Doppler echocardiographic studies were obtained on an IREX 3B system using a Pedoff 2-MHz continuous wave stand-alone transducer or on an ATL UltraMark 8 system, which uses a similar transducer. These small stand-alone transducers can be acutely angled in directions that larger transducers cannot achieve. The recordings were performed with the patient resting quietly in the left lateral decubitus position for the parasternal and apical transducer positions or supine for the subcostal transducer position. For the suprasternal notch transducer position the patient was supine with the neck extended and the head turned toward the right shoulder in order to obtain anterior alignment of the ultrasound beam. From each transducer position the transducer was angled to obtain the signal of highest velocity. The left parasternal area was evaluated with the transducer positioned in the second through fifth intercostal spaces and the highest velocity obtained was taken to represent the parasternal transducer position for analysis. Most studies were performed within the 18 hours before cardiac catheterization. The continuous wave Doppler signals were recorded on silver iodide paper at a speed of 50 mm/s, on one-half inch videotape for subsequent analysis or on both.

The continuous wave Doppler records were reviewed by one of us (EGF) without knowledge of catheterization results or prior echocardiographic interpretations. The Doppler signal was considered to be satisfactory when there was a well-defined outline of the envelope.[3] Maximal velocity was determined to the nearest 0.25 m/s. Doppler-estimated pressure differences were calculated by the simplified Bernoulli equation ($\Delta P = 4V^2$) and compared by linear regression analysis with measurements of peak-to-peak pressure difference obtained by pulmonary artery to right ventricle withdrawal during cardiac catheterization.

We studied 15 consecutive patients referred for pulmonary valvuloplasty prospectively. Continuous wave Doppler studies were performed during cardiac catheterization immediately after pulmonary artery to right ventricle catheter withdrawal before and after valvuloplasty. All Doppler recordings were obtained on an IREX 3B system without 2-dimensional guidance. The transducer position that produced the highest maximal velocity was assumed to approximate the axis of blood flow most closely. The Doppler signals were recorded and analyzed as already described without knowledge of cardiac catheterization findings. Adequate Doppler data from at least 2 transducer positions were obtained in 12 patients before valvuloplasty and in 10 patients after valvuloplasty. Doppler signals were not obtained from the apical transducer position in these patients. Peak-to-peak catheter pressure differences and Doppler-derived pressure differences from various transducer positions were compared by linear regression analysis.

To evaluate inter- and intraobserver variability, the maximal velocity of 50 of the Doppler recordings was interpreted by a second observer (NHS) and by the first observer (EGF) at a second reading without knowledge of prior interpretations. Interobserver variability was calculated as the difference between the 2 observers' readings divided by the average of their readings and expressed as a positive percentage. Intraobserver variability was calculated as the difference between the first observer's 2 readings divided by the average of the 2 readings and expressed as a positive percentage.[9]

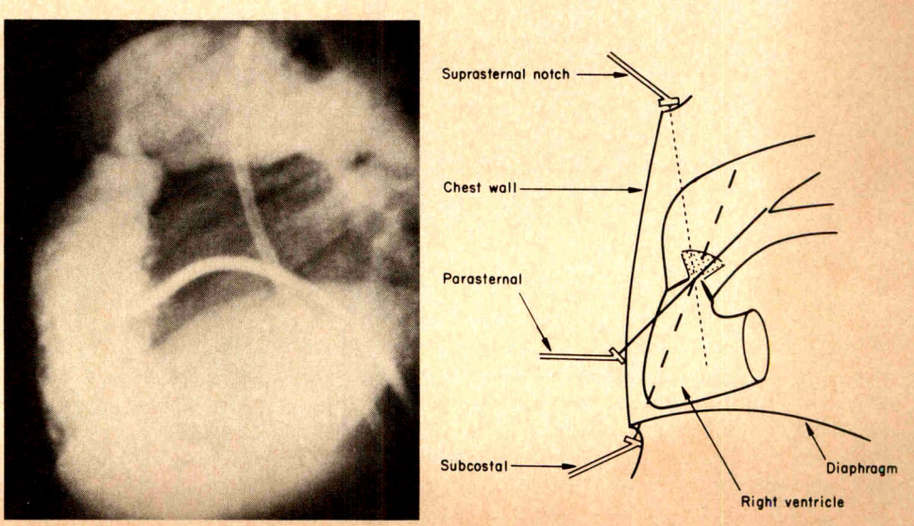

FIGURE 1. ***Left,*** **a lateral right ventricular angiogram showing an "eccentric" poststenotic jet in a patient with valvar pulmonic stenosis.** ***Right,*** **line drawing corresponding to angiogram showing the possible range of directions of a poststenotic jet (*shaded cone above pulmonary valve*) and the axis of ultrasound from multiple transducer positions.**

Results

Of the 48 patients who had nonsimultaneous catheterization and Doppler determinations of pressure difference, 24 had Doppler signals from parasternal and suprasternal, subcostal or apical transducer positions, 21 had parasternal signals alone and 3 had suprasternal signals alone. Of the 24 patients studied from multiple transducer positions, the maximal velocity from the parasternal transducer position was equal to or greater than the maximal velocity of the highest other transducer position in only 12 (50%). In the other 12 patients, a higher maximal velocity was obtained from the suprasternal, subcostal or apical transducer position. In a right ventricular angiogram obtained from 1 of the patients an anterosuperiorly directed poststenotic jet is demonstrated (Figure 1). Continuous-wave Doppler signals in this patient confirmed that suprasternal, subcostal and apical transducer positions produced higher maximal velocities that were more predictive of catheterization findings than the parasternal maximal velocity (Figure 2).

Linear regression analysis comparing nonsimultaneous Doppler-derived pressure differences using the parasternal transducer position versus catheterization pressure differences showed suboptimal strength of correlation ($r = 0.78$) with considerable variability (standard error of the estimate ± 20.6 mm Hg). More importantly, the least squares line of best fit ($y = 1.36x - 12.5$) deviated significantly from the line of identity reflecting underestimation of the more severe obstructions (Figure 3, top). When Doppler-derived pressure difference using the signal of highest maximal velocity (regardless of transducer position) was compared with catheterization pressure difference, the correlation was stronger ($r = 0.86$) with similar variability (standard error of the estimate ± 18.7 mm Hg) but the regression line ($y = 1.05x - 3.3$) very closely approximated the line of identity (Figure 3, bottom).

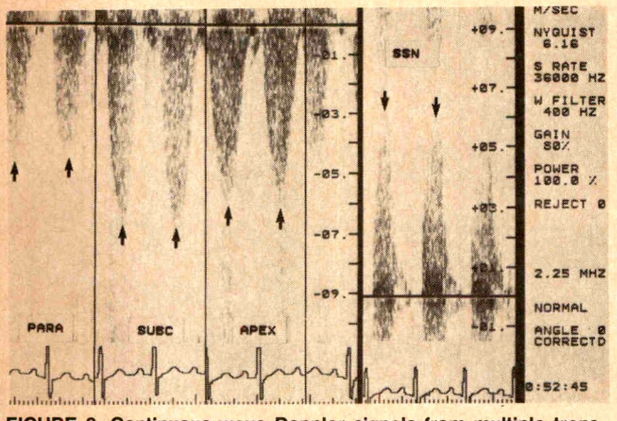

FIGURE 2. Continuous-wave Doppler signals from multiple transducer positions in the patient shown in Figure 1. Catheterization pressure difference was 154 mm Hg. The parasternal (PARA) maximal velocity is lower and less predictive than the subcostal (SUBC), apical (APEX) or suprasternal notch (SSN) maximal velocities (*arrowheads*). Note the inverted zero line and scale for the SSN velocities.

Of the 12 patients who underwent simultaneous catheterization and Doppler measurements before valvuloplasty, the parasternal maximal velocity was equal to or greater than the highest maximal velocity from a suprasternal or subcostal transducer position in only 4 (33%). A suprasternal or subcostal transducer position resulted in a higher maximal velocity than the parasternal transducer position in 8 patients (67%, Figure 4).

Despite the fact that the measurements in these 12 patients were made simultaneously, linear regression analysis resulted in a weak correlation ($r = 0.59$) with greater variability (standard error of the estimate ± 32.1 mm Hg) and poor approximation of the line of

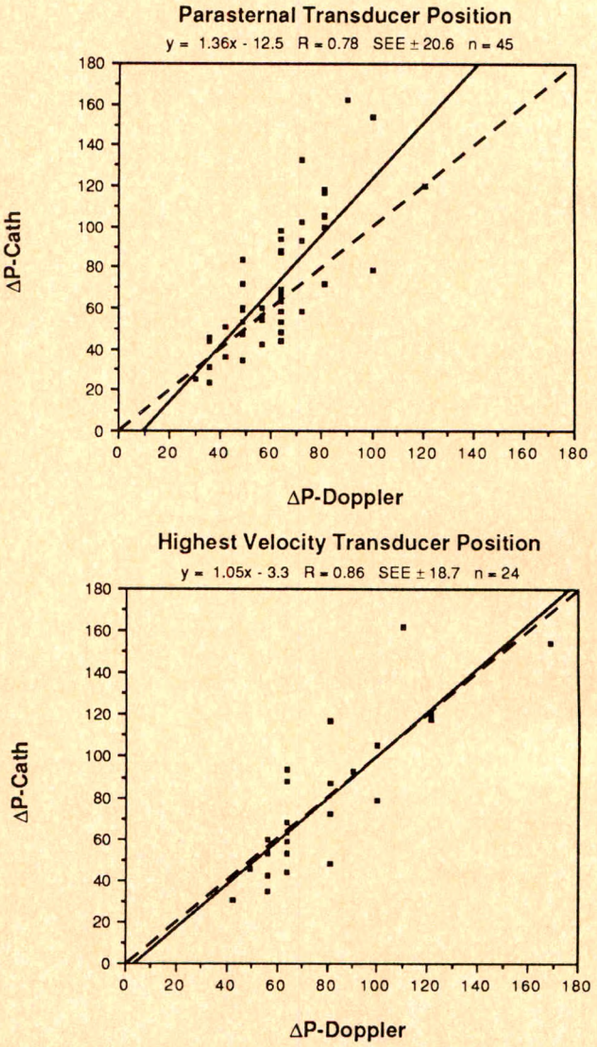

FIGURE 3. Linear regression plots comparing Doppler-derived pressure difference (ΔP Doppler) with catheterization pressure difference (ΔP Cath), both in mm Hg. At the *top*, ΔP Doppler was obtained using the nonsimultaneous parasternal maximal velocity in 45 patients. *Bottom*, ΔP Doppler was obtained using the highest maximal velocity regardless of transducer position in 24 patients. The *solid line* is the line of best fit. The *dashed line* is the line of identity.

identity (y = 1.36x + 5.1) when the parasternal signal was applied (Figure 5, top). However, the Doppler signals from the transducer position of highest maximal velocity correlated very strongly (r = 0.97) with catheterization measurements. The variability was reduced (standard error of the estimate ± 9.4 mm Hg) and the line of best fit (y = 1.09x − 2.7) closely approximated the line of identity (Figure 5, bottom).

After valvuloplasty, simultaneous Doppler and catheterization data were obtained in 10 patients. The parasternal signal (obtained in only 9 patients) was equal to or greater than the highest signal from the other position in only 4 patients (44%). The suprasternal or subcostal transducer position produced a higher maximal velocity in 5 patients (56%). An improved predictive accuracy using Doppler signals from the transducer position yielding the highest velocity is confirmed by linear regression analysis (Figure 6). The transducer position that yielded the highest velocity in an individual patient was the same before and after valvuloplasty.

Interobserver variability was 3.3 ± 4.3% (mean ± standard deviation) and intraobserver variability was 3.1 ± 3.9%. Linear regression analysis provides an interobserver correlation of y = 1.01x + 0.03, r = 0.97, standard error of the estimate ± 0.23 m/s and an intraobserver correlation of y = 0.95x + 0.09, r = 0.98, standard error of the estimate ± 0.17 m/s. In no patient was more than a 1/4 m/s difference found between the 2 observers' readings in any view.

Discussion

The parasternal transducer position has been the standard portal for the evaluation of valvar pulmonic stenosis by Doppler echocardiography. Oliveira Lima et al[7] reported a very high accuracy of prediction of nonsimultaneous catheterization findings by Doppler-estimated pressure difference in 16 patients using only the parasternal transducer position. Kosturakis et al,[8] also using only the parasternal approach, achieved acceptable predictive accuracy in 11 patients although some severe obstructions were underestimated. We were unable to achieve this degree of accuracy using parasternal measurements alone. In contrast, we identified patients in whom the parasternal approach alone had seriously underestimated true pressure difference at subsequent cardiac catheterization and, thus, led to this investigation.

Multiple Doppler transducer positions have been used in adults for the evaluation of aortic stenosis[10]

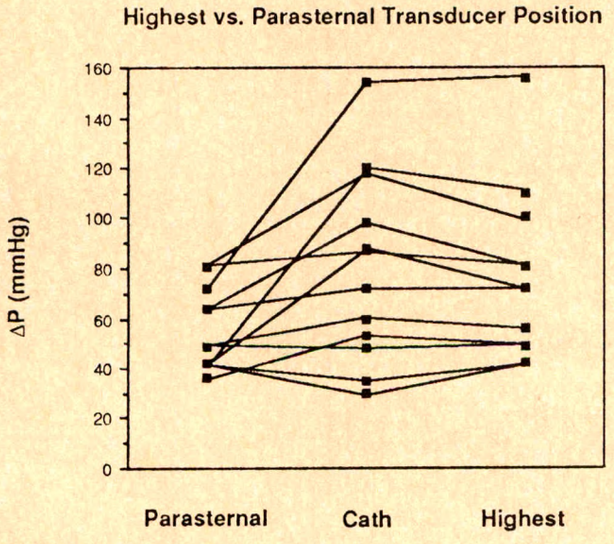

FIGURE 4. Patient-by-patient comparison of pressure difference (ΔP) predicted by the parasternal maximal velocity (*left*), the highest maximal velocity regardless of transducer position (*right*) or measured at catheterization (Cath, *middle*). Individual patient values are connected by lines.

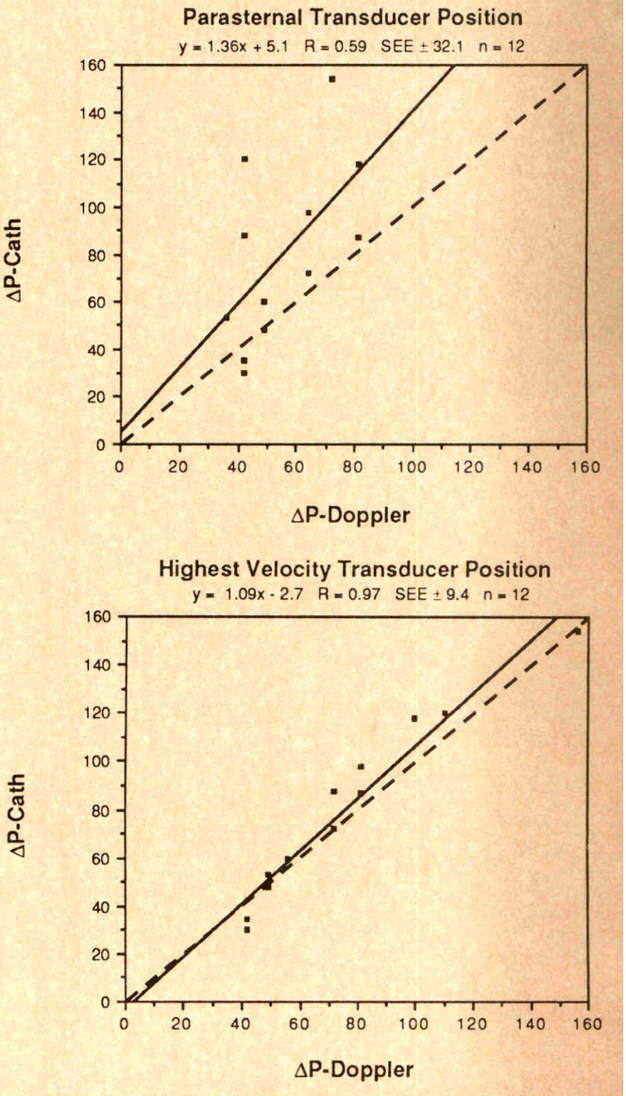

FIGURE 5. Linear regression plots comparing Doppler-derived pressure difference (ΔP Doppler) with catheterization pressure difference (ΔP Cath), both in mm Hg, before valvuloplasty. *Top*, ΔP Doppler was obtained using the simultaneous parasternal maximal velocity. *Bottom*, ΔP Doppler was obtained using the highest maximal velocity regardless of transducer position. The *solid line* is the line of best fit. The *dashed line* is the line of identity.

and nonstenotic pulmonary[11] and aortic[12] blood flow. Williams et al[10] reported improved assessment of aortic stenosis using 3 transducer positions, although the highest of 3 signals was only marginally more accurate than the apical signal alone. Stevenson and Kawabori[13] used both parasternal and subcostal approaches in applying modified pulsed Doppler systems to high velocity poststenotic flow in children with pulmonic stenosis but did not comment on the relative accuracy of the 2 transducer positions. Johnson et al[14] measured maximal velocities from the parasternal and subcostal approaches in 12 children with valvar pulmonic stenosis, but the subcostal signal substantially improved the prediction of catheterization pressure difference in only 1 patient. Murphy et al[15] also have supported the use of subcostal imaging but have suggested that the suprasternal position does not provide adequate alignment of the ultrasound beam. Based on these studies, the value of multiple transducer positions in valvar pulmonic stenosis had not previously been conclusively demonstrated.

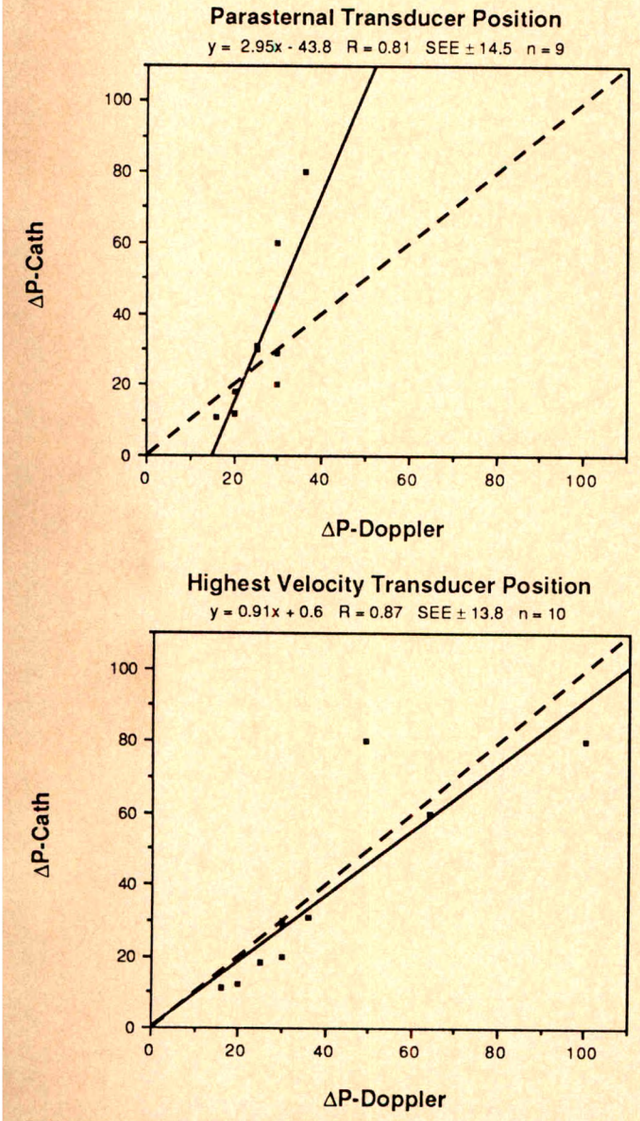

FIGURE 6. Linear regression plots comparing Doppler-derived pressure difference (ΔP Doppler) with catheterization pressure difference (ΔP Cath), both in mm Hg, after valvuloplasty. At *top*, ΔP Doppler was obtained using the simultaneous parasternal maximal velocity. *Bottom*, ΔP Doppler was obtained using the highest maximal velocity regardless of transducer position. The *solid line* is the line of best fit. The *dashed line* is the line of identity.

Our results, however, demonstrate superior prediction of catheterization pressure differences by applying the Bernoulli equation to the highest velocity signal obtained from multiple transducer positions. The direction of the poststenotic jet in valvar pulmonic stenosis is unknown and varies from patient to patient; thus, the transducer position that will produce the closest alignment with this jet and the highest velocity cannot be anticipated. In our 10 patients in whom echocardiographic studies were performed before and after valvuloplasty, the transducer position producing the highest velocity in an individual was not altered. However, because our sample size is small, we cannot generalize to the population at large. The direction of the poststenotic jet might be altered by valvuloplasty in some patients. For these reasons, multiple transducer positions should be used in each patient before and after valvuloplasty.

Several other findings of our study are notable. The highest Doppler velocities recorded at cardiac catheterization (Figure 5, bottom) more accurately predicted catheterization pressure difference than the highest velocities not recorded simultaneously (Figure 3, bottom). This may be due to the level of sedation and transvalvar flow rate, which were nearly identical in the former group and highly variable in the latter. A poor correlation was found using the parasternal velocities obtained at cardiac catheterization. (Figure 5, top), which might be related to technical limitations of performing Doppler echocardiography in the catheterization laboratory where optimal patient position and time constraints may have had an adverse impact on the Doppler study.

In 7 of 24 patients (29%) with nonsimultaneous measurements (Figure 3), Doppler-derived pressure difference overestimated catheterization findings by at least 10 mm Hg. Level of arousal and, thus, cardiac output are likely to be greater in unsedated outpatients than in sedated patients undergoing catheterization. Doppler-derived measurements are known to overestimate simultaneous peak-to-peak catheterization measurements and to correlate more closely with peak instantaneous pressure differences.[16,17] Nonetheless, we and others have found excellent predictive accuracy with peak-to-peak measurements without overestimation.[7,8,13,14] Accurate Doppler-derived estimates of severity especially in the range of values where treatment may be contemplated are valuable because they influence timing of balloon valvuloplasty and aid in the accurate follow-up thereafter.

Anomalous Origin of a Pulmonary Artery from the Ascending Aorta: Associated Anomalies and Pathogenesis

LYNN M. KUTSCHE, MD, and L.H.S. VAN MIEROP, MD

The pathologic anatomic features and associated cardiovascular anomalies of 9 patients with anomalous origin of 1 pulmonary artery (PA) from the ascending aorta seen at the University of Florida and 99 previously reported cases were analyzed. Anomalous origin of the right PA was much more common than anomalous origin of the left PA. The anomalous right PA usually arose from the posterior aspect of the ascending aorta close to the aortic valve. Less commonly, it originated from the lateral ascending aorta just proximal to the innominate artery. Patent ductus arteriosus and aorticopulmonary septal defect were commonly associated with anomalous origin of the right PA; other cardiovascular anomalies were rare. In contrast, tetralogy of Fallot and aortic arch anomalies, e.g., right aortic arch and anomalous origin of the subclavian artery, were common in anomalous origin of the left PA. An association with DiGeorge syndrome, frequently noted with persistent truncus arteriosus, was not seen with anomalous origin of a PA from the ascending aorta. The observations indicate that anomalous origin of the right PA and anomalous origin of the left PA are pathogenetically unrelated to each other and both are unrelated to persistent truncus arteriosus. Moreover, anomalous origin of the right PA arising close to the innominate artery is thought to be pathogenetically distinct from the type that arises close to the aortic valve. These pathogenetic relations should be considered in epidemiologic studies of congenital heart disease.

(Am J Cardiol 1988;61:850–856)

Anomalous origin of either the right or the left pulmonary artery (PA) from the ascending aorta is rare. The anomaly has been considered a partial form of persistent truncus arteriosus by some or to be due to abnormal truncal septation.[1-6] Some believe anomalous right PA to be the result of lack of leftward migration of the right sixth aortic arch,[7-10] while others consider it to represent a persistence of either the right fifth or distal right sixth arch with early involution of the proximal arch.[11-15]

In a recent review of cardiac anomalies associated with DiGeorge syndrome, interrupted arch type B and persistent truncus arteriosus were found in 48 (30%) and 37 (23%) patients, respectively, but not a single case of anomalous origin of a PA from the ascending aorta or aorticopulmonary septal defect was seen.[16] This seemed odd since both anomalies involve a region between the aortic and pulmonary roots and the aortic arch system. Moreover, both have been considered to be partial forms of persistent truncus arteriosus and therefore pathogenetically related. This stimulated us to review our own cases of anomalous origin of the PA from the ascending aorta as well as those reported previously by others.

Methods

Seven cases of anomalous origin of a PA from the ascending aorta were found among 7,329 patients with

From the Department of Pediatrics (Divisions of Research and Cardiology) and Pathology, University of Florida College of Medicine, Gainesville, Florida. Dr. Kutsche is the recipient of Clinical Investigator Award 5K08 HL00885 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland. Manuscript received October 19, 1987; revised manuscript received and accepted December 10, 1987.

congenital heart disease seen at the University of Florida. Of these, 5 had anomalous origin of the right PA; in 2 cases the anomalous artery was on the left. Six patients had cardiac catheterization and surgery, the seventh case was examined at autopsy. Two cases, one each of anomalous right and left PA studied by one of us (LHSVM) at the Montreal Children's Hospital, are included in this report. A review of previous publications yielded 99 cases, 83 with anomalous right PA and 16 with anomalous left PA.[1,3-8,10,12-15,17-59] Reported cases were included only if individual case descriptions were given, so that associated anomalies could be analyzed.

Results

Data concerning our 9 cases are listed in Table I. Those concerning the 99 previously reported cases are summarized in Table II. We will now consider all 108 cases together.

Anomalous origin of the right pulmonary artery: In 76 of the 89 cases (85%) the anomalous PA arose proximally from the posterior or left posterior aspect of the ascending aorta close to the aortic valve (Figure 1D). In 13 case (15%) it originated from the ascending aorta just proximal to the innominate artery or from the base of the artery itself (Figure 1B). In 7 of the 13, the anomalous right PA was narrowed, usually some distance from its origin. All patients had a left aortic arch and over two-thirds had a patent ductus arteriosus. Aorticopulmonary septal defect was a common associated anomaly (15%) in those in whom the anomalous PA arose proximally but was seen only in one with distal origin of the PA. Tetralogy of Fallot was present in only 3 cases (3%); in 1 of these the right PA arose close to the innominate artery. Interruption of the aortic arch type A or coarctation of the aorta was associated in 11 cases of proximal right PA origin; 8 of these also had an aorticopulmonary septal defect.

Anomalous origin of the left pulmonary artery: In these 19 cases the artery usually arose from the left lateral aspect of the ascending aorta close to the aortic valve and curved upwards and over the left main bronchus to enter the left lung (Figure 1C). Tetralogy of Fallot was associated in 74% of the patients, a right aortic arch (with or without tetralogy of Fallot) was present in 63%. All 19 patients had either tetralogy of Fallot, a right aortic arch, or both. Nine (47%) had an anomalous origin of the subclavian artery. None had an associated aorticopulmonary septal defect, interruption of the aortic arch type A or coarctation of the aorta. The ductus arteriosus was patent in 16%. It was on the right, associated with a right aortic arch, in all. In another 20% there was no trace of even a ligamentum arteriosum.

Thus, aorticopulmonary septal defect is common in anomalous origin of the right PA from the ascending aorta, and tetralogy of Fallot and aortic arch anomalies are the rule in anomalous origin of the left PA. We believe that interruption of the aortic arch type A and coarctation, associated in most cases with aorticopulmonary septal defect, are secondary, hemodynamically induced anomalies.

TABLE I Major Findings in Nine Cases of Anomalous Origin of One Pulmonary Artery from the Ascending Aorta

Case	Age*, Sex	Major CV Anomaly	Other Cardiovascular Anomalies
1	8 days, F	AOLPA	RAA, ALSA, PDA, ASD
2	5 yrs, M	AOLPA	TF, RAA, ALSA
3	5 yrs, F	AOLPA	TF, ARSA, PLSVC
4	3 wks, F	AORPA	PDA
5	5 days, M	AORPA	None
6	3 mos, F	AORPA	PDA
7	3 mos, M	AORPA	APSD, IAA-A, PDA
8	2 mos, M	AORPA	PDA
9	1 yr, F	AORPA	PDA

* At surgery or autopsy.

AL(R)SA = anomalous left (right) subclavian artery; AOL(R)PA = anomalous left (right) pulmonary artery; APSD = aorticopulmonary septal defect; ASD = atrial septal defect; CV = cardiovascular; IAA-A = interrupted aortic arch type A; PDA = patent ductus arteriosus; PLSVC = persistent left superior vena cava; RAA = right aortic arch; TF = tetralogy of Fallot.

TABLE II Anomalous Origin of One Pulmonary Artery from the Ascending Aorta in 99 Reported Cases

	Proximal—AORPA—Distal				AOLPA

IAA-B	0	(0)	1	(8)	0	(0)

COA = coarctation of the aorta. IAA-B = interrupted arch type B; other abbreviations as in Table I.

Embryology

The original arrangement in early vertebrate embryos of (usually) 6 pairs of branchial arch arteries (in mammalian embryology customarily referred to as the aortic arches), which connect the ventral aorta to the initially paired dorsal aorta, is retained into adulthood only in gill breathing fishes. With the advent of pulmonary respiration and loss of gills however, the aortic arch system undergoes profound modifications. In young embryos of airbreathing vertebrates the first 4 aortic arches and the primordia of the pulmonary arteries arise from a manifold-like structure, the (trunco) aortic sac (Figure 2). An invagination of the dorsal wall of the aortic sac between the fourth and the fused sixth arches (actually the pulmonary arteries[60,61] see below),

the aorticopulmonary septum, joins the distal face of the truncoconal septum, which meanwhile has divided the truncal part of the early embryonic heart into aortic and pulmonary roots.[62] The first 2 aortic arches involute and nearly disappear. In mammals the third arches become the common carotid and proximal in-

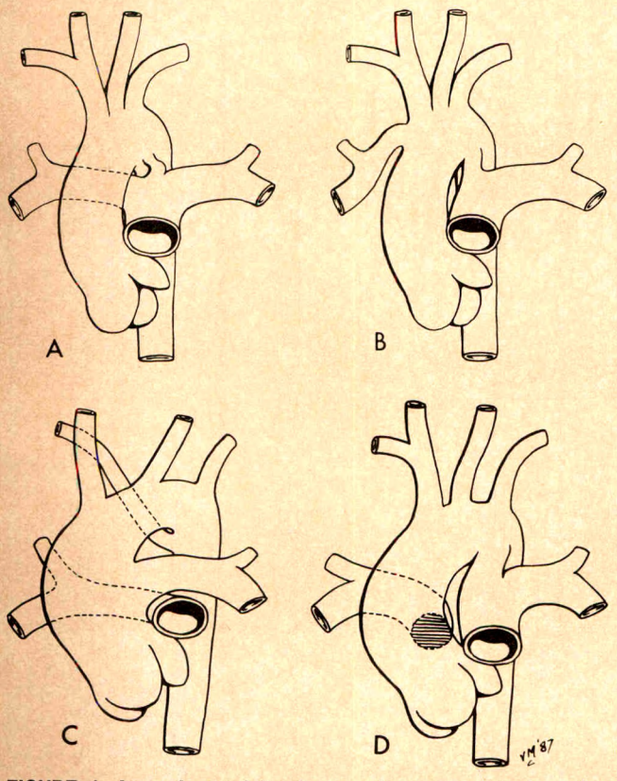

FIGURE 1. Anomalous origin of one pulmonary artery from the ascending aorta. *A*, normal; *B*, distal origin of right pulmonary artery; *C*, anomalous origin of left pulmonary artery (case 3); *D*, proximal origin of the right pulmonary artery (case 6).

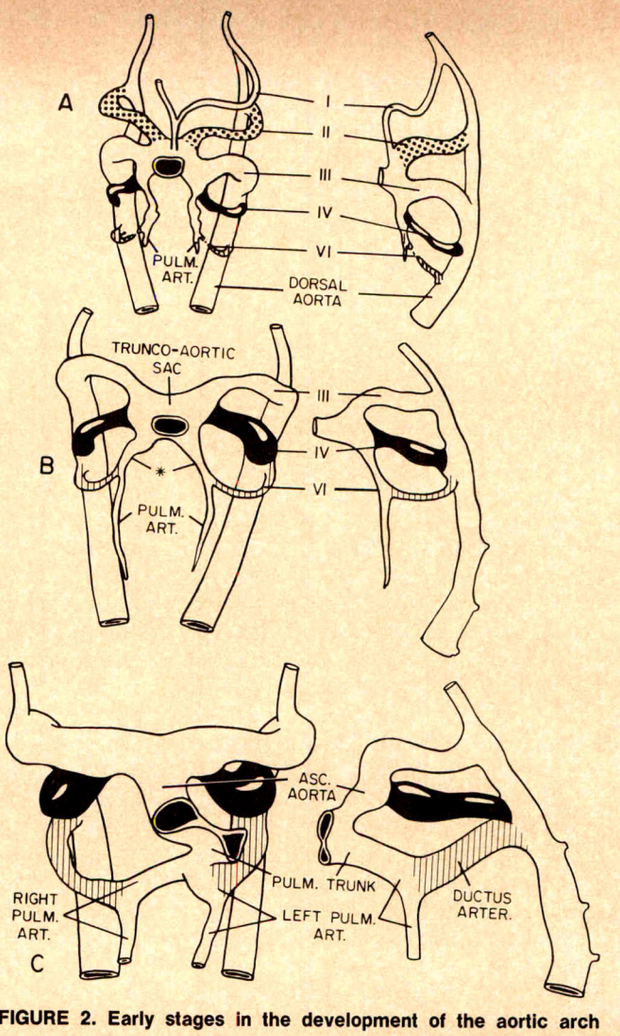

FIGURE 2. Early stages in the development of the aortic arch system. *Asterisk* indicates part of pulmonary artery usually and erroneously considered proximal part of sixth arch. ART = artery; ARTER = arteriosus; ASC = ascending; PULM = pulmonary (redrawn after Congdon[63]); A = 4 mm; B = 5 mm; C = 11 mm embryo.

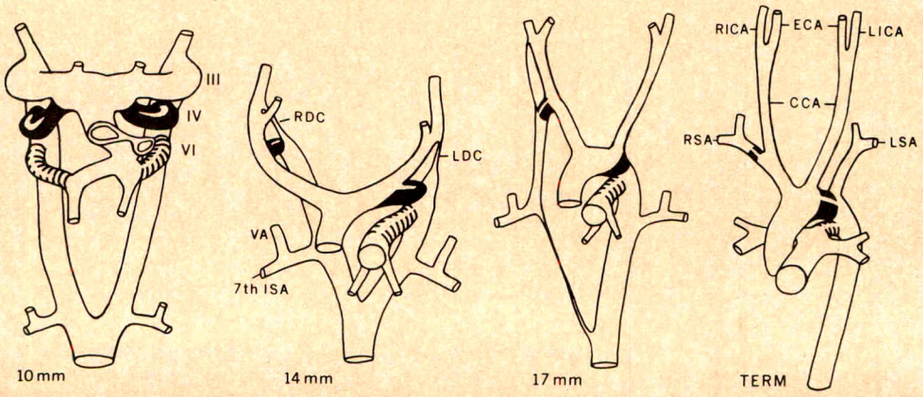
FIGURE 3. Late stages in the development of the aortic arch system, to show the development of the right subclavian artery and the relationships between the distal (dorsal) parts of the fourth and sixth arches and the ascending aorta. III, IV and VI = third, fourth and sixth aortic arches; 7th ISA = seventh intersegmental artery; CCA = common carotid artery; ECA = external carotid artery; L (R) DC = left (right) ductus caroticus; L (R) ICA = left (right) internal carotid artery; L (R) SA = left (right) subclavian artery; RDA = right dorsal aorta; VA = vertebral artery. Reproduced with permission from Kutsche et al,[70] Am J Cardiol.



ternal carotid arteries. The left fourth arch becomes part of the normal aortic arch and its right counterpart forms part of the proximal right subclavian artery (Figure 3). The right and left sixth branchial arches first appear as ventral and much larger dorsal buds arising from the already existing pulmonary arteries[60,61] (derived from the ventral pharyngeal plexus, Figure 2) and dorsal aorta, respectively. As Bremer[60] points out, the pulmonary arteries, from a developmental point of view, strictly speaking are not branches of the sixth arches (a misconception perpetuated by the well-known Rathke's diagram[63] and its various modifications). Rather, the sixth arches connect the primitive pulmonary arteries to the dorsal aortae. After completion of the sixth arch in 5 to 6 mm embryos the proximal part of the early embryonic PA is usually but erroneously considered to be the ventral part of the sixth arch with the PA then arising from this arch. The ductus arteriosus therefore is *all* of the sixth arch, not just its dorsal part as is usually stated. The right PA migrates to the left and proximally fuses with the left to create the distal most part of the pulmonary trunk.[60,61,64]

The right sixth arch exists only briefly, the left sixth arch is retained until after birth as the ductus arteriosus. The fifth aortic arches, already smaller than the third, fourth, and sixth in amphibians, is reduced further in birds and mammals. In higher mammals including man, if present at all, it is usually rudimentary and makes its appearance after the sixth arch. In human embryos of 7 to 9 mm CR length it is present transiently.

Although the fifth aortic arch is rudimentary in higher mammals, man is among the few species in which it may be quite well developed. In reconstructed models of 7 embryos in which the pulmonary arch was almost or just completed, Congdon[61] found 3 instances of well-developed fifth arch vessels arising from the aortic sac or proximal fourth arch and joining the distal end of the pulmonary (sixth) arch. Although Congdon did not refer to these vessels as fifth aortic arches, his rather lengthy discussion and illustrations leave little doubt as to their true nature. Tandler[65] was the first to describe the embryonic fifth arch in 2 human embryos. Coulter[66] comments that "the typical mammalian 5th aortic arch appears to be a vessel which arises from the aortic bulb and empties into the pulmonic arch near its junction with the dorsal aorta. The development is most complete in man and the mole, in which an unbroken arch is the rule." He finds the fifth arch also to be present, be it in much more rudimentary form, in the cat, pig and rabbit. That a fifth arch can and does occasionally develop in man finds further support in the description of several cases of this arch persisting postnatally.[67,68]

Discussion

We concur with the interpretation that in cases of a pulmonary artery arising from the innominate artery as a trifurcation with the internal carotid and subclavian arteries or from the undersurface of the mid-aortic

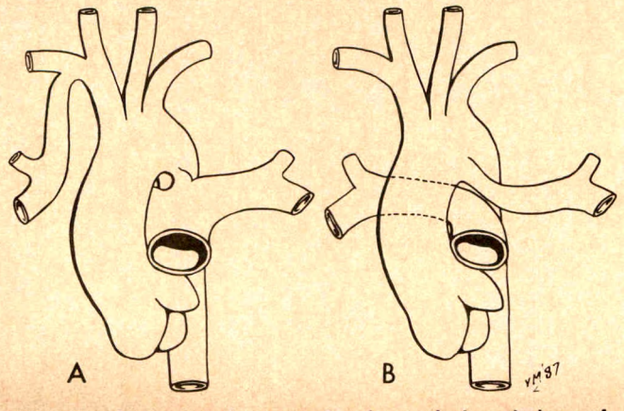


FIGURE 4. Origin of a pulmonary artery from a ductus arteriosus. *A*, from right subclavian artery; *B*, from aortic arch.

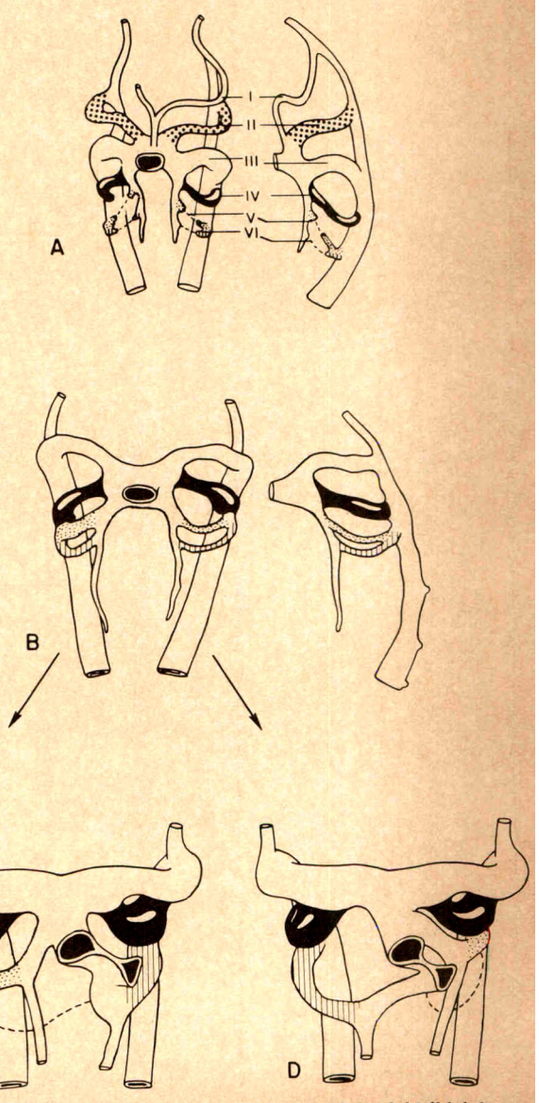

FIGURE 5. Pathogenetic mechanism of anomalous right (high type, *A*, *B*, *C*) and left pulmonary artery (*A*, *B*, *D*) if fifth arch is the dominant or only arch.

arch (Figure 4A and B), the proximal part of the anomalous PA in fact represents the ductus arteriosus, the proximal part of the embryonic pulmonary artery having retrogressed and disappeared early in development. The often reduced diameter of the proximal PA and the presence of ductal type tissue supports this view.

Anomalous origin of the right pulmonary artery: We agree with Schneiderman[10] and others[7-9] that in the proximal form of the anomaly the origin of the right PA from the left posterior aspect of the ascending aorta leave little doubt that the anomaly is due to incomplete (or delayed?) leftward migration of the right PA. The aorticopulmonary septum invaginates to its left rather than to its right as it does normally and leaves the right PA "stranded." The common association of aorticopulmonary septal defect is of interest in this regard since that anomaly may in some cases be due to malalignment of the aorticopulmonary and truncal septa.[69] The frequent association of aorticopulmonary septal defect with interruption of the aortic arch type A or coarctation is not coincidental and supports the proposal that the combination of anomalous origin of the right PA, distal aorticopulmonary septal defect and interruption of the aortic arch type A be considered a syndrome.[7] It is possible, however, that in some cases with the distal form of aorticopulmonary septal defect, in which the aorticopulmonary septum does not develop at all, the apparent anomalous origin of the right PA from the aorta is an illusion.

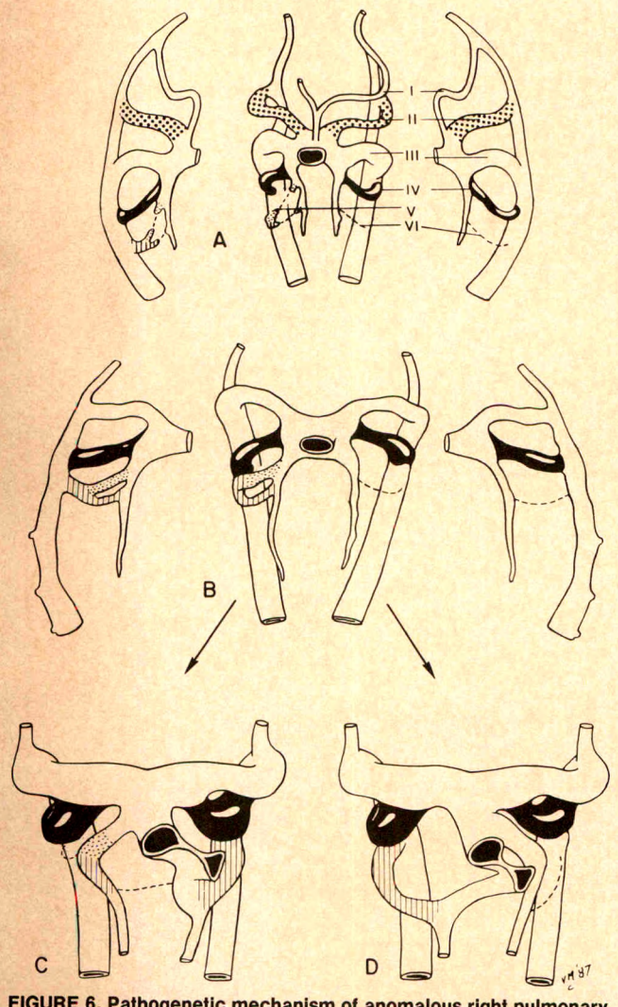

FIGURE 6. Pathogenetic mechanism of anomalous right pulmonary artery (distal origin *A*, *B*, *C*) if both fifth and sixth arches develop, and anomalous left pulmonary artery if neither fifth nor sixth arch develops. (See text.)

It is unlikely that the proximal right PA in cases in which it originates from the ascending aorta near the base of the innominate artery represents the ductus arteriosus, since the right fourth aortic arch forms part of the origin of the right subclavian artery (Figure 3). Three other, more plausible explanations for the anomaly are: (1) a right fifth arch developed and the sixth either did not or, if it did, it involuted early[11] (Figure 5A,B,C); (2) neither the fifth nor the sixth arch developed and the early embryonic PA retained its original position near the origins of the third and fourth arches, thus eventually appearing to have migrated up the ascending aorta rather than moving away from the third and fourth arches and occupying a position closer to the heart as it does normally (Figure 6A,B,D for anomalous origin of the left PA); or (3) a fifth arch developed, and the proximal PA as well as the distal (dorsal) part of the sixth arch disappeared, as it normally does (Figure 6A,B,C). This pathogenetic mechanism, proposed by Odell and Smith,[14] could explain the observation that a narrowing, as is present in about half the cases, usually does not involve the first part of the anomalous artery but is located further distal. The narrow area in some cases has been shown to contain ductal-type tissue. This may be the most likely pathogenetic mechanism, because associated cardiovascular anomalies involving the aortic arch system are not particularly common.

Anomalous origin of the left pulmonary artery: We do not find the theory by Cucci et al,[2] which for its pathogenetic explanation invokes a major abnormality of truncoconal septation, to be plausible because it does not explain the frequently associated aortic arch anomalies and any such deviation of aorticopulmonary septation might be expected to create a spectrum of abnormalities, not an either (normal)/or (anomalous origin) condition. We believe it more plausible that anomalous origin of the left PA from the proximal ascending aorta pathogenetically is an aortic arch anomaly, particularly since all known cases have been associated with tetralogy of Fallot, aortic arch anomalies, or both. A pathogenetic mechanism similar to that described previously for distal origin of the right PA from the ascending aorta, i.e., persistence of the left fifth arch with absence of the sixth or simply absence of the sixth arch, could also be invoked. Failure of development of the left sixth arch we believe to be the most likely cause for the anomaly. Finally, from an epidemiologic point of view it is important to bear in mind that the 3 forms of anomalous origin of a PA from

the ascending aorta are unrelated pathogenetically and none should be considered partial types of persistent truncus arteriosus.

Acknowledgment: We thank Dr. J-P de Chadarevian for allowing us to include the 2 cases from the Montreal Children's Hospital which were studied by one of us (LHSVM) with Dr. F.W. Wiglesworth, then Director of Pathology. We gratefully acknowledge the assistance of Debbie Abraham in manuscript preparation.

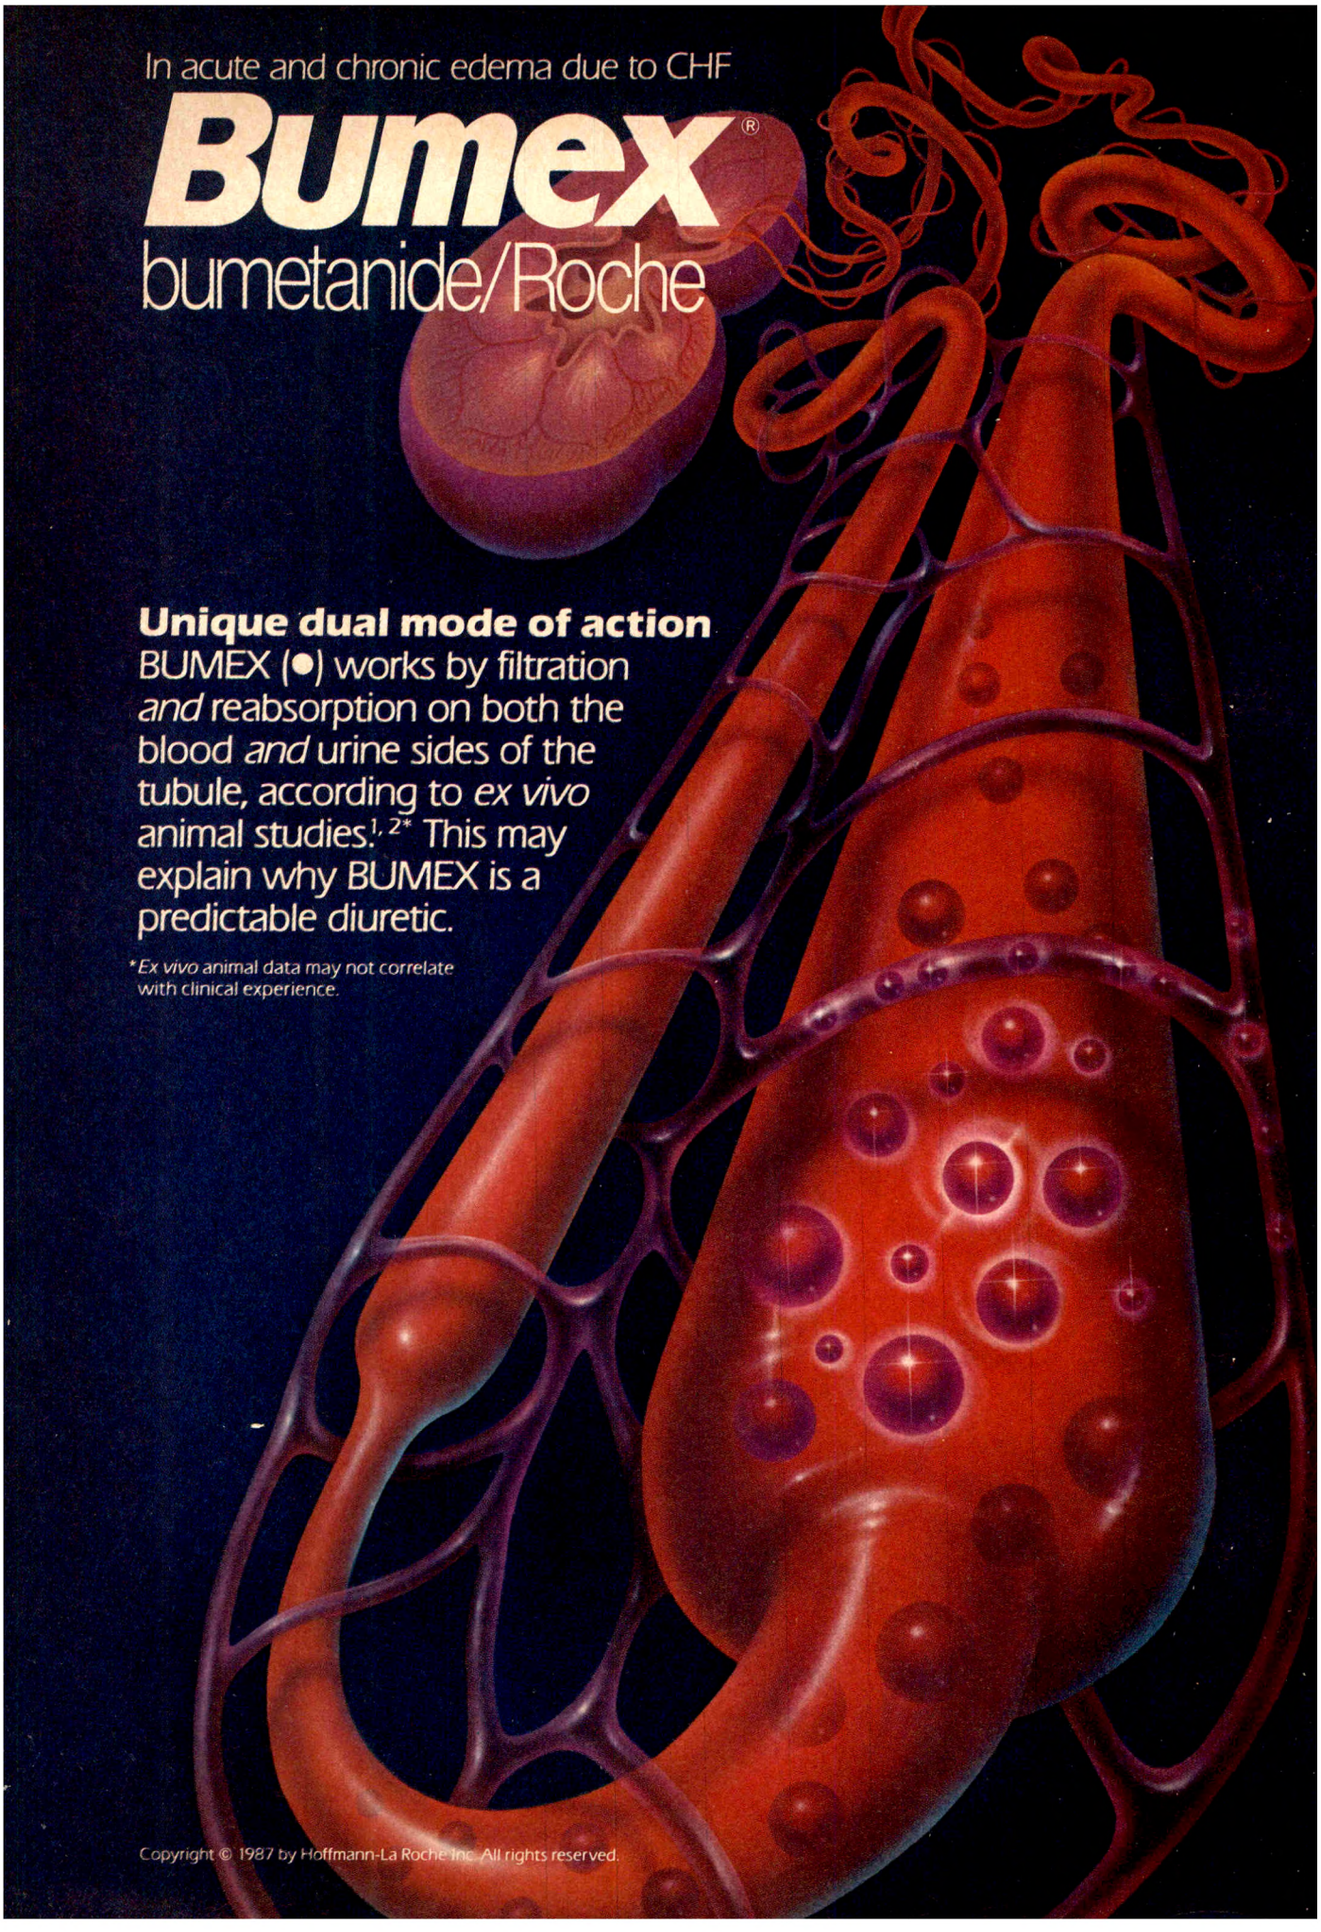
WHICH DIURETIC GIVES YOU PREDICTABLE CONTROL?



In acute and chronic edema due to CHF
Bumex®
bumetanide/Roche
Unique dual mode of action
BUMEX (•) works by filtration and reabsorption on both the blood and urine sides of the tubule, according to ex vivo animal studies.[1,2]* This may explain why BUMEX is a predictable diuretic.
*Ex vivo animal data may not correlate with clinical experience.
Copyright © 1987 by Hoffmann-La Roche Inc. All rights reserved.

THE UNIQUE PATHWAY TO PREDICTABLE CONTROL

Less potassium loss for a given amount of sodium excretion than with furosemide.[3-5] As with all loop diuretics, excessive doses of BUMEX can lead to profound diuresis with water and electrolyte depletion, including hypokalemia, so serum electrolytes should be monitored.

More predictable GI absorption—85% with BUMEX and 40%-60% with branded furosemide.[7] The unpredictable absorption rate of furosemide may cause uncertainty about the amount of drug needed.

Predictably easier transition from IV to oral therapy. The mg to mg equivalence of BUMEX dosage forms eliminates time-consuming titration.[6] Furosemide may require titration during the transition.[7]

Predictable dose response. BUMEX provides a straight line increase in diuretic effect as the oral dose increases.[8] Adverse effects characteristic of loop diuretics—muscle cramps, dizziness, hypotension, nausea and encephalopathy—have been reported with BUMEX.

There is only <u>one</u> BUMEX. When you prescribe BUMEX, you and your patients are assured of receiving the same product from prescription to prescription.

If you prescribe branded or generic furosemide, you and your patients may not know which of the approximately 50 generic versions of the oral will be dispensed or which of the approximately 10 versions of the injectable will be used.

Please see adjacent page for references and summary of product information.

Bumex®

bumetanide/Roche

0.5-mg, 1-mg and 2-mg scored tablets; 2-ml ampuls and 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

In acute and chronic edema due to CHF

FOR PREDICTABLE CONTROL

- **Less potassium loss for a given amount of sodium excretion than with furosemide[3-5]**
- **Predictable dose response[8]**
- **Better GI absorption[6,7]**
- **Diuresis completed hours faster than with furosemide after oral dosing[9]**
- **Early-evening dosing helps prevent nocturnal dyspnea**

Bumex®
bumetanide/Roche
0.5-mg, 1-mg and 2-mg scored tablets; 2-ml ampuls and 2-ml, 4-ml and 10-ml vials (0.25 mg/ml)

BUMEX®
(bumetanide/Roche)
0.5-mg, 1-mg and 2-mg scored tablets
2-ml ampuls, 2-ml, 4-ml and
10-ml vials (0.25 mg/ml)
Before prescribing, please consult complete product information, a summary of which follows:

WARNING: Bumex (bumetanide/Roche) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dosage schedule have to be adjusted to the individual patient's needs. (See under DOSAGE AND ADMINISTRATION in complete product information.)

INDICATIONS AND USAGE: Edema associated with congestive heart failure, hepatic and renal disease, including the nephrotic syndrome.
Almost equal diuretic response occurs after oral and parenteral administration of Bumex. If impaired gastrointestinal absorption is suspected or oral administration is not practical, Bumex should be given by the intramuscular or intravenous route.
Successful treatment with Bumex following instances of allergic reactions to furosemide suggests a lack of cross-sensitivity.
CONTRAINDICATIONS: Anuria. Hypersensitivity and in patients in hepatic coma or in states of severe electrolyte depletion. Although Bumex can be used to induce diuresis in renal insufficiency, any marked increase in blood urea nitrogen or creatinine, or the development of oliguria during therapy of patients with progressive renal disease, is an indication for discontinuation of treatment.
WARNINGS: Dose should be adjusted to patient's needs. Excessive doses or too frequent administration can lead to profound water loss, electrolyte depletion, dehydration, reduction in blood volume and circulatory collapse with the possibility of vascular thrombosis and embolism, particularly in elderly patients.
Prevention of hypokalemia requires particular attention in patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis and ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, certain diarrheal states, or other states where hypokalemia is thought to represent particular added risk to the patients.
In patients with hepatic cirrhosis and ascites, sudden alterations of electrolyte balance may precipitate hepatic encephalopathy and coma. Treatment in such patients is best initiated in the hospital with small doses and careful monitoring of the patient's clinical status and electrolyte balance. Supplemental potassium and/or spironolactone may prevent hypokalemia and metabolic alkalosis in these patients.
In cats, dogs and guinea pigs, Bumex has been shown to produce ototoxicity. Since Bumex is about 40 to 60 times as potent as furosemide, it is anticipated that blood levels necessary to produce ototoxicity will rarely be achieved. The potential for ototoxicity increases with intravenous therapy, especially at high doses.
Patients allergic to sulfonamides may show hypersensitivity to Bumex.

PRECAUTIONS: Measure serum potassium periodically and add potassium supplements or potassium-sparing diuretics, if necessary. Periodic determinations of other electrolytes are advised in patients treated with high doses or for prolonged periods, particularly in those on low salt diets.
Hyperuricemia may occur. Reversible elevations of the BUN and creatinine may occur, especially with dehydration and in patients with renal insufficiency. Bumex may increase urinary calcium excretion.
Possibility of effect on glucose metabolism exists. Periodic determinations of blood sugar should be done, particularly in patients with diabetes or suspected latent diabetes.
Patients should be observed regularly for possible occurrence of blood dyscrasias, liver damage or idiosyncratic reactions.
Especially in presence of impaired renal function, use of parenterally administered Bumex should be avoided in patients to whom aminoglycoside antibiotics are also being given, except in life-threatening conditions.
Drugs with nephrotoxic potential and bumetanide should not be administered simultaneously.
Since lithium reduces renal clearance and adds a high risk of lithium toxicity, it should not be given with diuretics.
Probenecid should not be administered concurrently with Bumex.
Concurrent therapy with indomethacin not recommended.
Bumex may potentiate the effects of antihypertensive drugs, necessitating reduction in dosage.
Interaction studies in humans have shown no effect on digoxin blood levels.
Interaction studies in humans have shown Bumex to have no effect on warfarin metabolism or on plasma prothrombin activity.
Pregnancy: Bumex should be given to a pregnant woman only if the potential benefit justifies the potential risk to the fetus.
Bumetanide may be excreted in breast milk.
Pediatric Use: Safety and effectiveness below age 18 not established.
ADVERSE REACTIONS: Muscle cramps, dizziness, hypotension, headache and nausea, and encephalopathy (in patients with preexisting liver disease).
Less frequent clinical adverse reactions are weakness, impaired hearing, rash, pruritus, hives, electrocardiogram changes, abdominal pain, arthritic pain, musculoskeletal pain and vomiting.
Other clinical adverse reactions are vertigo, chest pain, ear discomfort, fatigue, dehydration, sweating, hyperventilation, dry mouth, upset stomach, renal failure, asterixis, itching, nipple tenderness, diarrhea, premature ejaculation and difficulty maintaining an erection.
Laboratory abnormalities reported are hyperuricemia, azotemia, hyperglycemia, increased serum creatinine, hypochloremia, hypokalemia, hyponatremia, and variations in CO_2 content, bicarbonate, phosphorus and calcium. Although manifestations of the pharmacologic action of Bumex, these conditions may become more pronounced by intensive therapy.
Diuresis induced by Bumex may also rarely be accompanied by changes in LDH, total serum bilirubin, serum proteins, SGOT, SGPT, alkaline phosphatase, cholesterol, creatinine clearance, deviations in hemoglobin, prothrombin time, hematocrit, platelet counts and differential counts. Increases in urinary glucose and urinary protein have also been seen.
DOSAGE AND ADMINISTRATION:
Oral Administration: The usual total daily dosage is 0.5 to 2.0 mg and in most patients is given as a single dose.
Parenteral Administration: Administer to patients (IV or IM) with GI absorption problem or who cannot take oral. The usual initial dose is 0.5 to 1 mg given over 1 to 2 minutes. If insufficient response, a second or third dose may be given at 2 to 3 hour intervals up to a maximum of 10 mg a day.
HOW SUPPLIED: *Tablets,* 0.5 mg (light green), 1 mg (yellow) and 2 mg (peach), bottles of 100 and 500; Prescription Paks of 30; Tel-E-Dose® cartons of 100. Imprint on tablets: 0.5 mg—ROCHE BUMEX 0.5; 1 mg—ROCHE BUMEX 1; 2 mg— ROCHE BUMEX 2.
Ampuls, 2 ml, 0.25 mg/ml, boxes of ten.
Vials, 2 ml, 4 ml and 10 ml, 0.25 mg/ml, boxes of ten.

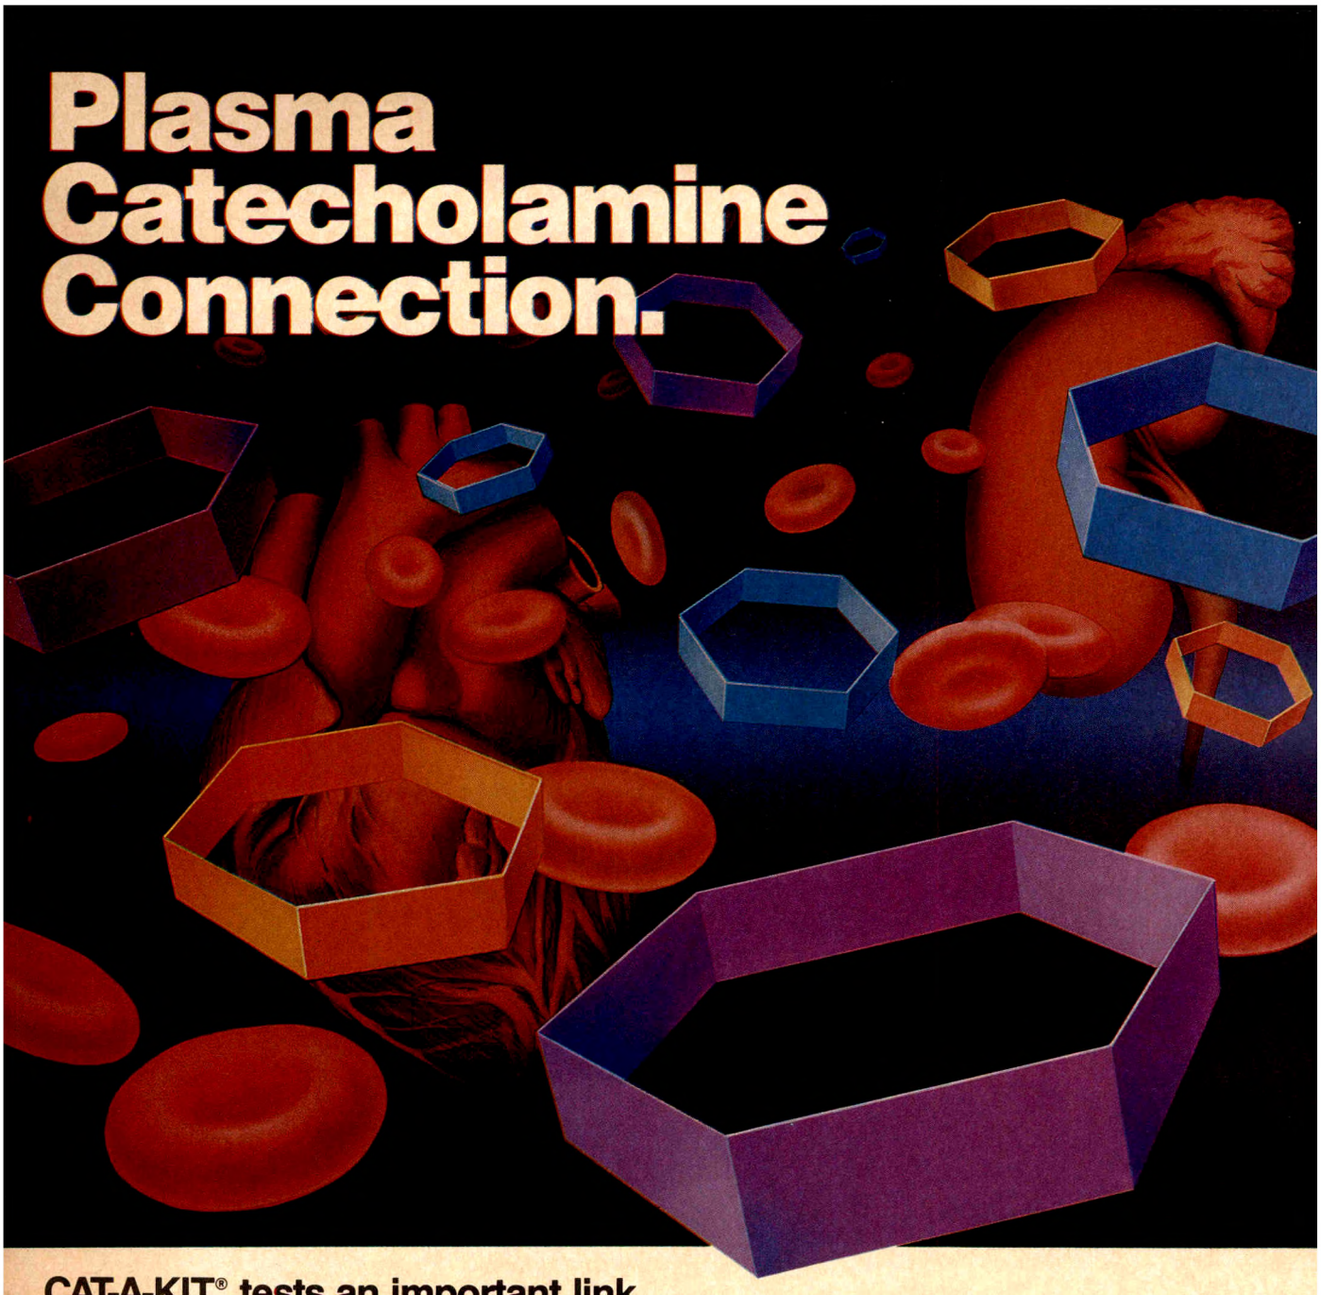
Plasma Catecholamine Connection.



CAT-A-KIT® tests an important link in cardiovascular abnormalities.

Recent research shows that measurement of plasma catecholamines may provide useful information about essential hypertension and congestive heart failure. Now Amersham offers you one of the most effective, reasonably priced ways to measure catecholamine levels in your patients.

CAT-A-KIT Radioenzymatic Catecholamine Assay Kit provides accurate measurement of fractionated or total plasma catecholamine levels, even when values are low and samples are as small as 10μl. Results are sensitive to 5pg for norepinephrine, 3pg for epinephrine and 20pg for dopamine per 50μl sample. Perform 10-15 fractionated assays in duplicate in a day or less, and 20 total cats in duplicate in half a day.

Don't miss the catecholamine connection. Write or call us now toll free for more information.

Epidemiology of Left Ventricular Hypertrophy

Part III
Morphology and Biochemical Changes

Part IV
Pathophysiology of Left Ventricular Hypertrophy

Part V
Clinical Aspects

Part VI
Antihypertensive Therapy and The Heart

Part VII
Special Considerations

ISBN 0-914316-45-1

"Like the kidney and the brain, the heart plays a three-fold role in essential hypertension: first, it is directly involved in the pathogenesis of arterial hypertension. ... Second, the heart suffers as a target organ of long-standing hypertension.... Third, cardiac function and structure are directly and indirectly affected by a variety of antihypertensive agents.

[This] book is intended to provide a synoptic view of present knowledge in this rapidly expanding area. [It] is written for physicians, cardiologists, or investigators who would like to deepen their understanding of cardiac involvement in hypertension, and of progression as well as regression of left ventricular hypertrophy, and the heart's structural and functional response to various blood pressure lowering agents."

— from the Editor's Preface

The Heart and Hypertension features contributions from 88 internationally recognized experts. *The Heart and Hypertension:* 482 pages—including a subject index—in 45 chapters.

No two are exactly alike.

Because body chemistry differs from person to person, we often need a choice of drugs to treat the same illness.

You've heard it said that no two snowflakes are exactly alike. The variety is endless. Much the same is true of the human body.

Take the case of two patients suffering from hypertension. Both under the care of the same physician, who prescribes the same medication for each. One patient responds to the medication while the other reports unpleasant side-effects. Thanks to the diversity of drugs available to treat this illness, the doctor is able to prescribe another medicine that works without the side effects.

To maintain the high standards of quality care, and because some drugs work better than others on different people, it is essential to have this diversity.

America's research-based pharmaceutical companies are committed to providing a wide range of drugs of the highest quality to serve the public. Why? Because the public is made up of different people requiring different treatment—even when they suffer from the same illness.

Pharmaceutical Manufacturers Association

IF A NEW MEDICINE CAN HELP, WE'RE WORKING ON IT.

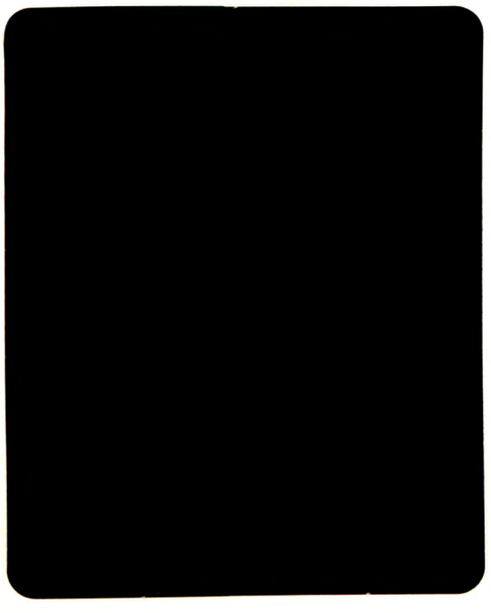
A142

There's a logical choice for mild-to-moderate pain relief in patients on MI/TIA aspirin therapy.
It's not more aspirin.

Analgesic doses of aspirin can result in therapeutic noncompliance.

GI side effects can increase when MI/TIA patients on low-dose aspirin use more aspirin for pain relief.

You know how important it is for your MI/TIA patients to adhere to a prescribed regimen of daily low-dose aspirin. Recent long-term studies on aspirin therapy for prevention of stroke or MI indicate that one regular-strength aspirin per day provides comparable antiplatelet effects to approximately four aspirin tablets per day but with reduced risk of GI side effects.[1-4]



But what might happen when your MI/TIA patient uses additional aspirin for pain relief when he or she has a headache or a cold or flu? Prophylactic therapy for MI/TIA may be compromised by the increased risk of GI side effects when your patient takes additional aspirin for other reasons.

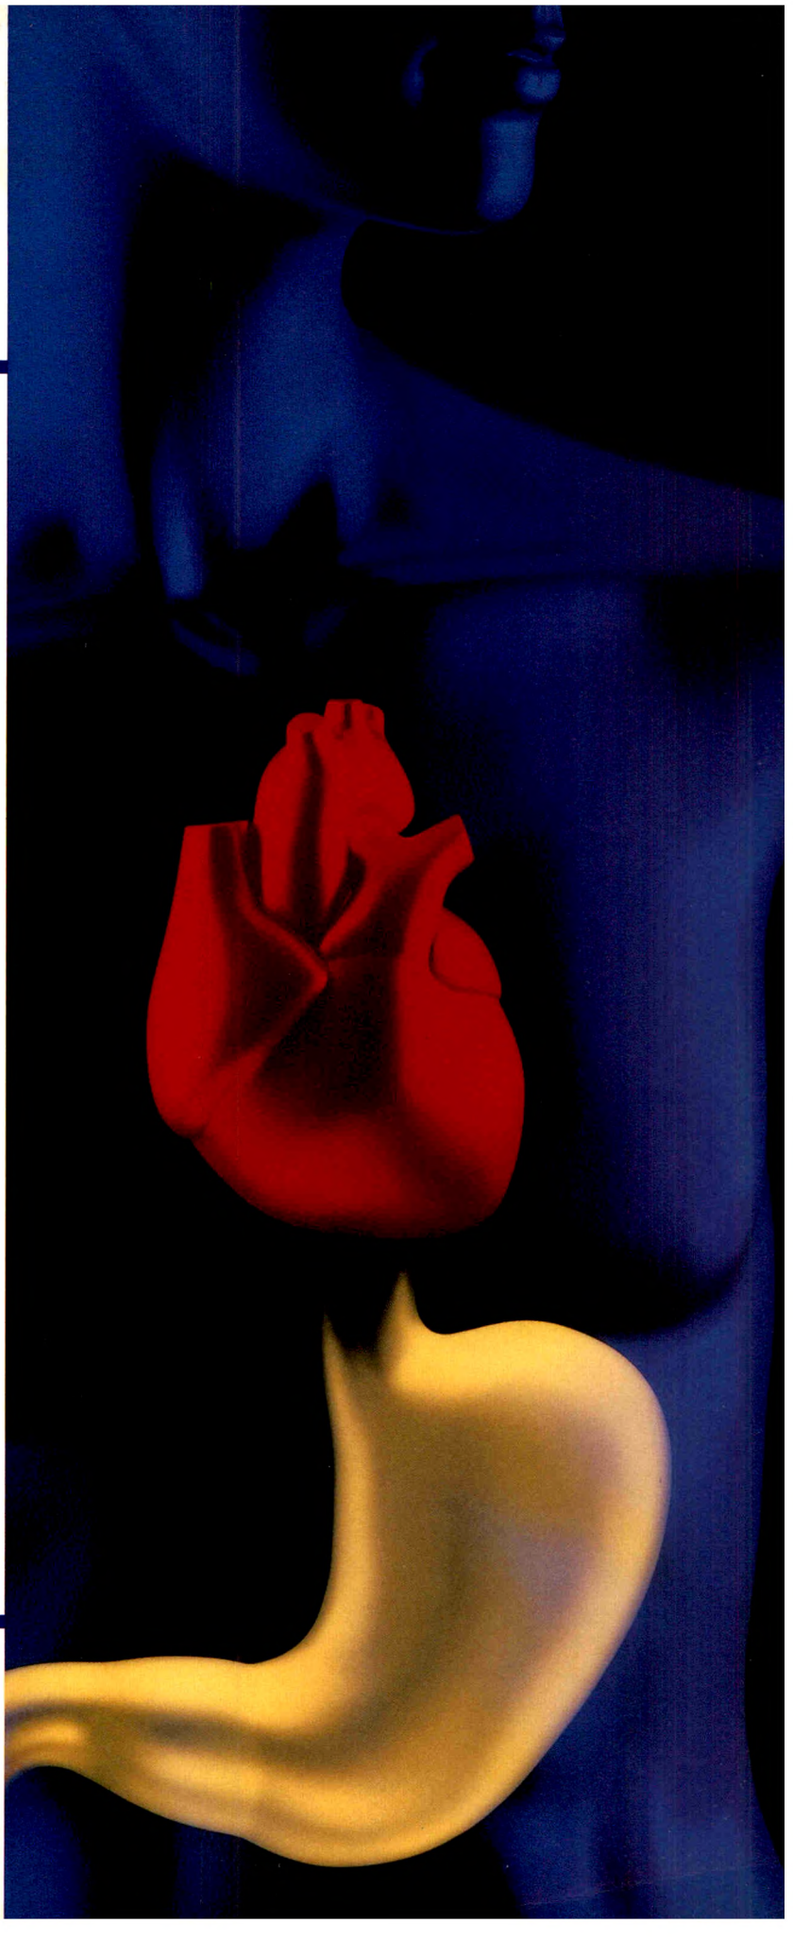
Studies have shown that even routine doses of aspirin can cause GI side effects. Aspirin-associated dyspepsia has been estimated to occur in 5% to 25% of all aspirin users. And endoscopic studies in healthy volunteers demonstrate that analgesic doses of aspirin can result in GI erosions, ulcerations, and submucosal hemorrhage.[5-7]

Extra-Strength TYLENOL® acetaminophen: The right choice for mild-to-moderate pain relief.

For patients on low-dose aspirin therapy, Extra-Strength TYLENOL® is the ideal analgesic for mild-to-moderate pai

EXTRA-STRENGTH
TYLENOL®
500 mg acetaminophen

First choice for mild-to-moderate pain relie in patients on low-dose aspirin therapy



Effective pain relief...

Clinical studies have demonstrated the superior efficacy of Extra-Strength TYLENOL® (1000 mg) for mild-to-moderate pain when compared to regular-strength aspirin (650 mg), and equal efficacy, mg for mg, to 1000 mg aspirin.[8,9] What's more, in a recent major headache study, Extra-Strength TYLENOL® was shown equal in efficacy to OTC ibuprofen (200 mg and 400 mg).[10]

...with little risk of GI irritation...

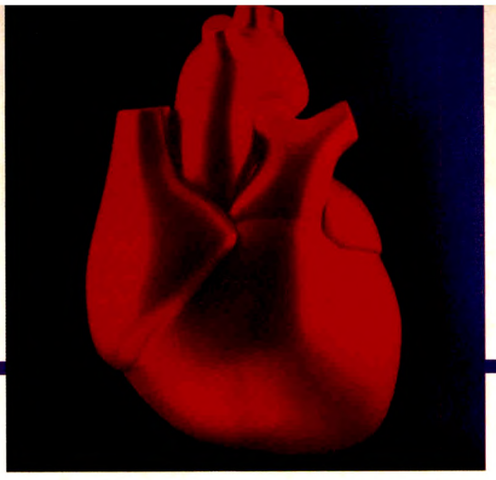
Although to a lesser degree than aspirin, even OTC ibuprofen can cause erosions, ulcerations, and submucosal hemorrhage.

With Extra-Strength TYLENOL®, there is little likelihood of this type of GI irritation.[11,12] By minimizing the risk of GI irritation, your patient's compliance is less likely to be jeopardized.

...that won't interfere with the antiplatelet effects of low-dose aspirin therapy.

Another important consideration for MI/TIA patients: Extra-Strength TYLENOL® won't influence the desired antiplatelet effects of low-dose aspirin, so antiplatelet therapy won't be affected.[12,13]

Reduce the risk of compromised therapy due to simple analgesia. When you recommend low-dose aspirin for MI/TIA patients, you may wish to advise them against taking additional aspirin for simple pain relief. Specify the logical choice: Extra-Strength TYLENOL®.



Why risk compromising therapy for the sake of simple analgesia?

Keep low-dose aspirin at low doses for MI/TIA therapy

For mild-to-moderate pain relief:

EXTRA-STRENGTH TYLENOL®

500 mg acetaminophen

- No OTC analgesic is more effective for mild-to-moderate pain
- Little risk of GI irritation
- Does not interfere with antiplatelet effects

First choice for mild-to-moderate pain relief in patients on low-dose aspirin therapy

An Echocardiographic Study of the Association of Ventricular Septal Defect and Right Ventricular Muscle Bundles with a Fixed Subaortic Abnormality

MICHAEL VOGEL, MD, JEFFREY F. SMALLHORN, BS, MB, ROBERT M. FREEDOM, MD, JOHN COLES, MD, WILLIAM G. WILLIAMS, MD, and GEORGE A. TRUSLER, MD

Since 1983, 36 patients with the combination of right ventricular muscle bundles and a perimembranous ventricular septal defect have been studied in our institution to address the incidence of an associated subaortic abnormality. Of that total 32 (88%) had echocardiographic evidence of such an abnormality (29 had a typical subaortic ridge protruding from the crest of the interventricular septum and the remaining 3 had an echodense area in the same location). Surgical confirmation of the presence or absence of a subaortic abnormality was available in 26. There was correlation between the surgical and echocardiographic findings in all patients. A resting Doppler gradient of ≥10 mm Hg was present in only 10. During the study period, 6 patients had Doppler evidence of progression of their gradient. The incidence of subaortic abnormalities in right ventricular muscle bundles and ventricular septal defects appears to be far greater than previously suspected. The exact significance of this finding in the absence of a pressure gradient is still unclear.

(Am J Cardiol 1988;61:857–860)

The combination of ventricular septal defect (VSD), anomalous right ventricular (RV) muscle bundles and a fixed subaortic abnormality has previously been described.[1–3] What is less clear is the incidence of a subaortic abnormality in the setting of RV muscle bundles and a VSD. This stems from the fact that previous studies have been based on angiographic evaluation, which is known to underestimate the presence of a subaortic abnormality in the setting of a VSD.[4] Cross-sectional echocardiography, on the other hand, provides a detailed assessment of the subaortic region, independently of the presence or absence of a VSD.[4–6] This study addresses the frequency of a subaortic abnormality in patients with VSD and RV muscle bundles as assessed by cross-sectional echocardiography.

From the Departments of Pediatrics and Surgery, Division of Cardiology and Cardiovascular Surgery, Faculty of Medicine, University of Toronto, and the Departments of Pediatrics and Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada. Dr. Vogel's work was supported by grant Vo390/01 from the Deutsche Forschungsgemeinschaft, Bonn, West Germany. Manuscript received July 8, 1987; revised manuscript received and accepted December 10, 1987.

Address for reprints: J.F. Smallhorn, MD, Division of Cardiology, Hospital for Sick Children, 555 University Avenue, Toronto M5G 1X8, Canada.

Methods

Only patients with the combination of a perimembranous VSD and anomalous RV muscle bundles were included. Although patients with typical anatomy of tetralogy of Fallot[7] may occasionally have an associated subaortic abnormality (the incidence at our institution being 0.7%), we arbitrarily chose to exclude them from this study.

Definitions: The diagnosis of either anomalous RV muscle bundles or a subaortic abnormality does not depend on a recorded pressure gradient across the right or left ventricular overflow tracts, respectively. For this reason, the term obstruction or stenosis has not been employed, but rather the term subaortic abnormality. We are aware that there is considerable morphological overlap between the various abnormalities encountered in the left ventricular outflow tract.[8]

Echocardiographic evidence of a subaortic abnormality was defined either as a typical subaortic ridge seen in the parasternal long- and short-axis views,

TABLE I Age and Pressure Gradient Across the Left Ventricular Outflow Tract in 6 Patients with Increase Doppler Gradient

Pt	Age (mo)		Pressure Gradient (mm Hg)	
	First Study	Second Study	First Study	Second Study
1	4	24	10	20
2	82	94	0	10
3	15	26	0	20
4	36	47	0	16
5	2	36	0	16
6	10	19	0	10

originating from the crest of the ventricular septum and protruding at right angles to the endocardial surface, with or without extension to the anterior mitral valve leaflet (Figure 1), or as an abnormal echodense area on the crest of the ventricular septum, seen in both the parasternal long- and short-axis views.

Owing to potential problems of differentiating specular reflections from a minor subaortic abnormality, we chose to examine the interobserver variant. Each of the 2 observers, independently and without prior knowledge of the diagnosis, reviewed 10 echocardiographic studies of patients with VSD and RV muscle bundles who had surgical confirmation of a subaortic abnormality, and also 10 studies from patients with an isolated VSD who also had undergone surgical repair.

In addition, there is considerable heterogeneity among the muscular structures resulting in the so-called double-chambered right ventricle.[9,10] The anomalous RV muscle bundles producing obstruction in the right ventricle may be considered abnormally positioned and hypertrophied septoparietal trabeculations.[10]

Anomalous RV muscle bundles assessed echocardiographically were defined as echodense structures protruding at right angles to the infundibular septum and RV free wall.[11] As a result, the right ventricle was divided into an upper chamber communicating with the pulmonary artery and a lower chamber connecting with the VSD and the inlet portion of the right ventricle.[10]

Echocardiographic technique: The echocardiographic examinations were performed using commercially available equipment. Imaging was carried out with either a 3.5-, 5- or 7.5-MHz transducer, depending on the size of the patient. The studies were recorded on either a 3/4- or 1/2-inch video display system with slow motion or single-frame analysis capability. Restless patients were sedated with chloral hydrate for the echocardiographic examination.

All studies were performed in a standard fashion by either 1 of 3 echocardiographic technicians. The left and right ventricular outflow tracts were evaluated in the standard long-axis views. In the standard parasternal short-axis view, the subaortic area was visualized just beneath the right aortic cusp in a scan from apex to base. In this view, the relation between the subaortic abnormality and the anomalous RV muscle bundles could be determined.

The subaortic region also was assessed from the subcostal long-axis view of the left ventricular outflow tract. From this view the transducer was then rotated clockwise and the right ventricular outflow imaged in its long axis for a demonstration of the right ventricular muscle bundles.[11]

Doppler interrogation of the left ventricular outflow tract was performed from the suprasternal and the apical 5-chamber view. Doppler scanning of the RV outflow tract was performed in the subcostal long-axis view. This position is superior to the parasternal short-axis view as the Doppler beam can be aligned parallel to the direction of blood flow.

Although the modified Bernoulli equation ($p = 4\ v^2$) was used to calculate gradients across the left and right ventricular outflow tract,[12] we were aware of its limitations when evaluating mild obstruction. As a result, a gradient of $\geq$10 mm Hg was considered to be abnormal if there was associated evidence of disturbed flow by Doppler. Serial Doppler evaluation of the left ventricular outflow tract has thus far been performed in 19 patients.

To determine whether the association of VSD and RV muscle bundles with a subaortic abnormality was due to more than just chance, the incidence of each abnormality alone was determined from our cardiac data center for the same time period. These incidences were then compared with the 2 lesions combined.

Patient population: Between January 1983 and May 1987, 36 consecutive patients with an echocardiographic diagnosis of perimembranous VSD and RV muscle bundles were identified. These patients were not preselected, being routine cases referred to the echocardiographic laboratory for evaluation. All patients had concordant atrioventricular and ventriculoarterial connections. The mean age of the group was 2.4 $\pm$ 2.5 years (1 week to 11 years). The male to female ratio was 3:1.

Results

Incidence of an associated subaortic abnormality: During the study period 11,300 patients were evaluated in the cardiology department. Of those, 36 were found to have a VSD and RV muscle bundles and 91 a diagnosis of fibromuscular subaortic stenosis (the diagnosis used in our current coding system). Therefore, the highest possible incidence of the association between these lesions by chance would be 8.5%, which in reality is far less than the observed value of 86% ($p < 0.001$).

Of the total group, 32 (88%) had either a typical subaortic shelf (29 of 32) or an abnormal echodense area (3 of 32) on the crest of the ventricular septum. A subaortic abnormality has been resected in 22 of the 26 patients, who have thus far undergone surgical repair of their lesion. Of these 22 patients, 20 had a typical shelf whereas the other 2 had an echodense area on the crest of the septum. In the remaining 4 patients, 3 had no evidence of an associated subaortic abnormality and 1 had a small ridge of fibrous tissue that the

surgeons could not resect through the VSD (this was one of our earlier cases and at that time it was elected not to open the aortic root).

The youngest patient identified with a subaortic abnormality in the setting of VSD and RV muscle bundles was a premature baby (35-week gestation) studied at 1 week of age.

Each of the 2 independent observers correctly identified those 10 patients with an abnormal subaortic area in association with a VSD and RV muscle bundles from the 10 patients with a VSD alone and a normal left ventricular outflow tract. Among the 10 patients presented for interobserver variability, 3 had an abnormal echodense area on the crest of the ventricular septum.

Although the subaortic abnormality was observed in every patient, the parasternal short-axis view appeared to be the best position for identifying it. From the parasternal long-axis view the abnormality could be seen in all but 3, whereas the subcostal long-axis view failed to identify it in 8 patients. Interestingly, the subaortic abnormality and the RV muscle bundles appeared to lie in the same plane when imaged in the precordial short-axis view.

Doppler evaluation: The combination of a gradient across the left ventricular outflow tract of ≥10 mm Hg and Doppler evidence of turbulent flow was observed in 10 patients at their last echocardiographic examination. The gradients ranged from 10 to 20, with a mean of 15 ± 4 mm Hg. Of those 19 who had undergone serial Doppler interrogation of the left ventricular outflow tract, progression of the pressure gradient was documented in 6 (29%). These data are summarized in Table I. The heart rate at the first study was 127 ± 15 and 105 ± 10 beats/min at the second ($p < 0.01$).

The VSD, located in the perimembranous region in all patients, was restrictive by Doppler criteria in 10, with spontaneous closure throughout the study period observed in 1 patient. There appeared to be a degree of septal malalignment between the infundibular and trabecular septum in all patients, with the infundibular septum being displaced slightly anteriorly (Figure 1).

Morphologic description of right ventrciular muscle bundles: At surgery, the right atrium was opened and the right ventricular cavity inspected through the tricuspid valve. In all cases, an obstructive hypertrophied septoparietal muscle bar was found. The tricuspid valve had attachments to this hypertrophied band in 5 patients and an abnormally placed papillary muscle of the tricuspid valve contributed to the obstruction in 1.

Discussion

Incidence of a subaortic abnormality: It would appear from our data that the incidence of a subaortic abnormality is far greater than previously reported.[1,3] This is most likely related to previous difficulties in identifying a subaortic abnormality by angiocardiography in the setting of a VSD, particularly when there is no pressure gradient across the left ventricular outflow tract.[4]

Our data would suggest that at the time of diagnosis the majority of patients do not have evidence of hemodynamic obstruction. This raises the issue of the significance of the subaortic abnormality. Certainly, if there is a resting gradient, it would seem advisable to resect the subaortic abnormality at the time of VSD closure and RV muscle bundle resection. In the absence of a resting gradient, if the abnormality is not removed, there is a potential for progression.[13-15] As the frequency and rate of progression are still unclear,[15,16] it would seem prudent to remove the abnormality because this could potentially avoid reoperation at a later stage.

Identification of a subaortic abnormality: From our data it would appear that observer variability did not play a part in the echocardiographic diagnosis of a

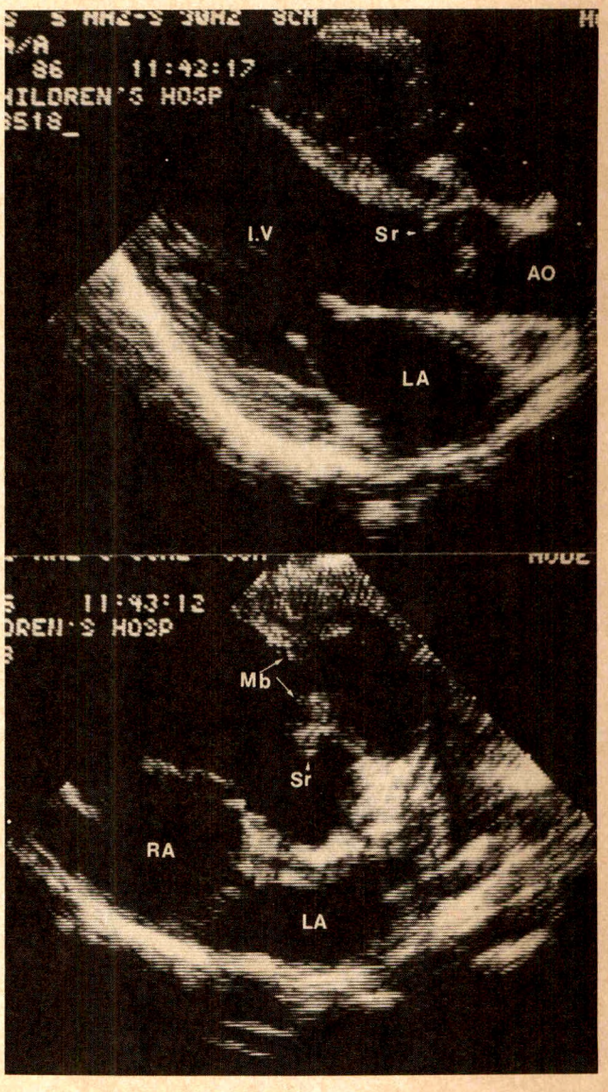

FIGURE 1. Typical subaortic ridge (Sr) protruding at right angles to the endocardial surface. The parasternal short-axis view shows both the RV muscle bundle and the subaortic ridge. AO = aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricular.

subaortic abnormality. This in part may be related to reliance on 2 imaging planes in most patients. Although those patients with a tyical subaortic shelf are straightforward from the diagnostic standpoint, we are aware that patients with an echodense area on the crest of the ventricular septum may be difficult to differentiate from specular reflections or the so-called T artifact.[17] In such a situation, careful serial assessment may shed light on the issue. Thus far, however, even these patients (who have been put forward for surgery) have had abnormal subaortic tissue resected.

Relation between right ventricular muscle bundles and a subaortic abnormality: The other interesting aspect of this study is the close relation between the anamalous RV muscle bundles and the subaortic abnormality. Whereas it might be tempting to speculate that these 2 lesions are predicated on the same myocardial abnormality, we have no histologic data to support this.

Although evidence would suggest that the muscle bundles are congenital[10] and the subaortic abnormality acquired,[15] the patient who was 1 week of age and premature at the time of diagnosis might lend some support to the argument that this is possibly a congenital lesion.[18] Certainly, the positive aspect of this relation lies in the ease of the diagnosis by cross-sectional echocardiography.

Finally, the VSD was similar to that described by previous investigators, with associated malalignment between the trabecular and infundibular septum.[19] It has been postulated that this septal malalignment may play a role in the pathogenesis of subaortic stenosis.[19] Of note is that, despite this anterior malalignment of the infundibular septum, these patients are clearly different from those with tetralogy of Fallot.

In conclusion, there appears to be a higher than previously suspected incidence of subaortic abnormalities in perimembranous VSD and RV muscle bundles. The exact significance of this, in the absence of a measurable pressure gradient, is still unclear, although data would suggest progression in some cases. For this reason, our current policy is to resect this abnormality at the time of surgical correction of the associated lesions.

TELL YOUR PATIENTS THEIR CHOLESTEROL NUMBER... BEFORE THEY ASK.

Reducing high blood cholesterol reduces the risk of heart disease. That's why we're telling Americans—through a national public service advertising campaign—to know their cholesterol number. Your patients may soon be asking you for their number and what it means.

And when they do, we can help. The National Cholesterol Education Program, administered by the National Heart, Lung, and Blood Institute, has developed adult treatment guidelines to help you identify high-risk patients and use the appropriate diet and/or drug therapy for those with elevated cholesterol levels.

Help your patients reduce their risk of heart disease. For a free copy of the *Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults,* complete the form below.

Transderm-Nitro® nitroglycerin
Transdermal Therapeutic System

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

INDICATIONS AND USAGE
This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.
In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.
Transdermal nitroglycerin systems should be removed before attempting defibrillation or cardioversion because of the potential for altered electrical conductivity which may enhance the possibility of arcing, a phenomenon associated with the use of defibrillators.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.
Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea and vomiting. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued. In some patients, dermatitis may occur.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 mg/24 hr system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area.
Transderm-Nitro system should not be applied to the distal parts of the extremities.
The usual dosage is one Transderm-Nitro 5 mg/24 hr system. Some patients, however, may require the Transderm-Nitro 10 mg/24 hr system. If a single Transderm-Nitro 5 mg/24 hr system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 mg/24 hr systems or one Transderm-Nitro 10 mg/24 hr system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 mg/24 hr system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone. The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.
Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

Cardiorespiratory Exercise Testing After Venous Switch Operation in Children with Complete Transposition of the Great Arteries

TONY REYBROUCK, DSc, MONIQUE DUMOULIN, MD,
and LUCAS G. VAN DER HAUWAERT, MD

In 14 children who underwent a venous switch operation for complete transposition of the great arteries, exercise testing was performed 3 to 15 years (mean 8) after the operation. Exercise performance capacity was assessed by the determination of the ventilatory threshold during exercise and by the oxygen uptake ($\dot{V}O_2$) reached at a heart rate of 170 beats/min ($\dot{V}O_2$,170). The ventilatory threshold was defined as the highest oxygen uptake ($\dot{V}O_2$) at which the pulmonary ventilation ($\dot{V}_E$) stops to increase linearly when related to $\dot{V}O_2$. During exercise above this threshold a disproportionate increase in $\dot{V}_E$ relative to $\dot{V}O_2$ is observed. The mean ventilatory threshold was significantly lower ($p < 0.01$) than the normal mean value and averaged 72 ± 15%, 67 ± 15% and 70 ± 13% of the predicted normal value for children of comparable age, weight and height, respectively. The mean value for $\dot{V}O_2$,170 also was significantly lower ($p < 0.05$) than the normal mean value for children of comparable age, weight and height, and averaged 81 ± 20%, 81 ± 18% and 80 ± 18%, respectively. Compared with normal control subjects of the same sex and age, the ventilatory threshold was surpassed sooner ($p < 0.001$) and reached after 2 ± 1 min instead of the 4 ± 1 min required by the controls. In nearly half of the patients, a lower than normal (i.e. below the 95% confidence limit) heart rate response to exercise was observed. Theoretically, this could be interpreted as indicating a normal or high physical performance capacity. However, the ventilatory threshold was subnormal in all but 1 of these patients. The blunted heart rate response observed in many patients after a venous switch operation suggests sinoatrial dysfunction secondary to extensive intraatrial operation.

(Am J Cardiol 1988;61:861–865)

After a venous switch operation, most patients with transposition of the great arteries (TGA) function normally and are clinically well. However, because the right ventricle has to cope with systemic pressures and right ventricular dysfunction has been frequently documented,[1–5] it may be questioned whether these patients have the same exercise capacity as their healthy peers. In patients operated for TGA, only limited information is available on maximal exercise performance assessed by maximal endurance time on a treadmill,[3,6–8] maximal workload on a bicycle ergometer[2,4] or maximal oxygen uptake.[7] To our knowledge, no data are available on gas exchange during submaximal exercise. The purpose of our study was to measure respiratory gas exchange during graded submaximal exercise and thus determine the ventilatory threshold, defined as the highest oxygen uptake ($\dot{V}O_2$) at which pulmonary ventilation ($\dot{V}_E$) stops to increase linearly with increasing $\dot{V}O_2$.[9,10] Above this exercise intensity a disproportionate increase in $\dot{V}_E$ relative to $\dot{V}O_2$ is observed. Because heart rate response during exercise still is widely used in the assessment of cardiorespiratory performance capacity, it also was evaluated in our study.

years (mean 8 ± 3 standard deviation) after a venous switch operation. Children <4 years and patients with overt sinoatrial node dysfunction, hemodynamically important associated lesions, gross cardiomegaly or mental retardation were excluded. The pertinent clinical data are listed in Table I.

The age at correction varied from 3 to 51 months (mean 22 ± 13). The Mustard operation was performed in 11 patients and the Senning procedure in 3. All patients were asymptomatic at the time of investigation. None was taking medication. The interval between operation and exercise testing varied from 3 to 15 years (mean 8 ± 3). In 4 patients, exercise testing was repeated 5 months to 2.4 years after the initial assessment. The overall result of surgery in this selected group was considered to be "excellent." Age, at the time of the exercise test, varied from 4 to 19 years (mean 9 ± 4), body weight ranged from 15 to 73 kg (mean 30 ± 16) and body height from 95 to 173 cm (mean 131 ± 23). When the data for height and weight were expressed as percentiles,[11] 1 out of 14 patients was below the third percentile for weight and 3 of 14 were below it for height.

Testing procedures: The methods used have already been reported in detail.[12–14] Briefly, graded exercise testing was performed on a treadmill. The speed of the treadmill was set at 4.8 km/hr and 5.6 km/hr for children below and above 6 years of age, respectively.[15] The inclination was increased stepwise by 2% every minute until a heart rate of 170 beats/min was reached. The electrocardiogram from a biopolar lead was continuously monitored.

Oxygen uptake ($\dot{V}O_2$) and carbon dioxide output ($\dot{V}CO_2$) were measured by the Douglas bag method. Exercise performance was assessed by determination of the ventilatory threshold, expressed in ml O_2/min/kg and in units of time (min). The ventilatory threshold was determined as the exercise intensity at which a continuous increase was found for the ventilatory equivalent for O_2 ($\dot{V}_E/\dot{V}O_2$) without a concomitant increase in the ventilatory equivalent for CO_2 ($\dot{V}_E/\dot{V}CO_2$).[12,16] Furthermore, the exercise intensity or $\dot{V}O_2$ reached at a heart rate of 170 beats/min ($\dot{V}O_2$,170) was determined and heart rate response assessed during submaximal exercise at various inclinations of the treadmill. Heart rate, expressed as a percentage of the mean normal value, was considered to be subnormal when it fell below the 95% confidence limit.[17] The values for ventilatory threshold and $\dot{V}O_2$,170 in these patients were compared with the values obtained in 234 age-matched healthy children.[12]

Differences between mean values were calculated by analysis of variance. For correlation analysis, the Pearson correlation method was used. The dispersion of the data is given by the standard deviation of the mean and for normal children also by the 95% confidence limits.

Results

Exercise performance: The ventilatory threshold could be determined in 12 of 14 patients. Individual

Pred = predicted; $\dot{V}O_2$,170 = oxygen uptake at a heart rate of 170 beats/min; VT = ventilatory threshold.

results are listed in Table II and Figure 1A and B. In 11 of these patients, the ventilatory threshold was below the 95% confidence limit obtained in normal children of comparable age. The mean value for the ventilatory threshold was significantly lower ($p < 0.01$) than the normal value, averaging 72 ± 15%, 67 ± 15% and 70 ± 13% of the normal mean value obtained in children of the same sex and of comparable age, weight or height, respectively. In 11 patients the ventilatory threshold was attained sooner than in normal controls and in 3 patients it was already surpassed at the start of the exercise test. When expressed in units of time, the ventilatory threshold was reached after 2.2 ± 1.2 minutes in the patients and after 4.0 ± 1.1 in normal children of the same sex and comparable age. The difference was statistically significant ($p < 0.01$).

In the 4 patients in whom the exercise test was repeated, the ventilatory threshold remained subnormal at the second assessment (Figure 1A and B). When expressed as a percentage of the age-predicted normal value, the ventilatory threshold averaged 72 ± 13% at the first evaluation and 85 ± 10% at the second evaluation.

The $\dot{V}O_2$ reached at a heart rate of 170 beats/min ($\dot{V}O_2$,170) was subnormal and averaged 81 ± 20%, 81 ± 18% and 80 ± 18% of the normal mean value obtained in children of the same sex and of comparable age, weight and height, respectively. The difference between normal subjects and patients was statistically significant ($p < 0.05$).

Heart rate response during graded exercise: Heart rate response could be studied throughout several exercise levels in 13 of the 14 patients (Figure 2). When expressed as a percentage of the age-predicted normal value, a subnormal value (below the 95% confidence limit for at least 2 exercise levels) was observed in 5 of these patients. In 4 of them, a subnormal value for ventilatory threshold was found. Of the remaining 8 patients, 4 had a normal heart rate response (between the 95% confidence limits) and 4 a heart rate response above the 95% confidence limit. In these 8 patients the ventilatory threshold was subnormal. Thus, no relation was found between ventilatory threshold and heart rate response. During exercise and during the immediate recovery period, premature atrial beats were recorded in 4 patients. In another patient, both premature atrial and ventricular beats and couplets were observed during and immediately after exercise.

Exercise performance and clinical data: No relation was found in this small series of patients between the age at surgery and the ventilatory threshold expressed as a percent of the predicted normal value for children of the same age ($r = 0.28$), weight ($r = 0.18$) and height ($r = 0.14$). Neither was there a significant relation between the exercise performance capacity (% of normal) and the time lapse between surgery and the exercise test ($r = 0.07$ for age, $r = -0.13$ for weight and $r = -0.08$ for height-predicted normal value).

Discussion

Despite the absence of clinical symptoms and the fact that all patients were normally attending school and took part in games, most showed a subnormal exercise tolerance when assessed by the ventilatory threshold method. Poor exercise tolerance has previously been reported in a considerable number of patients who underwent a Mustard or Senning operation for TGA.[4,6,8,18,19] The comparison of these studies is difficult because different methods for evaluating exercise performance were used: $\dot{V}O_2$max,[18] maximal endurance time on the treadmill[6,8,19] or maximal workload on the bicycle ergometer.[2] Also, different criteria for normality were applied, that is, maximal treadmill time <8 minutes,[18] $\dot{V}O_2$max <40 ml/min/kg[18] and 1 standard deviation below the mean normal value for maximal endurance time on the treadmill.[6,8,19]

Our observation that a larger fraction of patients had subnormal values for exercise performance than

noted in previous studies may be explained by the sensitivity of the method we elected to use. In previous investigations on cardiorespiratory endurance capacity in children with congenital heart disease and left-to-right shunt[13] and in children operated on for tetralogy of Fallot[14] it has been shown that the ventilatory threshold method is more sensitive to detect subnormal exercise capacity than other indexes of cardiorespiratory performance capacity such as $\dot{V}O_2$,170, $\dot{V}O_2$max[20] or the maximal endurance time on a treadmill.[21] A considerable advantage of the ventilatory threshold measurement is its independence of the child's motivation to perform a maximal effort as required in the Bruce treadmill protocol. Furthermore, when repeated within a time interval of 1 to 3 years after the initial testing, we found the measurements to be reproducible (Figure 1A and B). This confirms the results of Lipkin et al,[22] who found reproducible results in a group of adults with impaired ventricular function who underwent at least 3 exercise tests over 2 to 14 days. Although the ventilatory (anaerobic) threshold was originally defined as the exercise intensity or $\dot{V}O_2$ at which a concomitant disproportionate increase in $\dot{V}_E$ and lactate occurred relative to $\dot{V}O_2$,[9,23] we have been using this index of exercise performance in a pragmatic way, without implying a causal relationship with the onset of metabolic acidosis during graded exercise.

Subnormal exercise performance in patients after venous switch operations for TGA has generally been attributed to dysfunction of the right (systemic) ventricle,[1-5] as demonstrated by a depressed right ventricular ejection fraction,[24-26] failure to increase the right ventricular ejection fraction or stroke volume during exercise[2-5] or an increased right ventricular end-diastolic volume.[1,24,25] It has been suggested that the intrinsic geometry and fiber array of the right ventricle make it less suitable to function as a systemic pump.[25,27] Our findings, which indicate a reduced exercise performance and a lowered ventilatory threshold in the majority of patients, are in accordance with these hemodynamic studies.

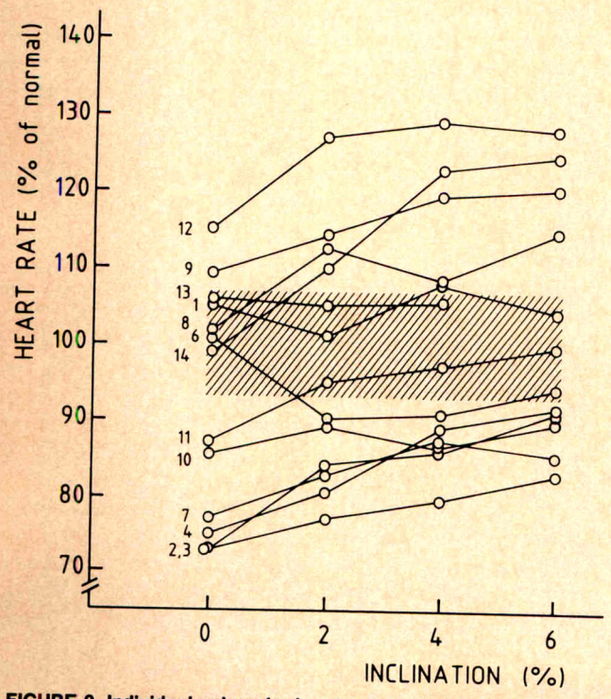

FIGURE 2. Individual values for heart rate response during graded treadmill exercise. The 95% confidence limits of the normal value are shown by the shaded area. The numbers refer to the patient numbers listed in Table I.

Another contributing factor to the reduction of exercise performance is the impaired chronotropic reserve. In patients operated for TGA, heart rate response to maximal exercise has been shown to be significantly reduced.[5-7,18,19] Therefore, when these patients undergo a given exercise, their heart rates should be considered to represent a higher percentage of the maximal exercise capacity than is the case in normal subjects. This is confirmed by the fact that TGA-operated patients experience an exercise at a heart rate of 170 beats/min as being close to their maximal capacity, whereas normal children will perceive it as only moderately heavy. In the present study, based on submaximal exercise, a lower than normal heart rate response was found in nearly half of the patients. Theoretically, a low or normal heart rate response during exercise—as observed in endurance-trained individuals—should be associated with a high or normal value for ventilatory threshold or maximal oxygen uptake. However, in our patients there was no relation between heart rate response and ventilatory threshold, which illustrates the fact that the latter, a parameter of aerobic function, is independent of heart rate response. This is also confirmed by the lower mean value for ventilatory threshold (72 ± 15%) expressed as a percentage of the age-predicted normal value, compared to the mean value for $\dot{V}O_2$,170 (81 ± 20%). In previous studies, a blunted heart rate response during submaximal exercise has been attributed to sinoatrial node dysfunction after intraatrial operation.[6,28]

At variance with other studies[6,18,28] in which multifocal ventricular premature beats, sinus node dysfunction and atrioventricular block were recorded during exercise in a large proportion of patients, no serious arrhythmia was observed in our study. The probable reason was our exclusion of patients with overt sinoatrial node dysfunction or other types of arrhythmia on the rest electrocardiogram.

Influence of Stenosis Severity on Coronary Collateral Development and Importance of Collaterals in Maintaining Left Ventricular Function During Acute Coronary Occlusion

STEPHEN E. EPSTEIN, MD

Previous angiographic and histologic studies have demonstrated that human coronary artery collaterals enlarge and mature in response to chronic coronary occlusive disease.[1,2] It also has been shown experimentally and in human subjects that these anatomic changes are associated with substantial enhancement of collateral vessel capacity to deliver blood to the region perfused by the occluded coronary artery[2-9] and that radiographic assessment of the degree of collateral development correlates with the functional capacity of these vessels.[3,4,8,9] Moreover, in the presence of chronic coronary occlusion, coronary collaterals not only enlarge, but also acquire a muscle layer[2,10,11] and become more responsive to the vasodilator effects of nitroglycerin.[12-14]

Rentrop and colleagues[15] have now extended these findings in a series of extremely important observations. First, they demonstrated what has been intuited by clinicians for many years. Namely, that when the site of coronary occlusion is in the right coronary artery or in the mid or distal left anterior descending coronary artery, the occlusion is less likely to precipitate marked left ventricular dysfunction than it would if it occurred in the proximal left anterior descending coronary artery. Second, they found that, for any given location of acute coronary occlusion, the degree of left ventricular function deterioration depends on the presence or absence of collaterals: the more extensive the collaterals, the less deterioration in left ventricular function. Third, they established an inverse quantitative relation between stenosis severity and collateral function.

From the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted December 28, 1987.

The data elucidating the quantitative relation between stenosis severity and extent of collateral development are especially intriguing and of potentially great clinical importance. In the series of patients studied by Rentrop et al, collaterals could not be visualized in patients with a coronary stenosis producing <70% narrowing. Once this threshold stenosis was reached, the magnitude of collateral development—assessed both angiographically and functionally—became greater as stenosis severity increased beyond 70%. The clinical relevance of these anatomic and functional results was substantiated by the course of patients who developed total coronary occlusion as a complication of elective angioplasty. The most severe hemodynamic compromise, including shock and ultimately death, occurred in those patients with proximal left anterior descending coronary stenoses that produced <70% narrowing before angioplasty.

These observations have interesting clinical implications, aside from those relating to coronary angioplasty. They suggest that profound left ventricular dysfunction would more likely develop after an acute spontaneous occlusion of a left anterior descending coronary artery with an underlying lesion causing <70% diameter stenosis, than after an occlusion of a more severely stenotic vessel. Thus, when an acute occlusive event occurs, the patient identified as having "only" a single 50% stenosis involving the proximal left anterior descending coronary artery might, in fact, be at higher risk of developing a hemodynamically severe acute infarction, or of dying, than the individual with a 90% stenosis. This concept undermines, at least in part, our traditional risk stratification approach to coronary artery disease patients, i.e., the common assumption that a patient with a 50% coronary diameter stenosis is at a lower risk than a patient with a narrowing producing 90% diameter narrowing. This is not to say that mild coronary stenoses pose greater net hazards *for an occlusive event occurring* than would

high-grade stenoses. In fact, the risk of an event occurring in a patient with a mild stenosis appears to be considerably less than that of the patient with a stenosis producing a >70% narrowing.[16,17] However, when an acute occlusion does occur in the patient with the mild stenosis, it is likely that the event will precipitate greater hemodynamic and clinical consequences.

These same considerations may relate to the issue of how much time can elapse from the precipitation of acute coronary occlusion before irreversible myocardial damage develops and coronary reperfusion no longer has beneficial effects. On the basis of these considerations, a patient with no ischemic symptoms before the occlusive event most likely will have had an underlying stenosis causing <70% narrowing, and therefore inadequate collaterals. This patient probably will develop myocardial necrosis soon after the precipitation of the acute occlusion, whereas the patient with long-standing angina will more likely than not have a more severe stenosis which, with time, will stimulate collateral growth. Such a patient might benefit from reperfusion long after the acute occlusive event occurred.

The inverse relation between stenosis severity and collateral development probably also partly explains the clinical dilemma as to why sudden death, or an acute infarction causing major destruction of myocardial tissue (often resulting in left ventricular aneurysm formation), occurs so commonly when the acute infarction is the *initial* presenting manifestation of coronary artery disease.[18,19] As above, the lack of any prior symptom suggests a very high likelihood that the underlying stenoses are ≤50%, a finding not uncommonly observed in patients experiencing an acute infarction who undergo early cardiac catheterization and thrombolytic therapy.[20] It would be unlikely for such a patient to have extensive collaterals and, if the acute occlusion were to involve the proximal left anterior descending coronary artery, the patient probably would be at high risk of either dying or of developing a large infarction.

The inverse relation between stenosis severity and collateral development may also explain why the value of exercise screening studies in totally asymptomatic subjects is so problematic. In the Seattle Heart Watch Study,[21] after several thousand asymptomatic middle-aged individuals were screened by exercise stress testing and risk factor analysis, a relatively small percentage of subjects exhibited abnormal test results, while the far larger subgroup had no abnormal findings. As expected, a much greater percentage of patients with abnormal results developed subsequent cardiac events. However, although the patients with normal outcomes experienced a low *percentage* of cardiac events, it was ironic that of the *total number* of events occurring in the entire study population, most derived from the very large "low-risk" subgroup.

Why should sudden deaths occur in the patients with normal stress tests? The results of Rentrop et al, and our more recent understanding of the pathophysiology of acute coronary occlusive syndromes, suggest an answer. It is probable that many middle-aged or older individuals who, despite a normal exercise stress test, have a mild stenosis present in the coronary bed that produces <50% diameter narrowing but does not cause ischemia and consequently, provides no stimulus for collateral development. In addition, coronary atherosclerosis may impair normal endothelial function.[22-24] This may result in the vessel being both more sensitive to stimuli able to cause coronary vasoconstriction, and more likely to stimulate platelet aggregation and fibrin deposition. The atherosclerotic plaque, even though it is not causing a hemodynamically significant stenosis, could also rupture, exposing flowing blood to thrombogenic elements in the vessel wall and thus further facilitate platelet deposition and fibrin formation.[25] Hence, when compared to a perfectly normal vessel, even disease mild enough to produce no clinical evidence of myocardial ischemia probably increases the risk of the eventual precipitation of an occlusive event which, because no collaterals had the opportunity to develop, would then lead to a catastrophic outcome.

These concepts probably apply only to patients with 1-vessel coronary artery disease or patients with multivessel disease with no narrowing >50% in diameter. The reason for this restricted interpretation can be illustrated by the extreme example of the patient with 3-vessel disease and extensive collaterals who has 2 total occlusions and a 90% narrowing of the coronary artery supplying the collaterals. An acute occlusion of this artery would be clinically disastrous, the opposite of what would be expected in the patient with 1-vessel disease and extensive collaterals. The catastrophic outcome, however, would reflect the critical importance of these collaterals. Thus, if their feeder artery were to occlude, collateral blood flow would fall precipitously and result in severe dysfunction of the dependent myocardium with ensuing profound hemodynamic compromise. In the patient with severe narrowing of a single coronary artery, its acute occlusion would not compromise existing coronary collateral flow because it would be the "recipient" rather than "feeder" vessel.

Thus, compelling evidence now indicates that the consequences of an acute coronary occlusion, at least in patients with 1-vessel disease, depend both on the location of the occlusion, which determines the mass of myocardium at risk, and on the severity of the underlying stenosis, which determines the degree of collateralization. Because the latter 2 factors relate *inversely* to each other, there would appear to be an *inverse* relation between stenosis severity and the consequences of an acute coronary occlusive event. These concepts are likely to have important clinical implications relating to risk stratification of patients with coronary artery disease and probably will influence our therapeutic approaches to many such patients.

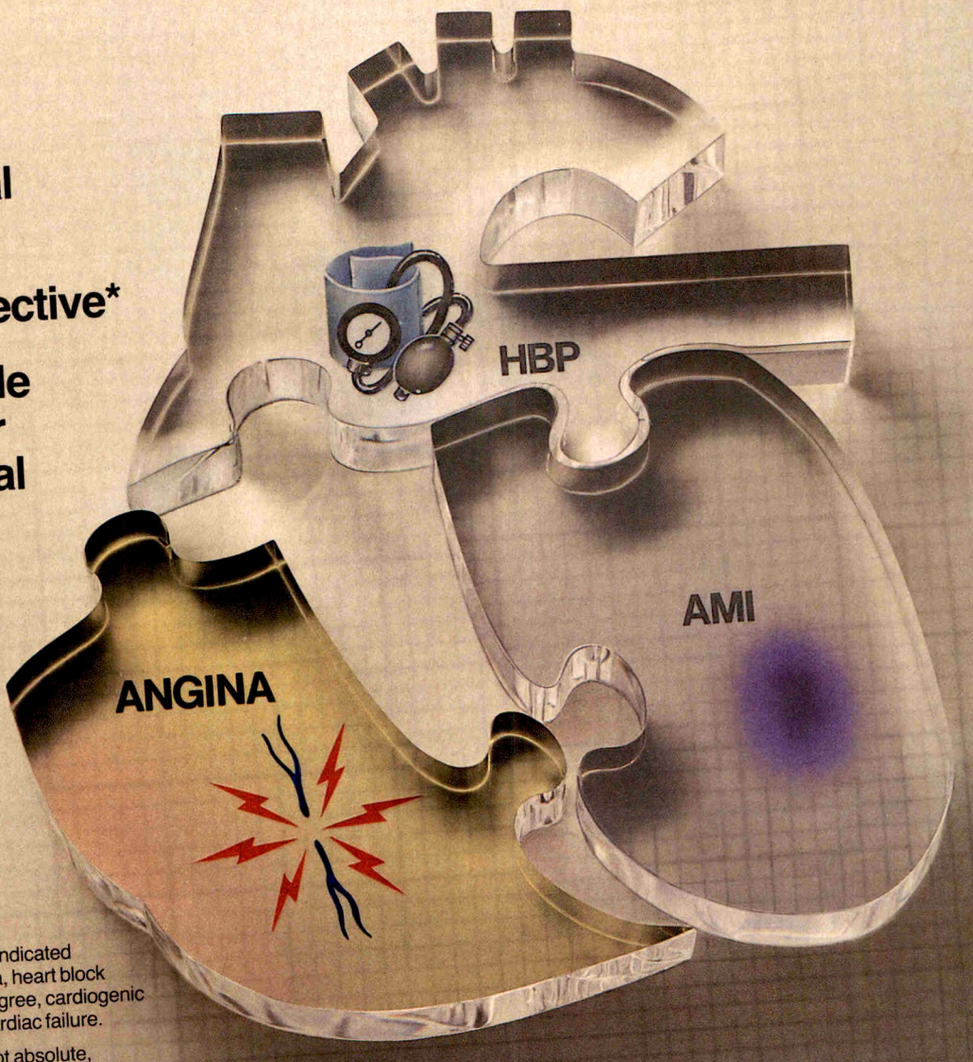
Lopressor® for ANGINA

Completes the picture of cardiovascular protection

- Reduces myocardial ischemia
- Cardioselective*
- Compatible with other antianginal therapies



Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

*Exerts a relative, not absolute, preference for beta-one receptors.

Please consult Brief Summary of Prescribing Information on next page.

Lopressor®
metoprolol tartrate

Changing the Course of Cardiovascular Care

Lopressor®
metoprolol tartrate USP

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

CONTRAINDICATIONS
Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.

Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.

During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.

Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.

If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.

Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.

Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.

All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.

No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.
Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension and Angina
Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS.**)

Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.

Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.

Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.

There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.

Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.

Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.

Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.

Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE
Acute Toxicity
Several cases of overdosage have been reported, some leading to death.

Oral LD_{50}'s (mg/kg): mice, 1158-2460; rats, 3090-4670.
Signs and Symptoms
Potential signs and symptoms associated with overdosage with Lopressor are bradycardia, hypotension, bronchospasm, and cardiac failure.
Treatment
There is no specific antidote.

In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly (see **WARNINGS, Myocardial Infarction**).

On the basis of the pharmacologic actions of Lopressor, the following general measures should be employed:

Elimination of the Drug: Gastric lavage should be performed.

Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.

Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.

Bronchospasm: A beta$_2$-stimulating agent and/or a theophylline derivative should be administered.

Cardiac Failure: A digitalis glycoside and diuretic should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol, or glucagon may be considered.

Left Axis Deviation and Left Anterior Fascicular Block

DAVID H. SPODICK, MD, DSc

Axis is common electrocardiographic shorthand for the mean manifest frontal plane QRS vector, omitting, by convention, not only the P, ST and T axes, but also the horizontal and sagittal plane QRS axes and the spatial QRS vector—the true net axis. Deviation of the frontal plane axis has long been a useful clinical finding,[1] serving even as a screening criterion for cardiac disease.[2] The pioneering contributions of Rosenbaum et al[3] strengthened electrocardiographic axis determination both in concept and in practice, yet cardiologists have perhaps been overenthusiastic in equating marked ($\geq -40°$) and occasionally *any* axis deviation to the left of $-30°$, or even $0°$, with left anterior fascicular ("hemi-") block. Undoubtedly, a marked left axis deviation is nearly always pathologic[2,4] and lesions blocking the anterior radiation of the left bundle system can produce left axis deviation. In addition, because the facile term "left anterior fascicular block" seems weightier than the straightforward and descriptive "left axis deviation," it has tended to displace the latter in electrocardiogram interpretation, even when Rosenbaum's criteria have not been fulfilled.[3] Yet, electrocardiographers should be more critical for at least 2 reasons. First, the left bundle system is not simply bifascicular or even trifascicular, but rather appears to be multifascicular[4–8] (making "fascicular block" more appropriate than "hemiblock"), albeit with strong anterior and posterior fascicular projections. Second, the Einthoven Triangle, a convenient and valuable (but erroneous) approximation from which frontal axes are plotted, necessarily confounds the accuracy of axis determination. Another contributor to some inaccuracy is the use of wave amplitudes rather than areas to calculate axes.

From the Cardiology Division, Saint Vincent Hospital and the Department of Medicine, University of Massachusetts Medical School, Worcester, Massachusetts. Manuscript received October 26, 1987; revised manuscript received and accepted December 10, 1987.

Alternative Lesions Producing Left Axis Deviation

Recent histopathologic studies[9] in even marked left axis deviation support previous anatomic demonstrations[4–8,10] of the complexity of the left ventricular conduction system, as well as the intricate distribution of lesions underlying electrocardiographic findings typical of left anterior fascicular block, some of which are located quite proximally.[9] This has been pointed out in the clinical literature along with the probability that left axis deviation can equally be due to myocardial lesions—traditionally, "periinfarction"[11] and "parietal"[12] blocks—in the anterolateral and basal left ventricles.[13] With some such myocardial lesions (admittedly, ill-defined), conduction would be so slowed by the injury or scar that this zone generates the final vector causing the terminal, and often, the net, left ventricular electromotive forces to point toward it, i.e., well to the left in the frontal plane. This does not negate the likelihood of reentry into the fascicular system distal to its interruption by such lesions.

Whereas the effects of the myocardial lesions noted require further investigation, detailed studies of the conduction system in patients by Nakaya et al[9] demonstrated anew that the left ventricular conduction system is "fan-like and spread broadly over the left septal surface." Most lesions associated with left axis deviation, although peripheral, were quite extensive. In others, the lesions were small and confined to the initial (proximal) left ventricular conduction system. This supported the proposal that in the left ventricle's conduction system the "wires" ultimately reaching the anterolateral fascicle must have their origin proximally in the common "cable," i.e., the bundle,[14] so that their selective interruption far from the left anterior fascicle would equally cause left axis deviation. Moreover, the His bundle proper is distinguished by longitudinal orientation of fibers with collagen partitions,[15] predisposing to such "longitudinal dissociation" when those proximal fibers are selectively injured. The point is that the electrocardiogram in such cases of strictly proximal injury is equivalent to that of peripheral (truly fascicular) lesions. Although left axis deviation is associated with left-sided heart disease,[2,4] it is a gross

correlate and some apparently normal subjects also have left axis deviation.[6] Moreover, the detailed anatomic studies of Nakaya et al[9] indicate that the variability in the location of lesions in patients with disease associated with left axis deviation explains why the prognosis is not uniform in them. Any strictly myocardial lesions responsible for left axis deviation would equally contribute to such nonuniformity. Indeed, in the investigations of Nakaya et al, both myocardial and conduction system lesions were present in several patients.[9]

Axis Determination: A Useful Oversimplification

Axis—mean manifest vector—has for long been a useful concept. It is expressed mathematically and, because it yields a number calculated to anywhere from a single degree to 15°, may lend undue confidence in its significance. Moreover, such mathematical expressions depend upon agreed reference systems, in this case the Einthoven Triangle, and over large numbers of subjects, deviation of axis from "normal" does prove useful.[1,2] However, clinicians and investigators frequently encounter exceptions. A principal reason for this, in terms of frontal plane axis, is the fact that the Einthoven reference frame is very helpful, but confounding owing to its gross oversimplification.

The Einthoven Triangle is equilateral. Unfortunately, nothing in nature is equilateral—or perfectly straight, smooth, round, spherical or orthogonal. We use it because it is infinitely simpler to calculate from than, for example, the Burger Triangle,[15] which is a scalene triangle that more accurately represents the imbalances among limb lead electromotive forces. A scalene triangle is not readily applied in practice, whereas the simple equilateral Einthoven Triangle permits us to measure, and even "eyeball," frontal axes with great precision (though with uncertain accuracy in terms of a "true" axis). Indeed, the predictive ability of the "axis" has been sufficient to permit acquisition of a practical data base of clinical and epidemiologic material. Yet, clinicians and investigators must be constantly aware that this useful approximation necessarily errs in individual patients. Finally, omission of the horizontal, sagittal and spatial axes with even more complicated problems of calculation must also contribute to uncertainty.

A situation analogous to Einthoven Triangle use is the application of the La Place relation to express ventricular wall tension. Conceptually, it has been very useful, despite the fact that it applies strictly to a thin-walled, isotropic sphere and the heart is not thin-walled, not isotropic and not a sphere. Increasing physiologic sophistication has replaced it with more realistic left ventricular models (e.g., the prolate ellipsoid of determinate wall thickness) and parameters such as wall stress. Fortunately, comparably increasing sophistication in understanding the complexities of the conduction system has not yet equally reduced the practical utility of axis oversimplification.

Axis Interpretation

While left fascicular lesions may well be the principal cause of left axis deviation, electrocardiogram interpreters cannot know that this is the cause in a given patient because of the alternative mechanisms for left axis deviation. What the electrocardiographer *actually* sees is left axis deviation. Thus, this is all that need be reported. The knowledgeable clinician and investigator will know that 1 explanation of left axis deviation is left anterior fascicular block, but, irrespective of whether it is the most likely explanation—and I believe this to be the case—it is a presumption. The situation is analogous to Q-wave and non-Q-wave myocardial infarcts. For decades, Q-wave infarcts were termed "transmural," i.e., equated with *anatomically* transmural infarction. This is often demonstrably wrong,[16] and, in fact, was inadequately supported in the original literature equating the two.[16] Although most Q-wave infarcts may well be anatomically transmural, all are certainly not, whereas many non-Q-wave infarcts are. Therefore, clinicians, electrocardiographers and investigators now report exactly what they see: a Q-wave infarct. Similarly, left axis deviation should be reported as such because that is what is seen. The knowledgeable manager of such information will know that transmurality and fascicular block, respectively, are highly likely, but not exclusive explanations.

The Logic of Using Either Two Mechanical Valves or Two Bioprosthetic Valves for Replacement of Both Mitral and Aortic Valves

N.G., a 53-year-old woman, at age 26 had mitral commissurotomy for mitral stenosis and at age 41 the stenotic mitral valve was replaced with a bioprosthesis (Hancock) and the regurgitant aortic valve, with a Bjork-Shiley prosthesis. At age 52, the bioprosthesis in the mitral position had degenerated (severely regurgitant) and it was now replaced with a St. Jude medical prosthesis. Multiple complications occurred postoperatively and she died in February 1988, 40 days after the third cardiac operation. Had the mitral valve been replaced 11 years earlier with a prosthetic rather than a bioprosthetic valve, it is unlikely that a third operation would have been required. After the second operation, she received daily warfarin therapy because of the prosthetic valve in the aortic valve position.

This case is not an infrequent occurrence. Among 54 patients having simultaneous replacement of both mitral and aortic valves and studied later at necropsy by Roberts and Sullivan,[1] 38 (70%) had mechanical prostheses in both valve positions, 4 (8%) had bioprostheses in both valve positions and 12 (22%) had 1 mechanical prosthesis and 1 bioprosthesis. To utilize a bioprosthesis in 1 left-sided valve position and a mechanical prosthesis in the other left-sided valve position is illogical because the advantages of each type of substitute valve are lost by the presence of the other type of substitute valve. The advantage, of course, of a mechanical prosthesis is that it should not wear out; its disadvantage is that all patients having one need long-term anticoagulant (warfarin) therapy. In contrast, the advantage of the bioprosthesis is that patients having one do not need long-term anticoagulant therapy; the disadvantage of the biopostheses is that it wears out if the patient lives long enough, usually 5 to 15 years, and then another operation is required. Thus, the placing of 1 bioprosthetic valve and 1 mechanical valve in the same patient translates into the loss for the patient of each of the advantages of the mechanical and bioprosthetic valves, and at the same time, the gain for the patient of the disadvantages of each of the 2 types of substitute cardiac valves. Either both left-sided valve substitutes should be mechanical prostheses or both should be bioprostheses!

CORRECTION AND CLARIFICATION ON TYPE OF 24-HOUR ELECTROCARDIOGRAPHIC ANALYZERS FOR VENTRICULAR ARRHYTHMIA DESCRIBED IN A RECENT PUBLICATION

Our article published in the December 1987 issue of the *AJC* contains the following error.[1] The CardioData Mark II analyzer was used for analysis of the recordings in that article, whereas the article erroneously reported that the Mark III analyzer was used. The Mark II analyzer preceded the Mark III in time and contained earlier versions of analysis software. This difference may have important implications on the applicability of the findings to today's scanning devices.

Three points are also worth making for purposes of clarification. First, for the interpretation of the data obtained on any device, it may be important to know the dates within which the analyes were made, as software updates may alter the accuracy of the analysis algorithms. The recordings were analyzed on the CardioData device between February 25, 1981, and October 15, 1981. The recordings were analyzed on the Avionics device between August 25, 1981, and August 26, 1982. Subsequent software upgrades may have altered the performance of the devices for quantitation of ventricular premature complexes.

Second, our report demonstrated that both the devices we tested had difficulty quantifying nonsustained ventricular tachycardia. Although, for research purposes, quantitation of nonsustained ventricular tachycardia is important, this quantitation may not be critical for clinical purposes. In fact, the detection of any events of nonsustained ventricular tachycardia before therapy and confirmation of "complete elimination" of these events on therapy may be a reasonable goal for devices used for clinical purposes. There were 6 recordings in our study that contained events of nonsustained ventricular tachycardia. The scanners successfully detected at least some of these events on each recording. Conversely, the final analysis report did not describe nonsustained ventricular tachycardia in any of the recordings that did not have such events detected by hand counting. Thus, these 2 devices appear reliable for the qualitative detection of nonsustained ventricular tachycardia, and therefore should be adequate for clinical purposes.

Finally, we tested the accuracy of the device and technician as a single unit. In all cases, the technician was allowed to interact with the analyzer and edit the data from the scanner. Technician decision errors in the identification of beats may have contibuted to the errors that we detected in the device-technician unit. However, since these devices are designed to function optimally with technician interaction, we felt it was inappropriate to test the equipment without this interaction.

CORRECTION

A fairly gross error was made in the publication of our article entitled "Linking by Collision Initiated in the Absence of Preexisting Reentrant Tachycardia: Electrophysiologic Demonstration and Significance," which appeared in the February 1988 *Journal*, pages 254 to 260.

The error involved transposition of the entire second paragraph from the legend of Figure 3 to the legend of Figure 2. Although all errors are unfortunate, this one in particular "hurts" because Figure 3 is so complex and plays a pivotal role in the concepts we endeavored to advance in our article.

Michael H. Lehmann, MD
Detroit, Michigan
12 February 1988

CORRECTION

It has come to my attention that there is an error in Table II of our article, "Echo Doppler Assessment of Cardiac Output and Its Relation to Growth in Normal Infants," published in the November 1987 *Journal*, pages 1112 to 1116.

The regression equations for cardiac output and stroke volume against weight given in the second line are incorrect. The regression equation for cardiac output should read $1.11 \times W + 0.19$, and the regression equation for stroke volume should read $1.0 \times W + 0.6$.

SURGICAL AND MEDICAL RESULTS OF COMPLETE ATRIOVENTRICULAR CANAL

I was surprised that Clapp et al[1] did not state the number of patients with the Down syndrome in their article. Although it was not the intent of their review to compare patients with Down syndrome and nonsyndromic patients, this important variable should have been included in at least part of their analysis. Complete atrioventricular canal is the most common cardiac defect in this syndrome; of patients with complete atrioventricular canal most have the Down syndrome. The postulated propensity toward pulmonary vascular obstructive disease in Down syndrome and its possible effect on morbidity and mortality should have been addressed. The presence of a chromosomal malformation syndrome in a patient with a congenital cardiac defect is not trivial.

AGING, MYOCARDIAL COMPLIANCE AND VENTRICULAR FILLING SOUNDS

Bryg and colleagues[1] have contributed significantly to the understanding of aging effects on left ventricular diastolic filling in normal subjects, which may be related to the well-known decrease in compliance of the left ventricle with normal aging. This same phenomenon has been seen in the typical low-compliance of abnormal hearts in coronary artery disease, dilated cardiomyopathy and hypertrophic cardiomyopathy[2] (in the absence of mitral regurgitation as also shown by Bryg and associates[3]). These differences agree nicely with the demonstration by Shaver and colleagues[4] of the mechanism of the normal third heart sound and with our studies showing an increased prevalence and audibility of fourth heart sounds with aging in normal subjects. Although it is not a part of their investigation, would the authors have any information on the prevalence of third and fourth heart sounds in their population?

raphy have demonstrated the increasing importance of atrial contribution to ventricular filling with aging. This phenomenon is believed to reflect alterations in left ventricular filling as the chamber becomes less compliant and is represented in the Doppler tracing as an increase in the atrial filling velocity when compared with the early diastolic filling velocities and, on phonocardiography or auscultation, by an increased prominence of the fourth heart sound. The etiology of the third heart sound, however, remains more enigmatic. A careful record of the prevalence of third and fourth heart sounds unfortunately was not recorded in our recently published study. We suspect, however, as Dr. Spodick suggests, that the fourth heart sound would have been heard more frequently in the older subjects and would have correlated inversely with the early diastolic to atrial velocity ratio. We have had the opportunity to recently evaluate 150 elderly individuals (mean age 70) with signs and symptoms suggestive of congestive heart failure. Of note was the fact that two thirds of these patients (group 1) had decreased left ventricular ejection fraction, while one third of them (group 2) had normal left ventricular ejection fractions and implied symptoms of heart failure secondary to abnormal diastolic function. While there was no significant difference in the prevalence of the fourth heart sound in these 2 groups (43 vs 42%), the third heart sound was significantly more prevalent in patients with abnormal systolic function (42 vs 21%, $p < 0.05$). These findings suggest that the genesis of the third heart sound is probably not a simple reflection of left ventricular chamber compliance. Further studies in normal elderly individuals comparing Doppler and phonocardiographic findings would be of great interest.

SIGNIFICANCE OF HIGH CK-MB/CK RATIOS WITH NORMAL CREATINE KINASE IN ACUTE MYOCARDIAL INFARCTION

Yusuf et al[1] reported on the significance of elevated creatine kinase (CK)-MB isoenzyme with normal CK values. They related the occurrence of this phenomenon to the existence of small myocardial infarctions. Since the introduction of CK-MB as a diagnostic parameter in clinical chemistry,[2] a lot of atypical CK isoenzyme patterns and atypical CK forms have been described.[3] As the heart tissue isoenzyme distribution of CK is altered by hypoxia,[4] the diagnostic specificity of CK-MB has recently been rediscussed. As hypoxic tissues preferably synthesize CK-B subunits, relative elevated CK-MB levels associated with normal CK activities have to be interpreted with care in patients with ischemic heart disease.

Spincemaille et al[5] demonstrated false-positive results of CK-MB analysis when ion-exchange techniques were used. Both macro CK-I and subisoenzymes of CK-MM have been shown to interfere with ion-exchange techniques. Further, in coronary artery disease, macro CK-I is a common finding. Up to 13% of patients with angiographically proven coronary artery disease were reported to be positive on macro CK-I.[6]

Physiochemical properties of CK-MB are not so significantly different from those of the other CK forms (M_r 85,000), simultaneous release of both CK-isoenzymes (CK-MM and CK-MB) can be expected. As the biological half-life of CK-MB is even shorter than that of CK-MM, one would expect that infrequent sampling can merely lead to false-negative CK-MB results. Prolonged "CK-MB" activity is most likely due to the presence of macro-CK, which is characterized by a long biological half-life time. The apparently long CK-MB half-life as reported in the article can be explained by the presence of macro-CK.

In the 4 diagnostic groups, as described by Yusuf et al[1], most atypical CK patterns are observed in group 2 (patients with history of angina and acute myocardial infarction). In these 2 conditions, the prevalence of macro CK-I has been reported to be high.

As Yusuf et al demonstrated the difficulties in interpreting CK/CK-MB analysis in patients with established cardiac disease, one should recommend highly specific methods for measuring CK-MB concentrations, such as electrophoresis or immuno-precipitation, which are less sensitive to aberrant CK forms.[7]

SILENT ISCHEMIA: AN UNPROVEN THERAPEUTIC CONCEPT

In the April 1, 1987, issue of *The American Journal of Cardiology*, 5 original articles and 2 editorials appeared relating to the extremely popular subject of silent myocardial ischemia. In their editorial, Pepine and associates[1] point out that silent ischemia as detected by stress testing and ambulatory electrocardiographic monitoring is common. They cite rather limited evidence that silent ischemia has important prognostic implications. They next take the giant step of recommending that silent ischemia must be documented and managed.

It is appropriate to investigate this concept thoroughly, but to recommend that clinicians embark on detecting and treating silent ischemia is premature at best and irresponsible at worst. The financial implication of the numerous ambulatory electrocardiogram stress tests, physician visits, drugs, angioplasties and coronary bypass procedures required to stamp out "the total ischemic burden" is staggering to contemplate. In addition, a great number of patients are likely to suffer real harm from well-intentioned treatment. Unfortunately the situation is somewhat analogous to the aggressive, expensive, unproven, often harmful drug therapy of ventricular premature complexes that has been so common in the past 2 decades.

I hope that practicing physicians will show restraint before they submit their patients to unnecessary, expensive tests and treatments in an effort to keep up with the latest popular concept.

Lewis H. Seager, MD
Woodland Hills, California
12 May 1987

1. Pepine CJ, Imperi GA, Hill JA. *Therapeutic implications of silent myocardial ischemia during daily activity. Am J Cardiol 1987;59:993–995.*

REPLY: We appreciate Dr. Seager's interest in our editorial on the implication of silent ischemia and the opportunity to respond. We stated several times that more data are needed but we are concerned that evidence linking silent ischemia and prognosis is becoming very strong. In the interim, it is our best opinion that certain high risk groups should be identified and antiischemic treatment instituted.

Dr. Seager makes a comparison between therapy of ventricular premature complexes and silent ischemia. We caution readers not to equate these 2 entities as Dr. Seager has done. Transient myocardial ischemia, be it silent or painful, is a serious pathologic process which is always associated with left ventricular dysfunction. Active ischemia, either painful or silent, does not occur in the normal heart and there is no question that myocardial ischemia precedes events like myocardial infarction. The antiischemic therapy that we have available (nitrates, calcium antagonists and β blockers) is safe and effective.

Ventricular premature complexes, in contrast, often occur in the setting of a normal heart or nearly normal ventricular function. They are not clearly linked to more malignant arrhythmias in many settings. Ample experience indicates that in many cases, antiarrhythmic therapy is not safe and proarrhythmic effects are a real problem. Efficiency and safety in patients at highest risk (e.g., poor left ventricular function) is not proven.

Finally, Dr. Seager urges restraint relative to the possibility of extensive costs. We must point out that in any cost assessment, one must consider both sides of the cost/benefit equation. If potential benefits (e.g. saving lives and preventing acute myocardial infarctions in relatively healthy productive middle-aged

men with coronary artery disease) appear to outweigh the anticipated costs of treating asymptomatic ischemia, then one can justify our recommendation until additional data are at hand.

NIFEDIPINE-INDUCED PAROTITIS: A HYPERSENSITIVITY REACTION

Nifedipine has been observed by various indexes to induce adverse effects, such as headache, flushing, dizziness, peripheral edema, weakness and transient hypotension, after oral administration.[1] Other rare pathologic events related to this drug, such as congestive heart failure, myocardial infarction and cerebral ischemia, have been reported.[2] Recently Bosch et al[3] described the first case of nifedipine-related parotitis. We recently studied a patient who developed acute swelling of parotid and salivary glands, after sublingual administration of nifedipine.

A 50-year-old man was admitted for hypertension crisis (220/120 mm Hg of blood arterial pressure) and suspected acute myocardial infarction. The patient was heparynized and treated with buprenorfine, isosorbide, lydocaine and nifedipine (20 mg sublingually every 6 hours). Ten hours later bilateral progressive enlargement of parotid and salivary glands appeared, with painless dry mouth, rhinorrea, fever and skin rash. Laboratory data disclosed virus infection of the parotid gland and nifedipine was interrupted. Three days after steroid therapy all symptoms disappeared and nifedipine was substituted with diltiazem.

Our data suggest a hypersensitivity reaction to nifedipine causing a parotid swelling as it is reported for other drugs.[4,5]

DOPPLER EVALUATION OF DIASTOLIC FLOW IN OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY

We read with interest the article by Bryg et al,[1] comparing Doppler parameters of patients with obstructive hypertrophic cardiomyopathy (HC) to normal subjects. We agree that left ventricular (LV) Doppler filling patterns may be altered in patients with HC, and age should be taken into consideration for valid interpretation of the data.[2,3] However, we disagree with the way the data were analyzed. In our opinion, it is inadequate to compare mean values of normal subjects with a wide age range to the mean values of patients with even wider age range. It would have been more appropriate to compare the data from subgroups with narrow age ranges. Alternatively, plotting the data of patients with HC on scattergrams against age of normal subjects (which the authors have previously done),[3] would have presented the results more convincingly. Furthermore, looking at the authors' data, one can appreciate the significant effect of age on LV diastolic filling in patients with HC. Thus, in many of their patients age had a more significant effect on E/A mitral peak velocity ratio than the presence or absence of mitral regurgitation. Age had even more effect on LV filling than the disease itself. Thus, in 4 young subjects with HC without mitral regurgitation the E/A ratio was high. In patient 11, the E/A was 1.3, while in patients 3, 4 and 12 the ratio was 1.6. Because of the method of analysis of the data the reader might overlook the significance of age on LV filling in patients with HC.

To avoid many of
he serious toxicities
f antiarrhythmics...
Guide your patients
o safety

Guide them to MEXITIL® (MEXILETINE HCl)

The uncompromising efficacy of a first-line agent

MEXITIL is as effective as quinidine, procainamide, disopyramide, and tocainide in controlling ventricular arrhythmias including PVCs, couplets, and V Tach.[1-6]

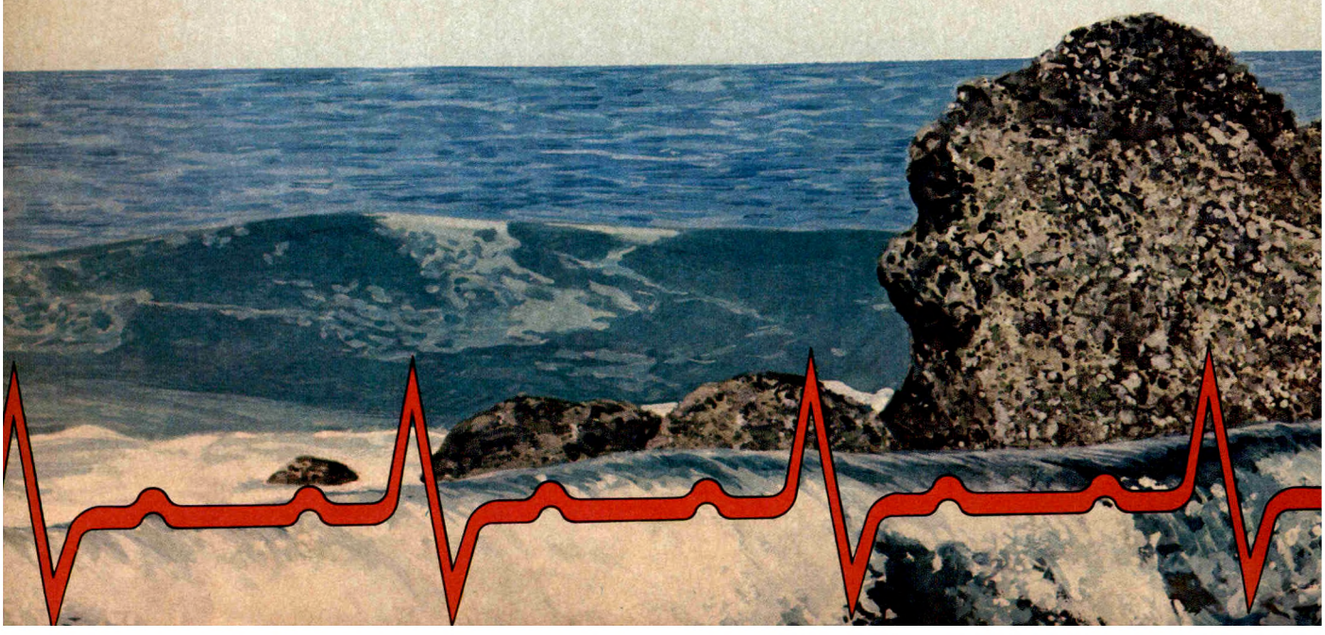
Avoids many late-onset toxicities encountered with other antiarrhythmics

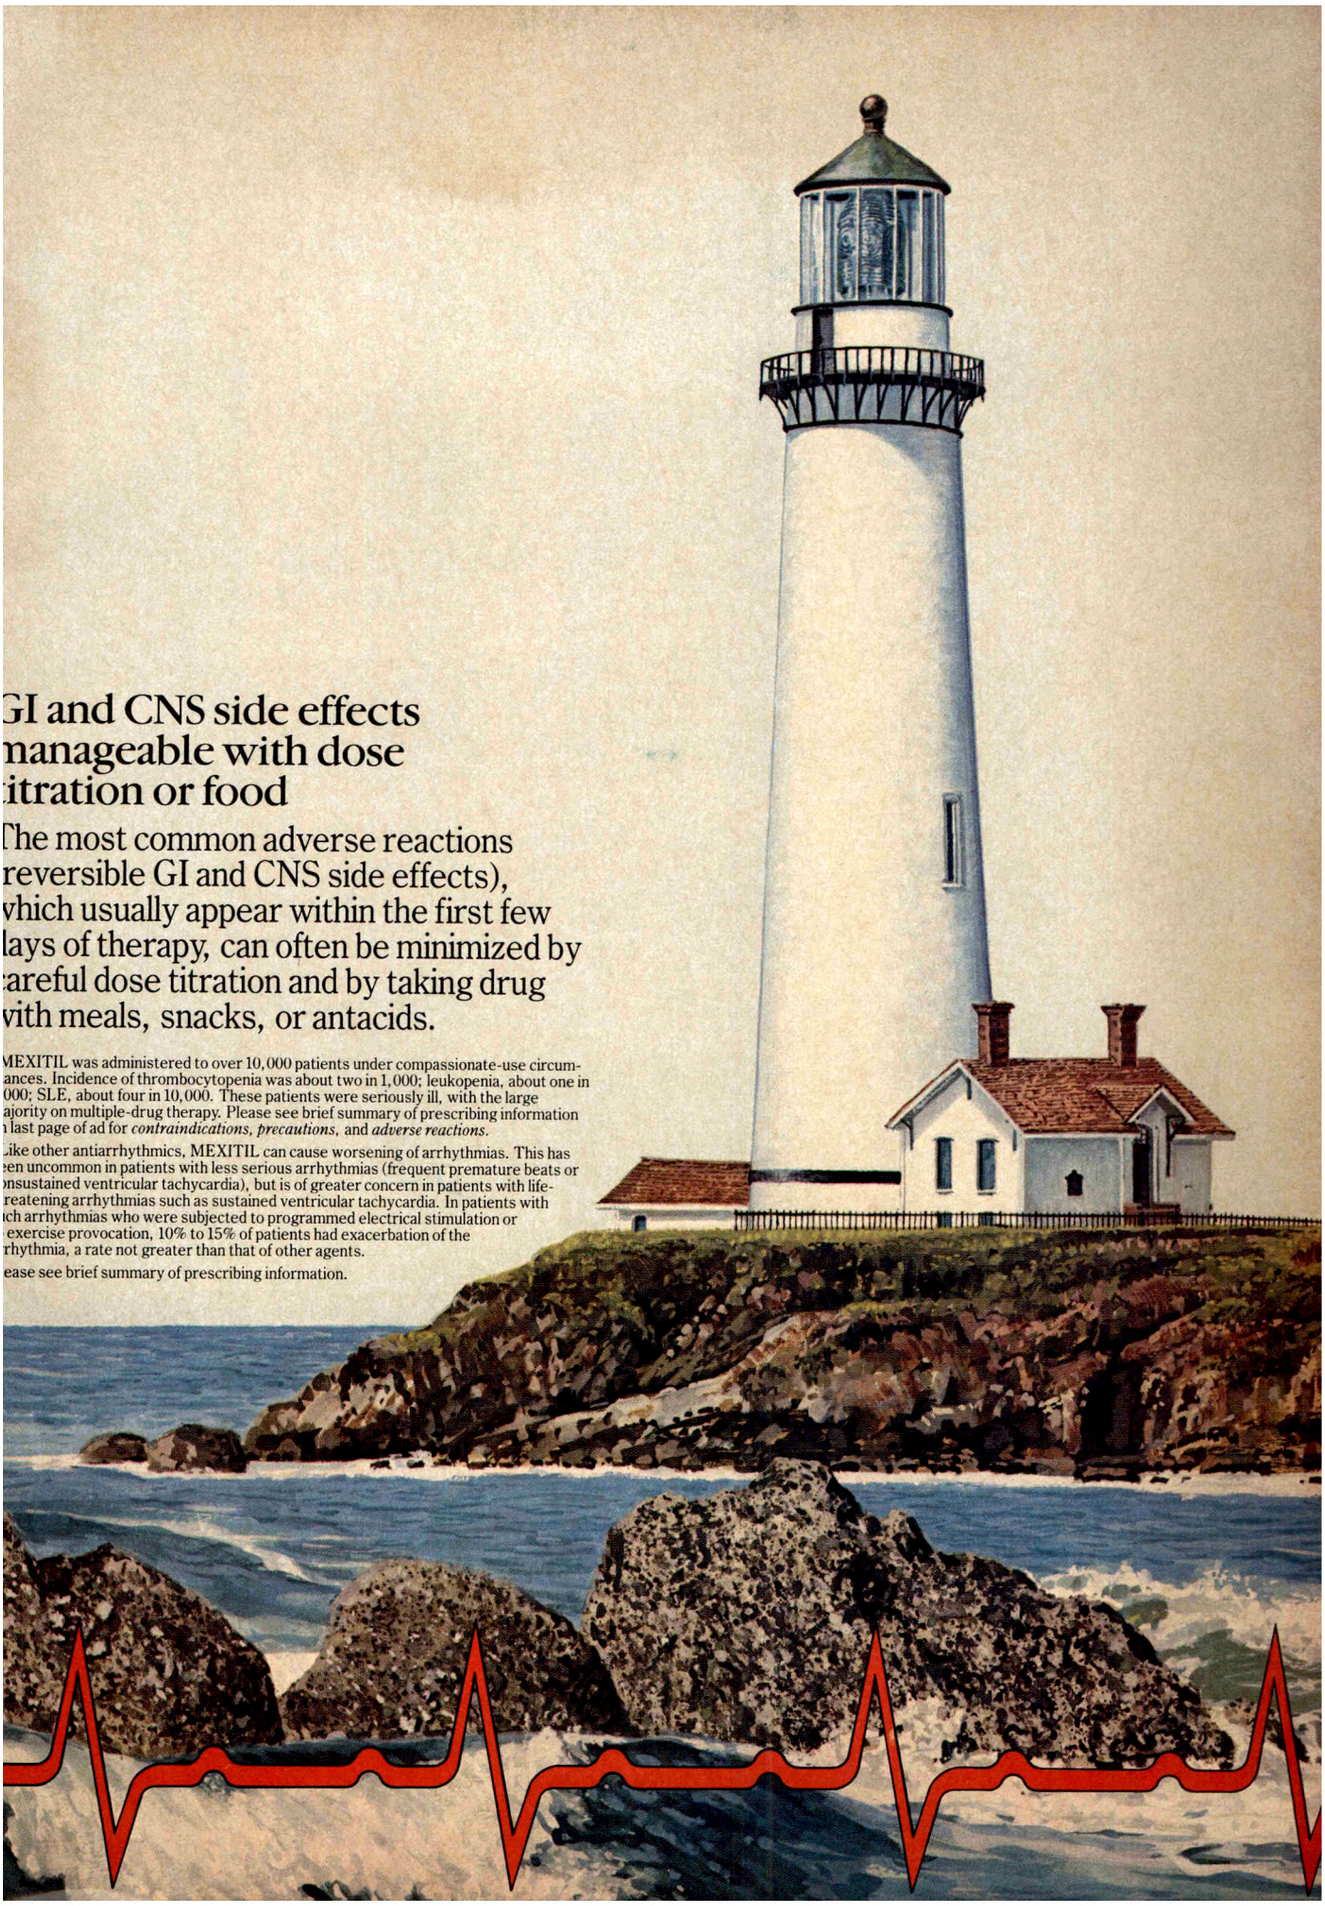
In controlled clinical trials, MEXITIL has not been associated with serious, late-onset toxicities such as hematologic effects, SLE, or pulmonary fibrosis.*

A favorable electrophysiologic and hemodynamic profile

MEXITIL is unlikely to aggravate arrhythmias in the clinical setting.[7-9†] It does not prolong the QT interval and, thus, is less likely than many other antiarrhythmics to produce torsades de pointes.[10,11]

MEXITIL has no significant negative inotropic effect, making it an excellent choice for use in patients with compromised cardiac function.[12-15]





GI and CNS side effects manageable with dose titration or food

The most common adverse reactions (reversible GI and CNS side effects), which usually appear within the first few days of therapy, can often be minimized by careful dose titration and by taking drug with meals, snacks, or antacids.

MEXITIL was administered to over 10,000 patients under compassionate-use circumstances. Incidence of thrombocytopenia was about two in 1,000; leukopenia, about one in 1,000; SLE, about four in 10,000. These patients were seriously ill, with the large majority on multiple-drug therapy. Please see brief summary of prescribing information on last page of ad for *contraindications, precautions,* and *adverse reactions.*

Like other antiarrhythmics, MEXITIL can cause worsening of arrhythmias. This has been uncommon in patients with less serious arrhythmias (frequent premature beats or nonsustained ventricular tachycardia), but is of greater concern in patients with life-threatening arrhythmias such as sustained ventricular tachycardia. In patients with such arrhythmias who were subjected to programmed electrical stimulation or exercise provocation, 10% to 15% of patients had exacerbation of the arrhythmia, a rate not greater than that of other agents.

Please see brief summary of prescribing information.

Mexitil®
(mexiletine hydrochloride)
Oral Antiarrhythmic

Capsules of 150 mg, 200 mg and 250 mg

Brief Summary of Prescribing Information

CONTRAINDICATIONS: Mexitil® (mexiletine hydrochloride) is contraindicated in the presence of cardiogenic shock or pre-existing second- or third-degree AV block (if no pacemaker is present).

PRECAUTIONS: General: If a ventricular pacemaker is operative, patients with second or third degree heart block may be treated with Mexitil® (mexiletine hydrochloride) if continuously monitored. A limited number of patients (45 of 475 in controlled clinical trials) with pre-existing first degree AV block were treated with Mexitil; none of these patients developed second or third degree AV block. Caution should be exercised when it is used in such patients or in patients with pre-existing sinus node dysfunction or intraventricular conduction abnormalities.

Like other antiarrhythmics Mexitil can cause worsening of arrhythmias. This has been uncommon in patients with less serious arrhythmias (frequent premature beats or non-sustained ventricular tachycardia: see ADVERSE REACTIONS), but is of greater concern in patients with life-threatening arrhythmias such as sustained ventricular tachycardia. In patients with such arrhythmias subjected to programmed electrical stimulation or to exercise provocation, 10-15% of patients had exacerbation of the arrhythmia, a rate not greater than that of other agents.

Mexitil should be used with caution in patients with hypotension and severe congestive heart failure.

Since Mexitil is metabolized in the liver, and hepatic impairment has been reported to prolong the elimination half-life of Mexitil, patients with liver disease should be followed carefully while receiving Mexitil. The same caution should be observed in patients with hepatic dysfunction secondary to congestive heart failure.

Concurrent drug therapy or dietary regimens which may markedly alter urinary pH should be avoided during Mexitil therapy. The minor fluctuations in urinary pH associated with normal diet do not affect the excretion of Mexitil.

SGOT Elevation and Liver Injury: In three-month controlled trials, elevations of SGOT greater than three times the upper limit of normal occurred in about 1% of both mexiletine-treated and control patients. Approximately 2% of patients in the mexiletine compassionate use program had elevations of SGOT greater than or equal to three times the upper limit of normal. These elevations frequently occurred in association with identifiable clinical events and therapeutic measures such as congestive heart failure, acute myocardial infarction, blood transfusions and other medications. These elevations were often asymptomatic and transient, usually not associated with elevated bilirubin levels and usually did not require discontinuation of therapy. Marked elevations of SGOT (>1000 U/L) were seen before death in four patients with end-stage cardiac disease (severe congestive heart failure, cardiogenic shock).

In foreign marketing experience rare instances of severe liver injury, including hepatic necrosis, have been reported in association with Mexitil treatment. It is recommended that patients in whom an abnormal liver test has occurred, or who have signs or symptoms suggesting liver dysfunction, be carefully evaluated. If persistent or worsening elevation of hepatic enzymes is detected, consideration should be given to discontinuing therapy.

Blood Dyscrasias: Blood dyscrasias were not seen in the controlled trials. Among 10,867 patients treated with mexiletine in the compassionate use program, marked leukopenia (neutrophils less than 1000/mm^3) or agranulocytosis were seen in 0.06%, and milder depressions of leukocytes were seen in 0.08%, and thrombocytopenia was observed in 0.16%. Many of these patients were seriously ill and receiving concomitant medications with known hematologic adverse effects. Rechallenge with mexiletine in several cases was negative. Marked leukopenia or agranulocytosis did not occur in any patient receiving Mexitil alone; five of the six cases of agranulocytosis were associated with procainamide (sustained release preparations in four) and one with vinblastine. If significant hematologic changes are observed, the patient should be carefully evaluated, and, if warranted, Mexitil should be discontinued. Blood counts usually return to normal within one month of discontinuation. (See ADVERSE REACTIONS.)

Convulsions (seizures) did not occur in Mexitil controlled clinical trials. In the compassionate use program, convulsions were reported in about 2 of 1000 patients. Twenty-eight percent of these patients discontinued therapy. Convulsions were reported in patients with and without a prior history of seizures. Mexiletine should be used with caution in patients with known seizure disorder.

Drug Interactions: In a large compassionate use program Mexitil has been used concurrently with commonly employed antianginal, antihypertensive, and anticoagulant drugs without observed interactions. A variety of antiarrhythmics such as quinidine or propranolol were also added, sometimes with improved control of ventricular ectopy. When phenytoin or other hepatic enzyme inducers such as rifampin and phenobarbital have been taken concurrently with Mexitil, lowered Mexitil plasma levels have been reported. Monitoring of Mexitil plasma levels is recommended during such concurrent use to avoid ineffective therapy.

In a formal study, benzodiazepines were shown not to affect Mexitil plasma concentrations. ECG intervals (PR, QRS and QT) were not affected by concurrent Mexitil and digoxin, diuretics, or propranolol.

Concurrent administration of cimetidine and Mexitil has been reported to increase, decrease, or leave unchanged Mexitil plasma levels; therefore patients should be followed carefully during concurrent therapy.

Mexitil does not alter serum digoxin levels, but magnesium-aluminum hydroxide, when used to treat gastrointestinal symptoms due to Mexitil, has been reported to lower serum digoxin levels.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Studies of carcinogenesis in rats (24 months) and mice (18 months) did not demonstrate any tumorigenic potential. Mexitil was found to be non-mutagenic in the Ames test. Mexitil did not impair fertility in the rat.

Pregnancy/Teratogenic Effects

Pregnancy Category C: Reproduction studies performed with Mexitil in rats, mice and rabbits at doses up to four times the maximum human oral dose (20 mg/kg in a 50 kg patient) revealed no evidence of teratogenicity or impaired fertility but did show an increase in fetal resorption. There are no adequate and well-controlled studies in pregnant women; this drug should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Mexitil appears in human milk in concentrations similar to those observed in plasma. Therefore, if the use of Mexitil is deemed essential, an alternative method of infant feeding should be considered.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Mexitil® (mexiletine hydrochloride) commonly produces reversible gastrointestinal and nervous system adverse reactions but is otherwise well tolerated. Mexitil has been evaluated in 483 patients in one-month and three-month controlled studies and in over 10,000 patients in a large compassionate use program. Dosages in the controlled studies ranged from 600-1200 mg/day; some patients (8%) in the compassionate use program were treated with higher daily doses (1600-3200 mg/day). In the three-month controlled trials comparing Mexitil to quinidine, procainamide and disopyramide, the most frequent adverse reactions were upper gastrointestinal distress (41%), lightheadedness (10.5%), tremor (12.6%) and coordination difficulties (10.2%). Similar frequency and incidence were observed in the one-month placebo-controlled trial. Although these reactions were generally not serious, and were dose-related and reversible with a reduction in dosage, by taking the drug with food or antacid or by therapy discontinuation, they led to therapy discontinuation in 40% of patients in the controlled trials. A tabulation of the adverse events reported in the one-month placebo-controlled trial follows:

Comparative Incidence (%) of Adverse Events among Patients Treated with Mexiletine and Placebo in the 4-Week, Double-Blind Crossover Trial

	Mexiletine N = 53	Placebo N = 49
Cardiovascular

Less than 1%: Syncope, edema, hot flashes, hypertension, short-term memory loss, loss of consciousness, other psychological changes, diaphoresis, urinary hesitancy/retention, malaise, impotence/decreased libido, pharyngitis.

An additional group of over 10,000 patients has been treated in a program allowing administration of Mexitil under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy. Twenty-four percent of the patients continued in the program for one year or longer. Adverse reactions leading to therapy discontinuation occurred in 15% of patients (usually upper gastrointestinal system or nervous system effects). In general, the more common adverse reactions were similar to those in the controlled trials. Less common adverse events possibly related to Mexitil use include:

Cardiovascular System: Syncope and hypotension, each about 6 in 1000; bradycardia, about 4 in 1000; angina/angina-like pain, about 3 in 1000; edema, atrioventricular block/conduction disturbances and hot flashes, each about 2 in 1000; atrial arrhythmias, hypertension and cardiogenic shock, each about 1 in 1000.

Central Nervous System: Short-term memory loss, about 9 in 1000 patients; hallucinations and other psychological changes, each about 3 in 1000; psychosis and convulsions/seizures, each about 2 in 1000; loss of consciousness, about 6 in 10,000.

Digestive: Dysphagia, about 2 in 1000; peptic ulcer, about 8 in 10,000; upper gastrointestinal bleeding, about 7 in 10,000; esophageal ulceration, about 1 in 10,000.

Laboratory: Abnormal liver function tests, about 5 in 1000 patients; positive ANA and thrombocytopenia, each about 2 in 1000; leukopenia (including neutropenia and agranulocytosis), about 1 in 1000; myelofibrosis, about 2 in 10,000 patients.

Other: Diaphoresis, about 6 in 1000; altered taste, about 5 in 1000; salivary changes, hair loss and impotence/decreased libido, each about 4 in 1000; malaise, about 3 in 1000; urinary hesitancy/retention, each about 2 in 1000; hiccups, dry skin, laryngeal and pharyngeal changes and changes in oral mucous membranes, each about 1 in 1000; SLE syndrome, about 4 in 10,000.

Hematology: Blood dyscrasias were not seen in the controlled trials but did occur among the 10,867 patients treated with mexiletine in the compassionate use program: (See PRECAUTIONS). Myelofibrosis was reported in two patients in the compassionate use program; one was receiving long-term thiotepa therapy and the other had pretreatment myeloid abnormalities.

HOW SUPPLIED:
Mexitil® (mexiletine hydrochloride) is supplied in hard gelatin capsules containing 150, 200 or 250 mg of mexiletine hydrochloride in bottles of 100 and individually blister-sealed unit-dose cartons of 100.

Consult package insert before prescribing.

It's been thirty years since the first pacemaker.

Who's counting?

1958 started as the worst year of Arne Larsson's life.

It ended as his best year.

Arne was suffering from hepatitis and myocarditis with total AV block. And he was only 43.

But he took a courageous step. He agreed to be the recipient of the world's first cardiac pacemaker, developed by Siemens-Elema.

Now, thirty years later, Arne is 72. Healthy, happy, and leading an active life. And today, Pacesetter Systems and Siemens-Elema, the cardiac pacing divisions of Siemens, continue this tradition of leadership in innovative pacemaker technology.

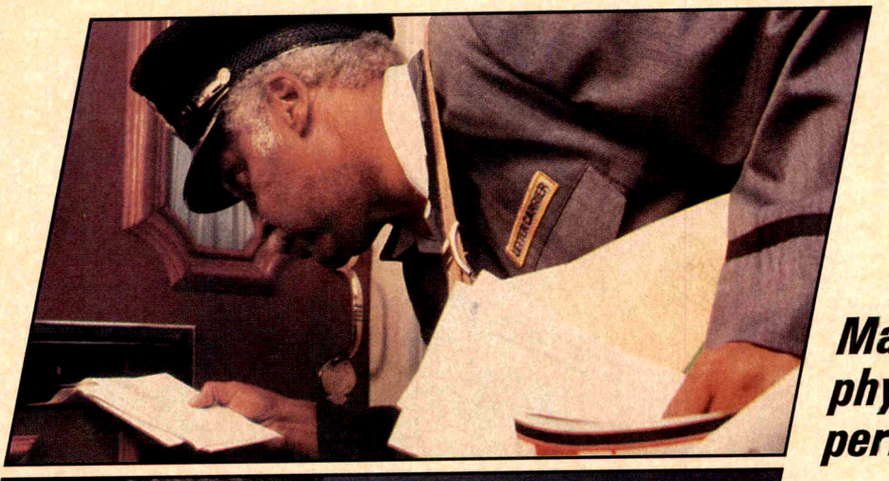
For example, we offered the first pacing system to utilize bidirectional telemetry—two-way communication between an implanted unit and an external programming device.

And we recently introduced the first activity-sensing, rate-responsive pacing system incorporating histograms that can be used to fine-tune the pacemaker's rate response to the patient's activity pattern.

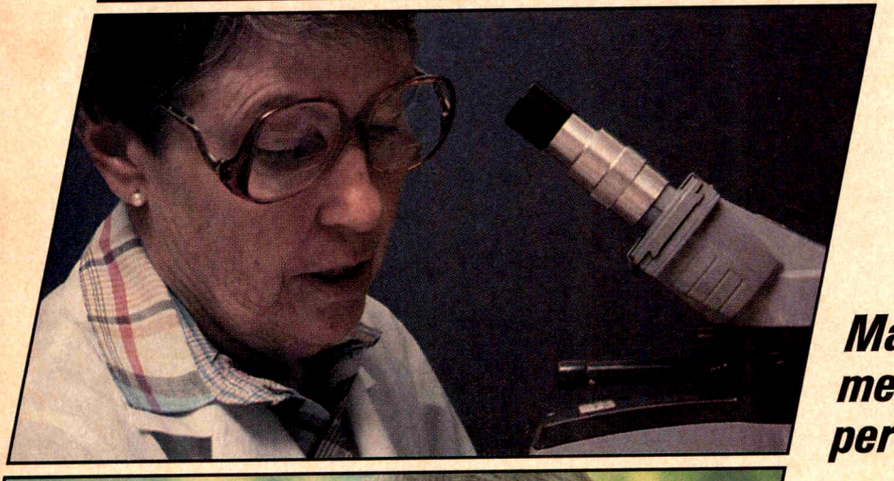
It's been a great thirty years. For us. And for Arne.

Arne Larsson

IN ANTIHYPERTENSIVE THERAPY
PERFORMANCE



Maintains physical performance



Maintains mental performance

Maintains sexual performance

COUNTS...

Maintains physical, mental, and sexual performance

- *Alpha$_1$ blockers maintain normal hemodynamics during rest and exercise*[1]
- *Seldom causes depression, confusion, loss of alertness*[2]
- *Impotence is rare—incidence equal to placebo*[3]

Significantly decreases total cholesterol*[4]

Effective in younger and older patients, blacks as well as whites[1]

Side effects generally were mild and transient. Dizziness and asthenia were most common. Others reported significantly more frequently than with placebo were nasal congestion, peripheral edema, somnolence, nausea, palpitations, and blurred vision. Incidence of syncope (1.0%) was not significantly different from placebo.

** HYTRIN is not indicated for the treatment of hyperlipidemia.*

HYTRIN® 1mg, 2mg, 5mg tablets

(terazosin HCl) **ONCE-A-DAY ONE PRICE**

The first once-a-day alpha$_1$ blocker

ABBOTT 1 Wellcome

advancing cardiovascular care

Please see adjacent page for Brief Summary of prescribing information.

HYTRIN®

(terazosin hydrochloride tablets)

Brief Summary

CLINICAL PHARMACOLOGY: Pharmacodynamics: Clinical studies of terazosin used in once-a-day (majority) and b.i.d regimens with total doses usually in the range of 5-20mg/day, in patients with mild or moderate hypertension. Because terazosin, like all alpha antagonists, can cause large falls in blood pressure after the first dose or first few doses, the initial dose was 1mg in virtually all studies, with subsequent titration to a specified fixed dose or titration to a specified blood pressure end point.

Blood pressure responses were measured at the end of the dosing interval (usually 24 hrs.) and effects were shown to persist throughout the interval, with usual supine responses 5-10mmHg systolic and 3.5-8mmHg diastolic greater than placebo. The responses in the standing position tended to be somewhat larger, although this was not true in all studies. The magnitude of blood pressure responses was similar to prazosin and less than hydrochlorothiazide (in a single study). In measurements 24 hrs. after dosing, heart rate was unchanged.

Limited measurements of peak response (2-3 hrs. after dosing) during chronic terazosin administration indicate that it is more than twice the trough (24 hr.) response, suggesting some attenuation of response at 24 hrs., presumably due to a fall in blood terazosin concentrations at the end of the dose interval. This explanation is not established with certainty and is not consistent with the similarity of blood pressure response to once-a-day and b.i.d. dosing. With the absence of an observed dose-response relationship over a range of 5-20mg, i.e., if blood concentrations fall to the point of providing less than full effect at 24 hrs., a shorter dosing interval or larger dose should lead to increased response. Measure blood pressure (BP) at the end of the dose interval; if response is not satisfactory, patients may be tried on a larger dose or b.i.d. regimen. The latter should be considered if side effects, such as dizziness, palpitations, or orthostatic complaints, are seen within a few hours after dosing.

The greater BP effect associated with peak plasma concentrations (first few hours after dosing) appears somewhat more position-dependent (greater in the erect position) than the effect of terazosin at 24 hrs. In the erect position there is a 6-10 bpm increase in heart rate in the first few hours after dosing. During the first 3 hrs. after dosing 12.5% of patients had a systolic pressure fall of 30mmHg or more from supine to standing, or standing systolic pressure below 90mmHg with a fall of at least 20mmHg, compared to 4% of a placebo group.

INDICATIONS AND USAGE: Indicated for the treatment of hypertension.

CONTRAINDICATIONS: None known.

WARNINGS: Syncope and "First-dose" Effect: Terazosin, like other alpha-adrenergic blocking agents, can cause marked hypotension, especially postural hypotension, and syncope in association with the first dose or first few doses. A similar effect may occur if therapy is interrupted for more than a few doses. Syncope has been reported with other alpha-adrenergic blocking agents in association with rapid dosage increases or introduction of another antihypertensive drug. Syncope may be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by severe supraventricular tachycardia with heart rates of 120-160 bpm.

To decrease the likelihood of syncope or excessive hypotension, always initiate treatment with a 1mg dose at bedtime. The 2mg and 5mg tablets are not indicated as initial therapy. Increase dosage slowly, and add additional antihypertensive agents with caution. Caution patients to avoid situations where injury could result if syncope occurs during initiation of therapy.

In early studies, where increasing single doses up to 7.5mg were given at 3 day intervals, tolerance to the first dose phenomenon did not necessarily develop and the "first dose" effect was observed at all doses. Syncopal episodes occurred in 3 of 14 subjects given doses of 2.5, 5, and 7.5mg, which are higher than the recommended initial dose. Severe orthostatic hypotension (BP 50/0mmHg) was seen in two others and dizziness, tachycardia, and lightheadedness occurred in most subjects. These adverse effects all occurred within 90 min. of dosing.

In multiple dose clinical trials involving nearly 2000 patients, syncope was reported in about 1% of patients, in no case severe or prolonged, and was not necessarily associated with early doses.

If syncope occurs, place patient in recumbent position and treat supportively. There is evidence that the orthostatic effect of terazosin is greater, even in chronic use, shortly after dosing.

PRECAUTIONS: *General: Orthostatic Hypotension:* While syncope is the most severe orthostatic effect of terazosin, other symptoms of lowered BP, such as dizziness, lightheadedness and palpitations, are more common, occurring in 28% of patients in clinical trials. Patients with occupations in which such events represent potential problems should be treated with particular caution.

Information for Patients: Make aware of possibility of syncopal and orthostatic symptoms, especially at initiation of therapy, and to avoid driving or hazardous tasks for 12 hrs. after the first dose, after a dosage increase, and after interruption of therapy when treatment is resumed. Caution to avoid situations where injury could result should syncope occur during initial therapy. Advise to sit or lie down when symptoms of lowered BP occur and to rise carefully from a sitting or lying position. Bothersome dizziness, lightheadedness, or palpitations should be reported to physician.

Tell patients that drowsiness or somnolence can occur, requiring caution in people who must drive or operate heavy machinery.

Laboratory Tests: Small but statistically significant decreases in hematocrit, hemoglobin, WBC, total protein and albumin were observed in clinical trials. The magnitude of decreases did not worsen with time. These findings suggest the possibility of hemodilution.

Drug Interactions: In controlled trials, terazosin was added to diuretics, and several beta-adrenergic blockers; no unexpected interactions were observed. Terazosin has also been used concomitantly without interaction in at least 50 patients on the following: 1) analgesic/anti-inflammatory (acetaminophen, aspirin, codeine, ibuprofen, indomethacin); 2) antibiotics (erythromycin, trimethoprim and sulfamethoxazole); 3) anticholinergic/sympathomimetics (phenylephrine HCl, phenylpropanolamine HCl, pseudoephedrine HCl); 4) antigout (allopurinol); 5) antihistamines (chlorpheniramine); 6) cardiovascular agents (atenolol, hydrochlorothiazide, methyclothiazide, propranolol); 7) corticosteroids; 8) gastrointestinal agents (antacids); 9) hypoglycemics; 10) sedatives and tranquilizers (diazepam).

Carcinogenesis, Mutagenesis, Impairment of Fertility: HYTRIN was devoid of mutagenic potential when evaluated *in vivo* and *in vitro*.

HYTRIN, administered in feed to rats at doses of 8, 40, and 250mg/kg/day for 2 yrs., was associated with a statistically significant increase in benign adrenal medullary tumors of male rats exposed to the 250mg/kg dose. This dose is 695 X max. recommended human dose (20mg/55kg). Female rats were unaffected. HYTRIN was not oncogenic in mice when administered in feed for 2 yrs. at a maximum tolerated dose of 32mg/kg/day.

The absence of mutagenicity in a battery of tests, of tumorigenicity of any cell type in the mouse carcinogenicity assay, of increased total tumor incidence in either species, and of proliferative adrenal lesions in female rats, suggests a male rat species-specific event. Numerous other diverse pharmaceutical and chemical compounds have been associated with these tumors in male rats without supporting evidence for carcinogenicity in man.

Effects on fertility were assessed in a standard fertility/reproductive performance study in which male and female rats were administered oral doses of 8, 30 and 120mg/kg/day. Four of 20 male rats given 30mg/kg and 5 of 19 male rats given 120mg/kg failed to sire a litter. Testicular weights and morphology were unaffected. Vaginal smears at 30 and 120mg/kg/day appeared to contain less sperm than smears from control matings and good correlation was reported between sperm count and subsequent pregnancy.

Oral use for 1 or 2 yrs. elicited a statistically significant increase in testicular atrophy in rats exposed to 40 and 250mg/kg/day, but not in rats exposed to 8mg/kg/day (> 20 X max. recommended human dose). Testicular atrophy was observed in dogs dosed with 300mg/kg/day (> 800 X max. recommended human dose) for 3 months but not after 1 yr. when dosed with 20mg/kg/day. This lesion has also been seen with Minipress®.

Pregnancy: Teratogenic effects: Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women and the safety of terazosin in pregnancy has not been established. HYTRIN is not recommended during pregnancy unless potential benefit justifies potential risk to mother and fetus.

Nonteratogenic effects: In a peri- and post-natal development study in rats, significantly more pups died in the group dosed with 120mg/kg/day (> 300 X max. recommended human dose) than in the control group during the 3-week post partum period.

Nursing Mothers: It is not known whether terazosin is excreted in breast milk; therefore, exercise caution when administering terazosin to a nursing woman.

Pediatric Use: Safety and effectiveness have not been determined.

ADVERSE REACTIONS: The prevalence of adverse reactions has been ascertained from 14 placebo-controlled studies conducted primarily in the U.S. The studies involved once-a-day administration of terazosin as monotherapy or in combination with other antihypertensive agents, at doses ranging from 1 to 40mg. All adverse events reported during these studies were recorded as adverse reactions. Adverse events where the prevalence rate in the terazosin group was at least 5%, where the prevalence rate for the terazosin group was at least 2% and was greater than the prevalence rate for the placebo group, or where the reaction is of particular interest are summarized below. Only asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations and somnolence were significantly ($p < 0.05$) more common in patients receiving terazosin than in patients receiving placebo. Other events include **[%TERAZOSIN-%PLACEBO]**, asthenia (11.3%-4.3%), back pain (2.4%-1.2%), blurred vision (1.6%-0%), depression (0.3%-0.2%), dizziness (19.3%-7.5%), dyspnea (3.1%-2.4%), edema (0.9%-0.6%), headache (16.2%-15.8%), impotence (1.2%-1.4%), libido decreased (0.6%-0.2%), nasal congestion (5.9%-3.4%), nausea (4.4%-1.4%), nervousness (2.3%-1.8%), pain-extremities (3.5%-3%), palpitations (4.3%-1.2%), paresthesia (2.9%-1.4%), peripheral edema (5.5%-2.4%), postural hypotension (1.3%-0.4%), sinusitis (2.6%-1.4%), somnolence (5.4%-2.6%), tachycardia (1.9%-1.2%), weight gain (0.5%-0.2%).

Adverse reactions were usually mild or moderate in intensity but sometimes were serious enough to interrupt treatment. Adverse reactions that were most bothersome as judged by being reported as reasons for discontinuation of therapy by at least 0.5% of the terazosin group and being reported more often than in the placebo group **[%TERAZOSIN-%PLACEBO]** are: asthenia (1.6%-0%), blurred vision (0.6%-0%), dizziness (3.1%-0.4%), dyspnea (0.9%-0.6%), headache (1.3%-1%), nasal congestion (0.6%-0%), nausea (0.8%-0%), palpitations (1.4%-0.2%), paresthesia (0.8%-0.2%), peripheral edema (0.6%-0%), postural hypotension (0.5%-0%), somnolence (0.6%-0.2%), syncope (0.5%-0.2%), tachycardia (0.6%-0%).

Additional adverse reactions have been reported, but these are not distinguishable from symptoms that might have occurred in the absence of exposure to terazosin. The following additional adverse reactions were reported by at least 1% of 1987 patients who received terazosin in clinical studies or during marketing experience: abdominal pain, abnormal vision, anxiety, arrhythmia, arthralgia, arthritis, bronchitis, chest pain, cold symptoms, conjunctivitis, constipation, diarrhea, dry mouth, dyspepsia, epistaxis, facial edema, fever, flatulence, flu symptoms, gout, increased cough, insomnia, joint disorder, myalgia, neck pain, pharyngitis, pruritus, rash, rhinitis, shoulder pain, sweating, tinnitus, urinary frequency, urinary tract infection, vasodilation, vomiting.

DOSAGE AND ADMINISTRATION: Dose and dose interval (12 or 24 hrs.) should be adjusted according to BP response.

Initial Dose: 1mg at bedtime. Observe the initial dosing regimen strictly to minimize potential for severe hypotensive effects.

Subsequent Doses: Slowly increase dose to achieve desired BP response. Usual dose range is 1mg to 5mg once a day. Some patients may benefit from doses up to 20mg/day. Doses over 20mg do not appear to provide further BP effect. Doses over 40mg have not been studied. Monitor BP at the end of dosing interval to assure control is maintained. It may be helpful to measure BP 2-3 hrs. after dosing to see if maximum and minimum responses are similar, and to evaluate symptoms which can result from excessive hypotensive response. If response is substantially diminished at 24 hrs. consider an increased dose or b.i.d. regimen. **If administration is discontinued for several days or longer, reinstitute therapy using initial dosing regimen.** In clinical trials, except for the initial dose, the dose was given in the morning.

Use With Other Drugs: Caution should be observed when terazosin is administered concomitantly with other antihypertensive agents (e.g., calcium antagonists) to avoid the possibility of significant hypotension. When adding a diuretic or other antihypertensive agent, dosage reduction and retitration may be necessary.

CARDIOLOGIST—The University of California, San Francisco and the Central California Faculty Medical Group seek a staff cardiologist to join the teaching faculty at their affiliate, Valley Medical Center of Fresno. Applicants should be board certified or eligible. The scope of practice at VMC includes full invasive and non-invasive cardiology services. Geographic location offers a large population with a variety of cardiological diseases. VMC has 350 active beds and conducts residency training programs in most major clinical disciplines. The central California location offers enjoyable and affordable California living. Competitive salary and benefits. UCSF is an equal opportunity employer. Address inquiries to: Lauren Grayson, M.D., Chief of Cardiology, CCFMG, 2212 N. Winery, #130, Fresno, CA 93703, (209) 252-1835.

International Symposium on Inflammatory Heart Disease: A Multidisciplinary Approach to Myocarditis and Heart Allograft Rejection
Snowmass, Colorado — July 27–July 31, 1988

Sponsor: University of Nebraska Medical Center, Omaha, Nebraska

Topics: The international program faculty of cardiovascular physicians and scientists and abstract presenters will address pivotal issues in the etiology, clinical presentation, immunopathogenesis, therapy and biological impact of major categories of inflammatory heart disease. Discussions will focus on both human and animal model experience with heart allograft rejection and idiopathic inflammatory heart disease, as well as infectious, toxic and allergic forms of inflammatory myocardial injury.

ABSTRACTS FOR POSTERS AND EXHIBITS ARE BEING ACCEPTED NOW!

For further information: Ms. Marge Adey, Center for Continuing Education, University of Nebraska Medical Center, 42nd and Dewey Avenue, Omaha, Nebraska 68105, or call (402) 559-4152.

CARDIOLOGY—Several vacancies exist for Board Certified Cardiologists in the U.S. Army Medical Department. Unique professional opportunities are available at locations in the United States and overseas. Interested individuals must not have attained their 58th birthday. For further information on benefits and professional opportunities, call LTC Touchard at (303) 361-3208. Call collect.

THE UNIVERSITY OF TEXAS HEALTH CENTER AT TYLER IS SEEKING A BOARD CERTIFIED/ELIGIBLE NON-INVASIVE CARDIOLOGIST

Full time position available. Need physicians who are board certified or board eligible in cardiology to join the clinical faculty of The University of Texas Health Center at Tyler. Physicians are needed for the practice of clinical non-invasive cardiology in a modern 200-bed hospital dedicated to heart and lung disorders. Tyler offers a mild climate and the community is an excellent environment for raising families. Salaries are competitive. Contact:

Allen B. Cohen, M.D., Ph.D.
Executive Associate Director
The University of Texas Health Center at Tyler
P.O. Box 2003, Tyler, TX 75710
Affirmative Action/Equal Opportunity Employer

CARDIOLOGIST—BC/BE to join busy cardiology practice in Los Angeles/Orange County area. University affiliation, excellent benefits and early partnership. Send CV to Box 805, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

CARDIOLOGIST, non-invasive, interested in general Internal Medicine, ICU care, echo, treadmill, holter, and rehab, to join another non-invasive Cardiologist in a 6 person Internal Medicine group in South Central Pennsylvania college town. Box 800, The American Journal of Cardiology, 249 W. 17th St., New York, N.Y. 10011.

...7, Searle & Co.

SEARLE

new Calan® (verapamil HCl) 40 *mg tablets* for added dosing flexibility

7W060T

Calan® Tablets
Verapamil HCl 120 mg 80 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block, atrial flutter/fibrillation with an accessory bypass tract (eg, WPW or LGL syndromes).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with any degree of ventricular dysfunction if they are receiving a beta-blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension, usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Elevations of liver enzymes have been reported. Four cases have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). Because of this risk, oral verapamil is contraindicated in such patients. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. Concomitant use of verapamil and carbamazepine may produce increased plasma concentrations of free carbamazepine. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use.

Adverse Reactions: Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, spotty menstruation, ecchymosis, bruising, impotence, gynecomastia, and psychotic symptoms. Overall continuation rate was 94.5% in 1,166 patients. 9/86 • 5W021V4

NOVA II. It's the world's smallest pacemaker–weighing just 23 grams and measuring a thin 6.5 mm in width. NOVA II's small size and unique, elliptical shape give new dimensions to patient comfort.

In addition, its new Side-Lock™ lead connector lets you fasten leads quickly and simply, without any special tools.

NOVA™ II gives you the most for your pacing prescription in one small dose.

And whether NOVA II is used in the atrium or ventricle, its full-function programmability, patient and system diagnostics give you the most for your pacing prescription. For more information on how to get single-chamber pacing's biggest advantages in one small dose, call your Intermedics Sales Representative. Or call Intermedics toll-free at 1-800-231-2330. (In Texas, call collect 409-233-8611.) Telex: 4620584 INTL UI.

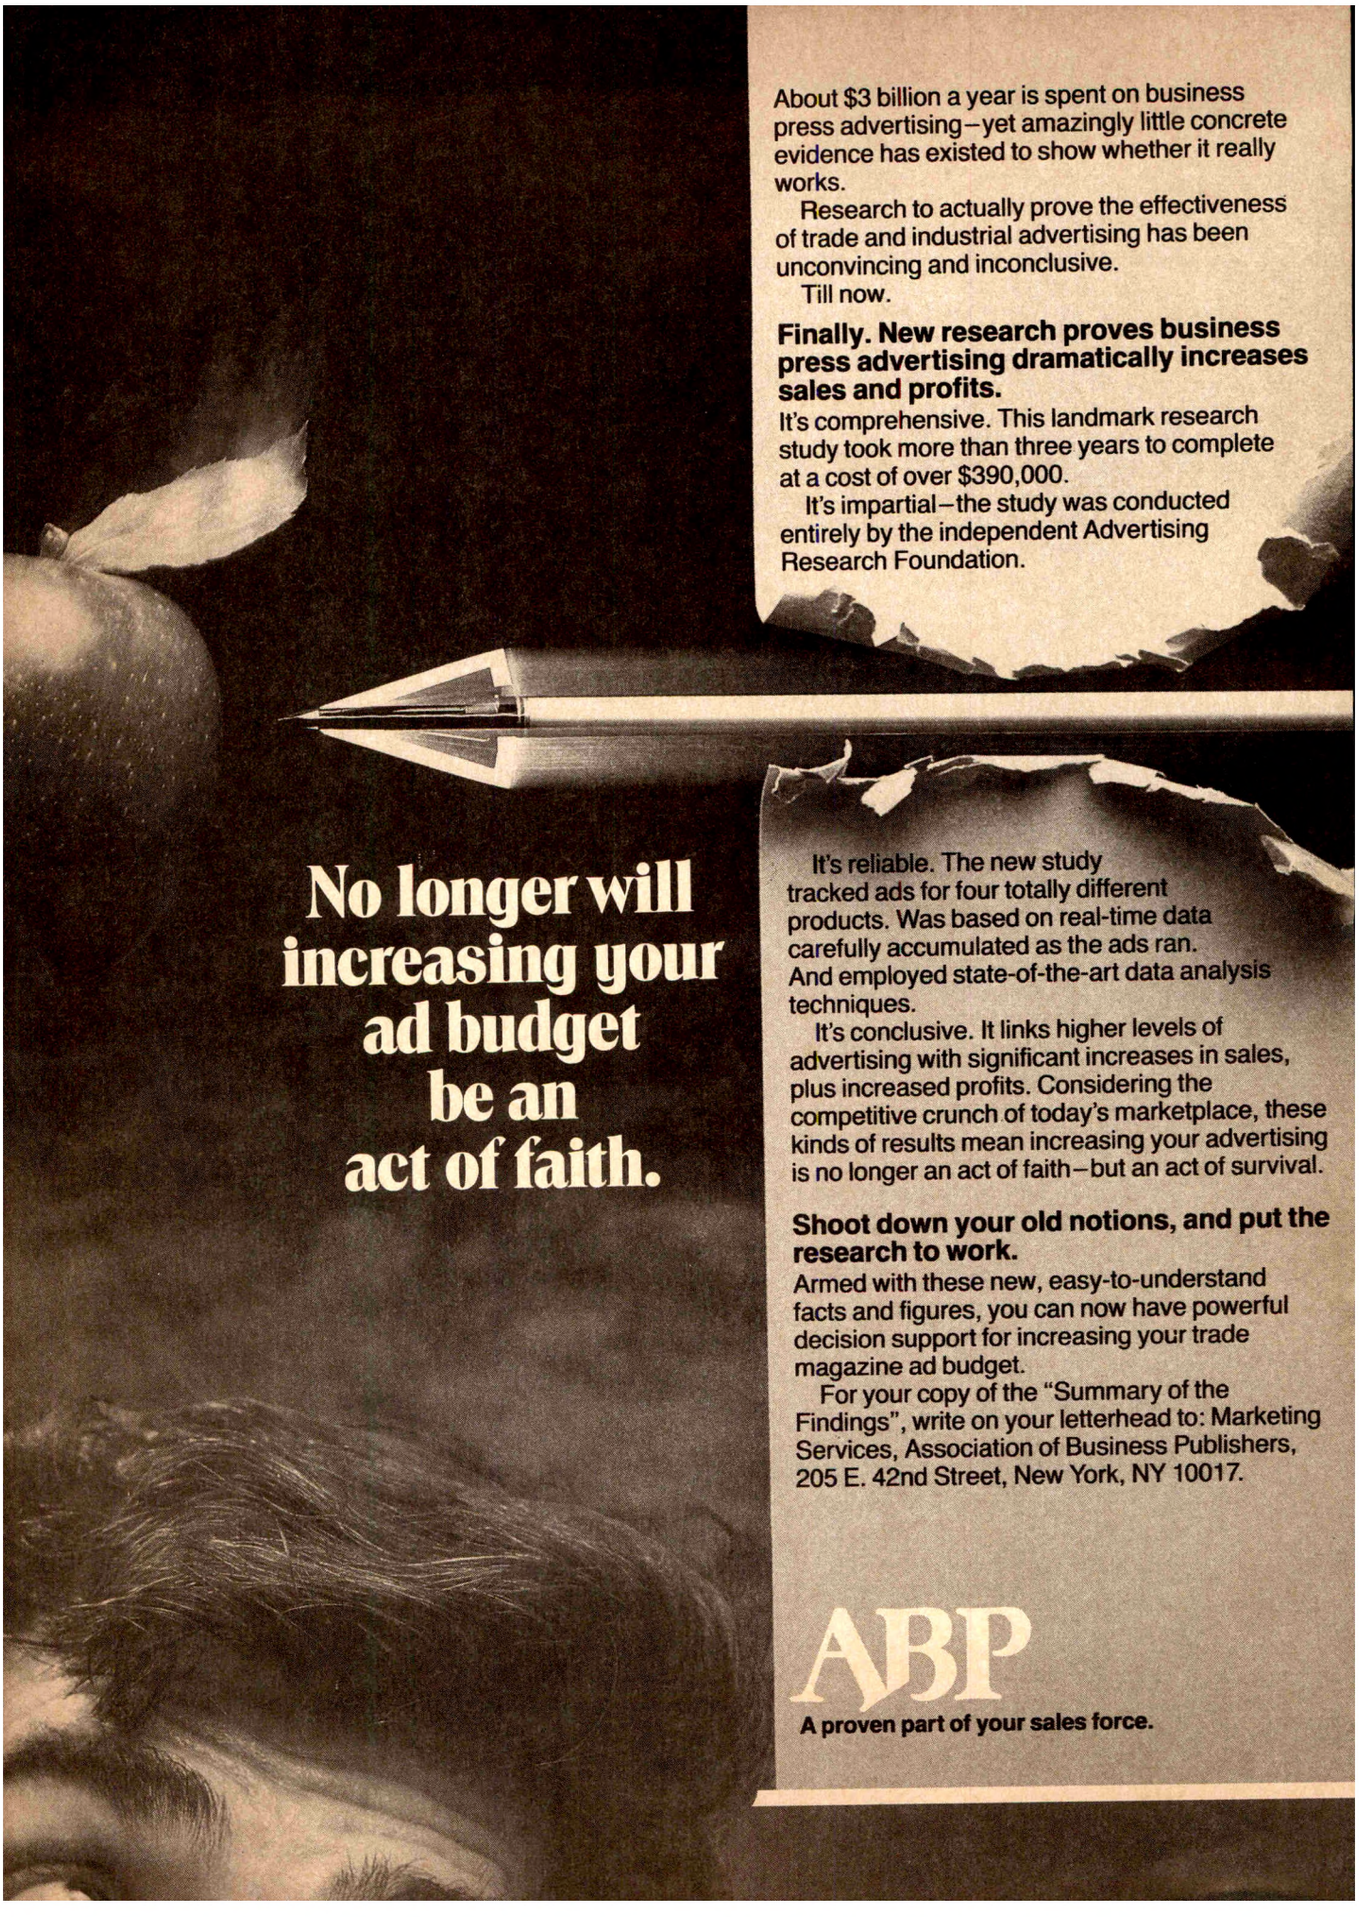
Quality comes to life.™

©1987 Intermedics, Inc. NOVA II conforms to VS-1 (Voluntary Standard for lead-to-pulse-generator connections)



About $3 billion a year is spent on business press advertising—yet amazingly little concrete evidence has existed to show whether it really works.

Research to actually prove the effectiveness of trade and industrial advertising has been unconvincing and inconclusive.

Till now.

Finally. New research proves business press advertising dramatically increases sales and profits.

It's comprehensive. This landmark research study took more than three years to complete at a cost of over $390,000.

It's impartial—the study was conducted entirely by the independent Advertising Research Foundation.

No longer will increasing your ad budget be an act of faith.

It's reliable. The new study tracked ads for four totally different products. Was based on real-time data carefully accumulated as the ads ran. And employed state-of-the-art data analysis techniques.

It's conclusive. It links higher levels of advertising with significant increases in sales, plus increased profits. Considering the competitive crunch of today's marketplace, these kinds of results mean increasing your advertising is no longer an act of faith—but an act of survival.

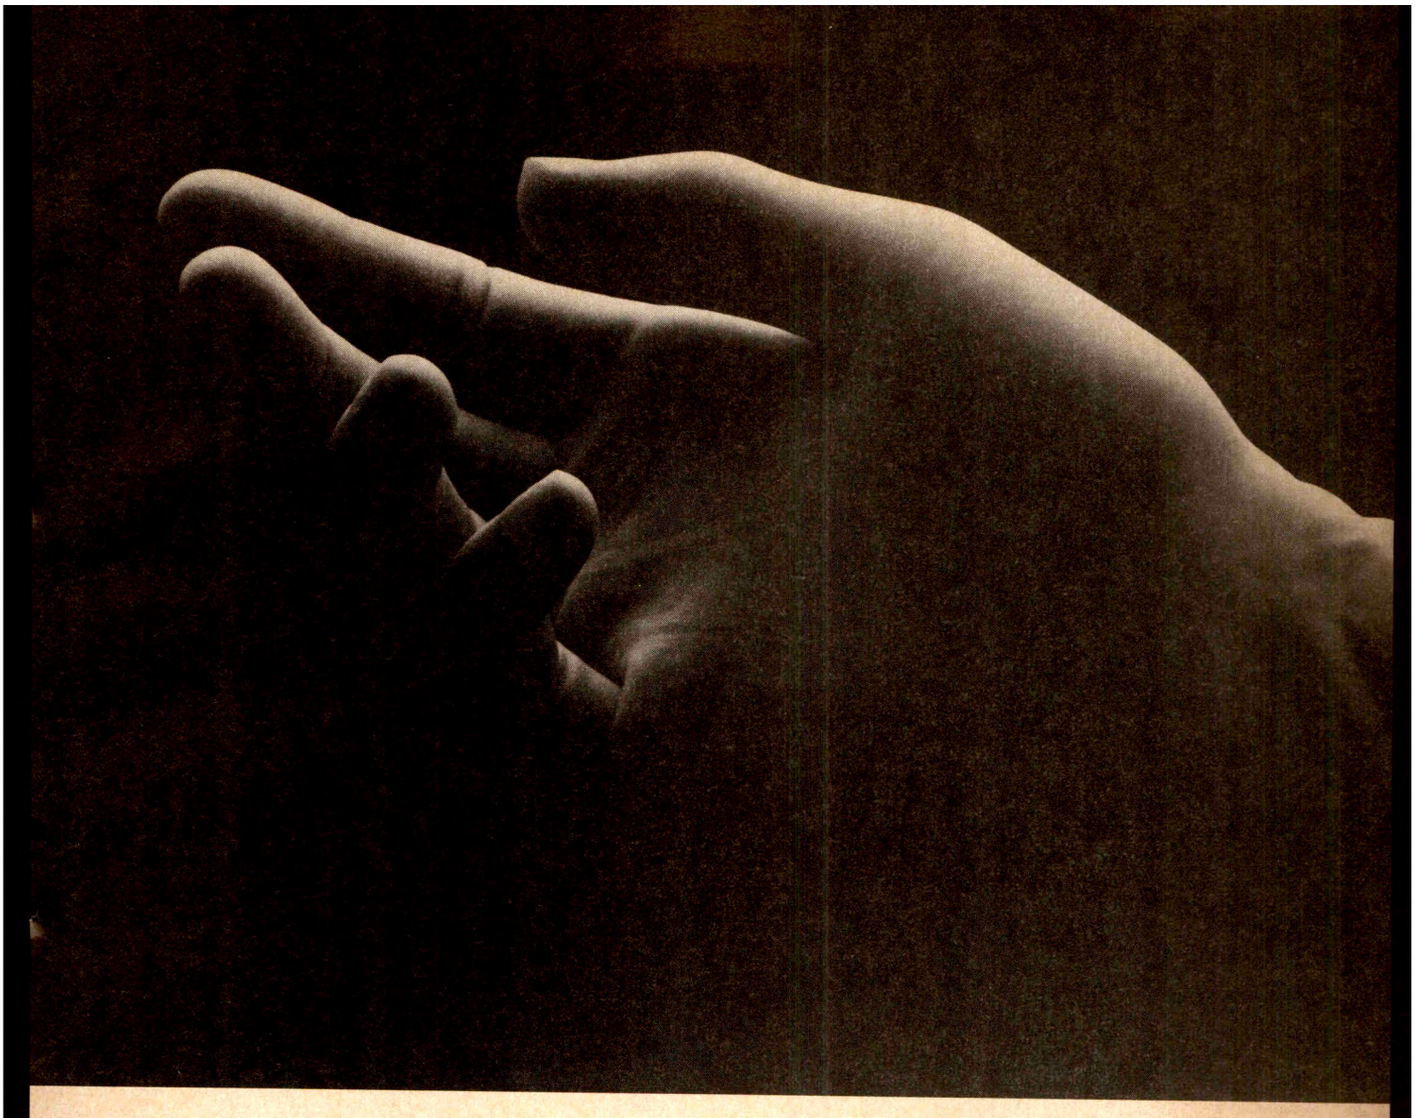
Shoot down your old notions, and put the research to work.

Armed with these new, easy-to-understand facts and figures, you can now have powerful decision support for increasing your trade magazine ad budget.

For your copy of the "Summary of the Findings", write on your letterhead to: Marketing Services, Association of Business Publishers, 205 E. 42nd Street, New York, NY 10017.

ABP

A proven part of your sales force.



Simply insert the lead into NOVA II's header, press the Side-Lock,™ and the lead is locked in place. You don't need any tools or accessories. It's that easy.

This connector, plus NOVA II's full-function programmability, extensive patient and system diagnostic capabilities and small size (23 grams and 6.5 mm) bring the biggest advantages in single-chamber pacing down to size.

Intermedics NOVA™ II lets you make lead connections with a tool you already have.

For more information, call your Intermedics Sales Representative.

Practical New Books in Cardiology From Yorke Medical Books

For the clinician's working library, the publishers of The American Journal of Cardiology give you only the best

Manual of Cardiac Arrhythmias

BY EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C. 0-914316-43-5, November 1985, appx. 324 pp., $30.00

The eminent clinician, professor, and medical writer Dr. Edward K. Chung, has produced the most current "how to" manual on cardiac arrhythmias. The book has been formatted and edited to facilitate its use as a ready reference to up-to-date material on diagnosing and managing arrhythmias commonly seen in daily clinical practice. Its purpose is not to discuss in-depth every aspect of various cardiac rhythm problems, but rather to provide the reader with a concise easy-to-use guide. An invaluable resource for all physicians and allied health professionals seeking to add to their clinical knowledge of a complex topic without the necessity of purchasing a large general text on cardiology.

Table of Contents

- Introductory Remarks
- Anatomy and Electrophysiology
- Diagnostic Approach to Cardiac Arrhythmias
- Sinus Arrhythmias
- Atrial Arrhythmias
- A-V Junctional Arrhythmias
- Intraventricular Conduction Disturbances
- Differential Diagnosis of Tachyarrhythmias
- Aberrant Ventricular Conduction
- Carotid Sinus Stimulation
- Wolff-Parkinson-White Syndrome
- Sick Sinus Syndrome
- Therapeutic Approach to Cardiac Arrhythmias
- Digitalization
- Digitalis Intoxication
- Antiarrhythmic Drug Therapy
- Artificial Cardiac Pacing
- Direct Current Shock
- Cardiopulmonary Resuscitation
- Uncommon Cardiac Arrhythmias

Cardiac Arrhythmias

Self Learning Companion Volume to Manual of Cardiac Arrhythmias

BY EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C. 0-914316-46-X, November 1985, appx. 440 pp., $30.00

Conceived by Dr. Chung as a companion volume to Manual of Cardiac Arrhythmias, this book includes 200 cases showing common cardiac arrhythmias frequently encountered in clinical practice.

Interpretation of the ECG training is aided by short case histories. The reverse side of each page gives a full analysis of the interpretation of the tracing, enabling readers to assess their own ECG diagnosis. In the majority of cases, three simultaneous ECG leads (leads V, II, and V_5) recorded by 3-channel ECG equipment, are shown for accurate diagnosis. In addition to the ECG diagnosis, the pertinent clinical significance and therapeutic approach are included in many instances.

The arrangement of the text and illustrations is based upon the author's extensive experience in teaching medical students, house staff, cardiology fellows, cardiac care nurses, and physicians with diversified backgrounds and specialties.

The unique feature of this book, is its practical approach to clinical applications that directly assist readers in the diagnosis and management of their patients.

Contents

- A-V Block
- Intraventricular Block
- Sinus Arrhythmias
- Atrial Arrhythmias
- A-V Junctional Arrhythmias
- Ventricular Arrhythmias
- Differential Diagnosis of Cardiac Arrhythmias
- Wolff-Parkinson-White Syndrome
- Cardiac Arrhythmias Related to Artificial Pacemakers
- Miscellaneous ECG Findings

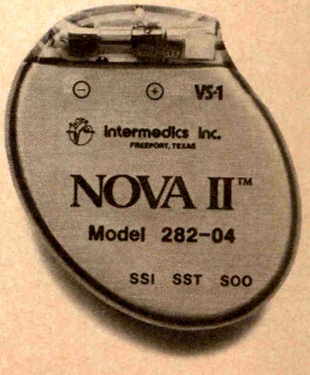
NOVA II's wide range of diagnostic capabilities, including a rate histogram and a high rate event counter, simplify patient follow-up. NOVA II also offers broad programming flexibility so you can titrate pacing parameters in very fine increments to better meet your patient's need.

All this comes in the world's smallest pacemaker, with the simplest lead connector system available today.

Intermedics NOVA™ II offers you more diagnostic data than any other single-chamber pacemaker.

Shown actual size.



For more information, call your Intermedics Sales Representative. Or call us toll-free at 1-800-231-2330. (In Texas, call collect 409-233-8611.) Telex: 4620584 INTL UI.

Nitro-Dur II

NOW EVEN ITS NAME IS SIMPLER.

Since we introduced Nitro-Dur II, it has remained, in our opinion, the easiest patch to open, handle, and apply. But now, it's also becoming easier to prescribe.

Key Pharmaceuticals, Inc., has deleted the Roman numeral "II" from the name of the transdermal nitroglycerin system formerly known as "Nitro-Dur II." In all other respects, the product will remain identical to the Nitro-Dur II system you have been prescribing.

The original large, white Nitro-Dur system is being discontinued. From now on, prescriptions you write for either "Nitro-Dur" or "Nitro-Dur II" will be filled with the renamed Nitro-Dur product.

Key Pharmaceuticals has retained the name Nitro-Dur because of its wide recognition among patients and health care professionals. Now you can simply write Nitro-Dur, and be confident that patients are getting the most advanced, easy-to-use nitroglycerin patch design available today.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System
Easy to open...apply...remove.

Formerly named Nitro-Dur II.

Please see next page for summary of prescribing information.
All transdermal nitroglycerin products are being marketed pending final evaluation of effectiveness by the FDA.

Nitro-Dur®
(nitroglycerin)
Transdermal Infusion System
Easy to open...apply...remove.

Formerly named Nitro-Dur II.

BRIEF SUMMARY

INDICATIONS AND USAGE: This drug product has been conditionally approved by the FDA for the prevention and treatment of angina pectoris due to coronary artery disease. The conditional approval reflects a determination that the drug may be marketed while further investigation of its effectiveness is undertaken. A final evaluation of the effectiveness of the product will be announced by the FDA.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia.

WARNINGS: The NITRO-DUR system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced or use of the product discontinued.

NITRO-DUR is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

Pregnancy: Pregnancy Category C. Animal reproduction studies have not been conducted with NITRO-DUR. It is also not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when NITRO-DUR is administered to a nursing woman.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing NITRO-DUR therapy. If headache persists, the NITRO-DUR dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the NITRO-DUR dosage should be reduced or use of the product discontinued.

CAUTION: Federal law prohibits dispensing without prescription.

Double-take.

Introducing dual-chamber paced patient arrhythmia monitoring from HP.

When it comes to arrhythmia monitoring, Hewlett-Packard does it again. And again. The latest breakthrough—an algorithm so accurate it eliminates excessive false alarms for dual-chamber paced patients.

Through improved beat classification, HP's new algorithm provides greater accuracy. More sensitive detection of VPBs and ventricular rhythms. Less double counting. And more accurate recognition of true QRS complexes. Regardless of pacemaker type.

What's more, coupled with the reduced false alarm rate, the HP 78720's latest software upgrade provides you with more comprehensive information and clearer documentation for patient assessment.

The bottom line? Whether you're monitoring non-paced, single or dual-chamber paced patients, the HP 78720's enhanced algorithm gives you the confidence and accuracy you need.

Add HP reliability. Service. Training. Support. And a commitment to innovative upgrades. Hewlett-Packard continues to set the pace in arrhythmia monitoring.

For further information on the HP 78720 and its full range of capabilities, contact your local HP representative. Or return the coupon today.

ENKAID®
(encainide HCl)

An alternative to classic antiarrhythmic therapy

For symptomatic non-sustained V-Tach and frequent PVCs

Treatment of symptomatic PVCs and non-sustained V-Tach should be reserved for patients in whom, in the opinion of the physician, the benefits of antiarrhythmic therapy outweigh the risks (e.g., proarrhythmia).

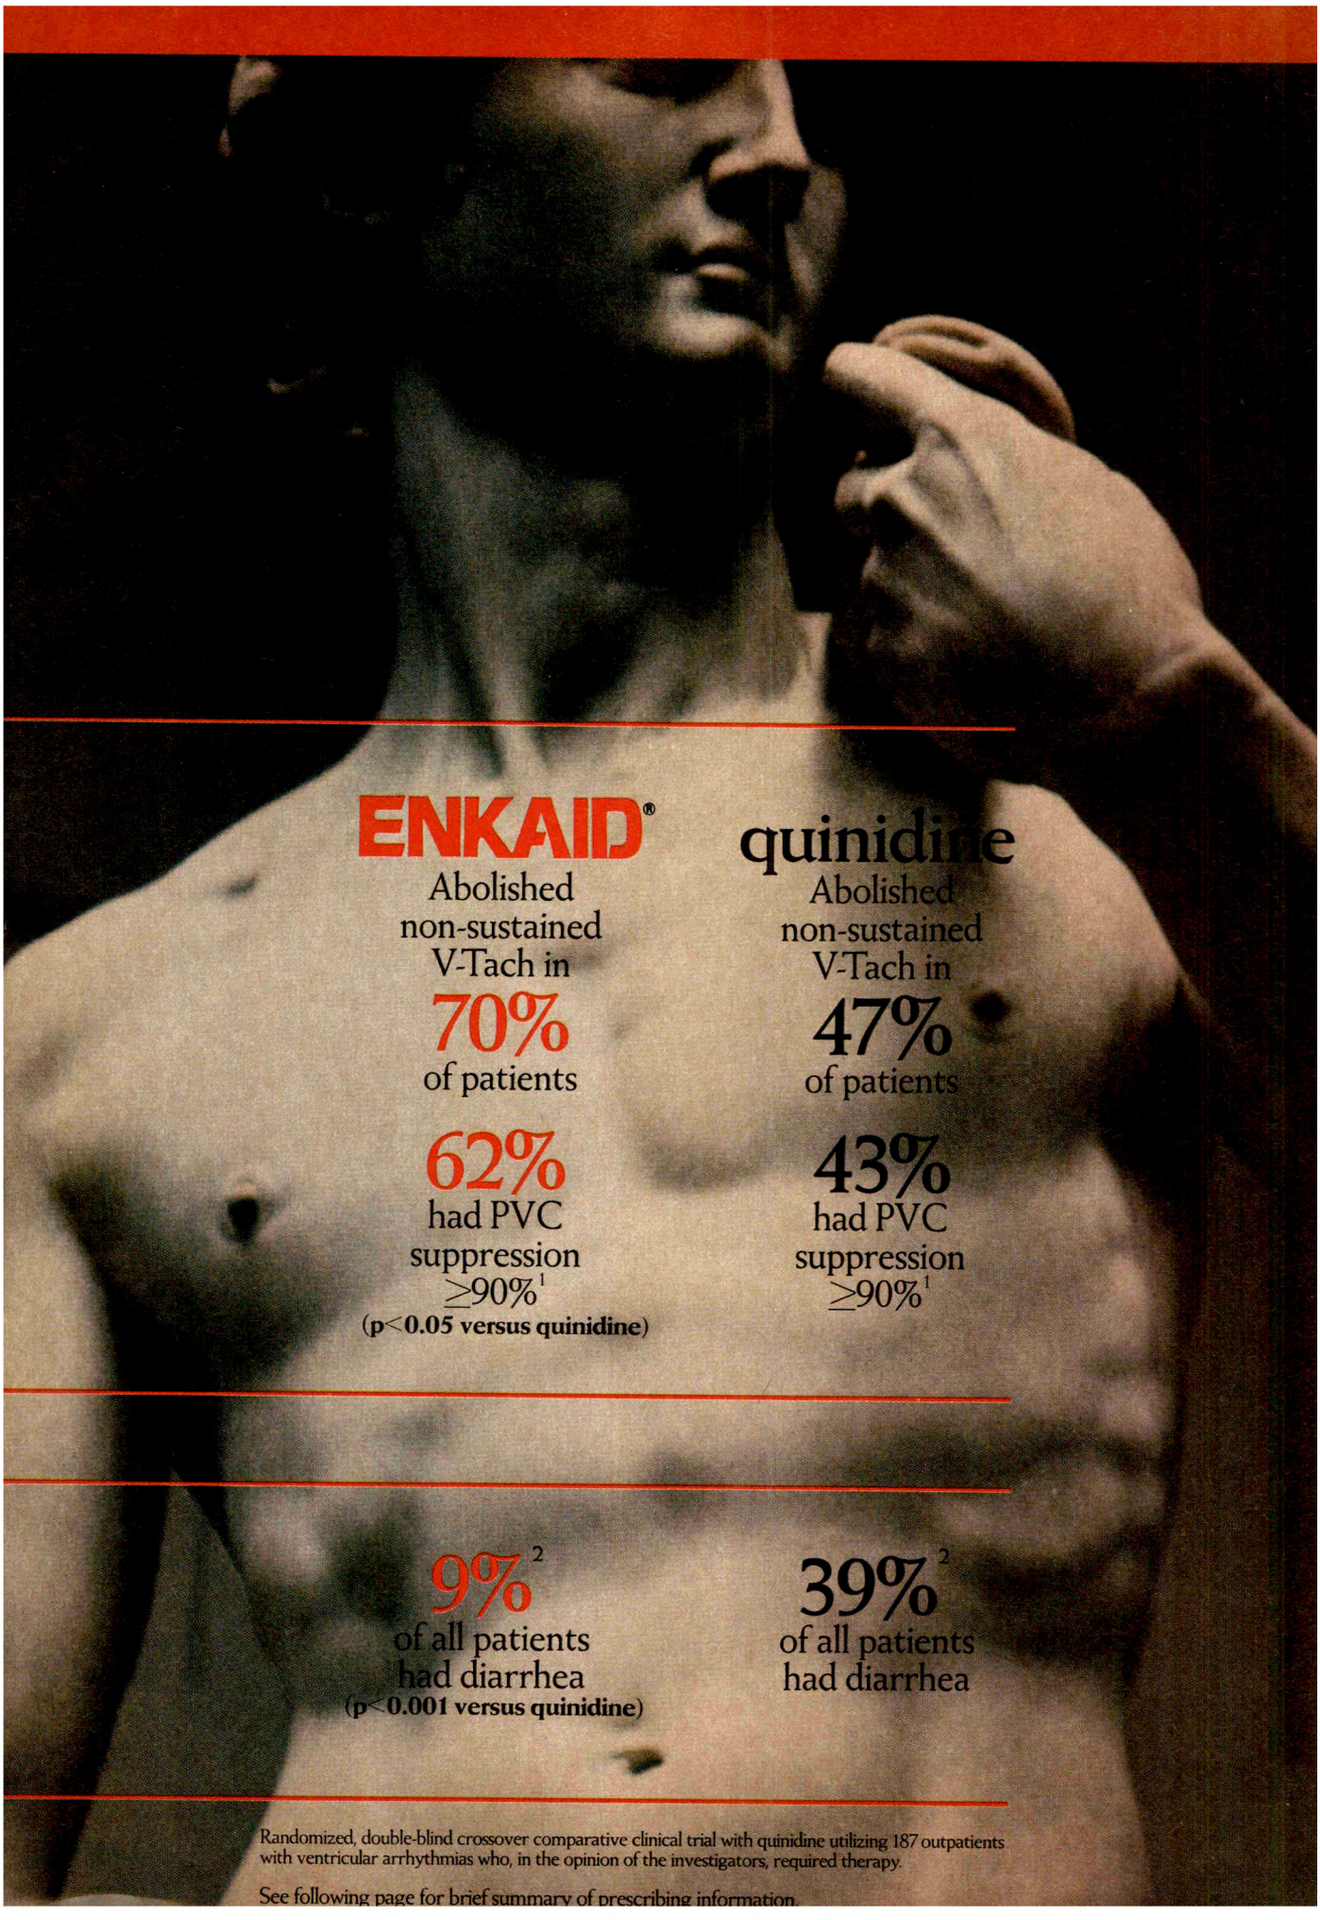
For documented life-threatening arrhythmias

Therapy should be initiated in the hospital for patients with sustained V-Tach and is also advisable for patients with a relatively high risk of proarrhythmia and at the time of a dose increase to 200 mg/day or above.

The antiarrhythmic benefits of quinidine,

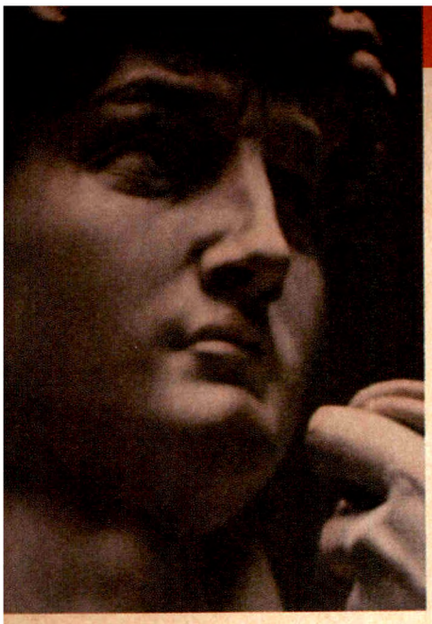
with fewer non-cardiac side effects

© 1988 Bristol-Myers U.S. Pharmaceutical and Nutritional Group
Evansville, Indiana 47721 U.S.A.



Randomized, double-blind crossover comparative clinical trial with quinidine utilizing 187 outpatients with ventricular arrhythmias who, in the opinion of the investigators, required therapy.

See following page for brief summary of prescribing information.



ENKAID®
(encainide HCl)

Effective with no changes in cardiac performance

- Studies of hemodynamic effects show no changes in:
  - left ventricular ejection fraction
  - cardiac or stroke volume index
  - pulmonary capillary wedge pressure
- Effective even in patients refractory to other antiarrhythmics.

ENKAID® (encainide HCl)

Dosage	Usual Recommendation
Initial dose	25 mg t.i.d.*
First increment (if required)	35 mg t.i.d.*
Second increment (if required)	50 mg t.i.d.*
Maximum recommended	50 mg q.i.d.**

*approximately q8h **approximately q6h

Initiate therapy at lowest dosage and increase gradually. Allow 3 to 5 days between dosing increments.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION

INDICATIONS AND USAGE

ENKAID is indicated for the treatment of documented life-threatening arrhythmias, such as sustained ventricular tachycardia.

ENKAID is also indicated for the treatment of patients with symptomatic non-sustained ventricular tachycardia and frequent premature ventricular complexes. Because of the proarrhythmic effects of ENKAID, its use in these less severe arrhythmias should be reserved for patients in whom, in the opinion of the physician, the benefits of treatment outweigh the risks.

For patients with sustained ventricular tachycardia, ENKAID, like other antiarrhythmics should be initiated in the hospital. Hospitalization is also advisable for other patients with a relatively high risk of proarrhythmia including patients with symptomatic congestive heart failure, cardiomyopathy or non-sustained ventricular tachycardia, depending on their cardiac status and underlying cardiac disease. Patients should also be hospitalized at the time of a dose increase to 200 mg per day or above (see **DOSAGE AND ADMINISTRATION**).

The effects of ENKAID in patients with a recent acute myocardial infarction and in patients with supraventricular arrhythmias have not been adequately studied.

As is the case for other antiarrhythmic agents, there is no evidence from controlled trials that the use of ENKAID favorably affects survival or the incidence of sudden death.

CONTRAINDICATIONS

ENKAID is contraindicated in patients with preexisting second- or third-degree AV block, or with right bundle branch block when associated with a left hemiblock (bifascicular block), unless a pacemaker is present to sustain the cardiac rhythm should complete heart block occur. ENKAID is also contraindicated in the presence of cardiogenic shock or known hypersensitivity to the drug.

WARNINGS

Proarrhythmia

ENKAID, like other antiarrhythmic agents, can cause new or worsened arrhythmias. Such proarrhythmic effects range from an increase frequency of PVCs to the development of more severe ventricular tachycardia; e.g., tachycardia that is more sustained or more resistant conversion to sinus rhythm, with potentially fatal consequences.

In patients with malignant arrhythmias, it is often difficult to distinguish a spontaneous variation in the patient's underlying rhyth disorder from drug induced worsening, so the following occurrence rates must be considered approximations.

Overall, in clinical trials with ENKAID about 10% of all patients had proarrhythmic events, about 6% of them representing new or worsen ventricular tachycardia. Provocation or aggravation occurred most frequently in patients who had a history of sustained ventricular tachycard (12% of such patients), cardiomyopathy (16%), congestive heart failure (12%) or sustained ventricular tachycardia with cardiomyopathy congestive heart failure (17%). The incidence of proarrhythmic events in patients without ventricular tachycardia or overt manifestations clinical heart disease ranged from 3 to 4%. Proarrhythmia occurred least frequently in patients with no known structural heart disea Age, sex, baseline ECG intervals, or ECG changes caused by ENKAID were not predictive of the occurrence of proarrhythmia.

A review of deaths in clinical trials indicates that about 1% of patients might have died of a possible proarrhythmic effect of ENKA virtually all of them patients with a history of ventricular tachycardia. In most cases patients had a history of sustained ventricular tachycard or ventricular fibrillation.

Proarrhythmic events occurred most commonly during the first week of therapy and were much more common when doses exceed 200 mg/day. Initiating therapy at 75 mg/day combined with gradual dose adjustment reduced the risk of proarrhythmia (See DOSAGE A ADMINISTRATION).

Congestive Heart Failure

New or worsened congestive heart failure (CHF) attributed to ENKAID occurred infrequently (< 1%); nevertheless, ENKA should be used cautiously in patients with CHF or congestive cardiomyopathy.

Electrolyte Disturbances

Hypokalemia or hyperkalemia may alter the effects of Class I antiarrhythmic drugs. Preexisting hypokalemia or hyperkalem should be corrected before administration of ENKAID.

Sick Sinus Syndrome—(Bradycardia-Tachycardia Syndrome)

ENKAID should be used only with extreme caution in patients with sick sinus syndrome because it may cause sinus bra cardia, sinus pause, or sinus arrest.

Electrocardiographic Changes

ENKAID slows conduction and consequently produces dose related changes in the PR and QRS intervals. The interva increase in a linear manner at doses from 30 to 225 mg/day. There is no consistent change in JT. The QTc interval increased, but only to the extent of the increase in QRS interval.

Clinically significant changes in cardiac conduction have been observed. Sinus bradycardia, sinus pause, or sinus arre occurred in 1% of the patients and prolongation of QRS interval to greater than/or equal to 0.20 sec developed in about 7 of the patients. The incidence of second- or third-degree AV block was less, 0.5% and 0.2% respectively.

Effects on Pacemaker Thresholds

The safety of ENKAID in patients with permanently implanted programmable pacemakers has been established in a sm (10 patient) study which evaluated the effects of increasing doses on pacemaker thresholds. ENKAID has a limited potent for increasing pacemaker thresholds. Only one subject had a clinically significant change that would require pacemaker programming and that occurred only at the highest dose tested (75 mg t.i.d.). These effects were reversed when the drug w discontinued. It is advisable to establish pacemaker threshold prior to encainide administration and at regular intervals duri therapy. Reprogramming of multiprogrammable pacemakers may be required to increase voltage or pulse width. ENKA should not be administered to patients with existing poor thresholds or non-programmable pacemakers unless suitat pacing rescue is available. In addition to possible rise in pacing threshold, ENKAID may suppress ventricular escape rhythr

PRECAUTIONS

Drug Interactions

In prospective studies single and multiple doses of ENKAID have had no significant effect on serum digoxin levels. Likewi combined digoxin/ENKAID therapy has been administered without adverse effects.

Experience has indicated no obvious problems with the combined use of ENKAID and other antiarrhythmic age diuretics, beta blockers or calcium channel blockers. However, because of possible additive pharmacologic effects, caut is indicated when ENKAID is used with another antiarrhythmic agent or any other drug that affects cardiac conducti

Cimetidine (300 mg q.i.d.) increases plasma concentrations of encainide and its active metabolites. Although no clinica

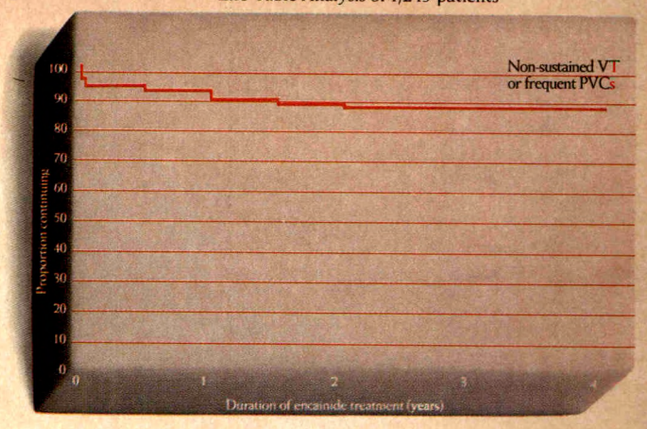
Well tolerated in long-term therapy

■ Few discontinuations due to side effects even after 4 years.

The most serious side effects of Enkaid are dizziness and blurred vision. In clinical studies with Enkaid, about 10% of patients had proarrhythmic events, occurring most frequently in patients with sustained ventricular tachycardia or underlying heart disease.

See brief summary for more information on Enkaid's side effects in life-threatening arrhythmias. Hospitalization is recommended in a facility with cardiac monitoring capabilities for patients with sustained V-Tach, sinus node dysfunction, cardiomyopathy and/or CHF, or at the time of a dose increase to 200 mg/day or above.

Discontinuations due to side effects[3]
Life Table Analysis of 1,245 patients



ENKAID®
(encainide HCl)

An alternative to classic antiarrhythmic therapy

significant consequences have been reported, caution should be utilized when the two drugs are administered simultaneously. ENKAID dosage should be reduced if cimetidine is to be given to a patient taking ENKAID.

In vitro binding studies with several drugs that may be administered concomitantly have not revealed any significant alteration in the protein binding of encainide, ODE, or MODE; nor did high concentrations of encainide and its metabolites alter the binding of the other medications including such highly protein bound drugs as warfarin.

Hepatic Impairment
Patients with hepatic impairment have a significantly reduced rate of elimination of encainide, probably as a consequence of decreased metabolism to ODE and MODE; serum concentrations of ODE and MODE, however, are little altered. There is insufficient experience to be certain about the need for alterations in the dose and/or dosing interval of ENKAID in patients with hepatic disease, but it is prudent to increase doses cautiously.

Renal Impairment
Limited data suggest that reduction in the elimination of encainide and its active metabolites ODE and MODE in patients with severe renal impairment (serum creatinine >3.5 mg/dl or creatinine clearance of less than 20 ml/min) results in significant accumulation of metabolites and, to a lesser degree, encainide. In such patients therapy with ENKAID should be initiated with a single daily dose of 25 mg. If needed the dose may be increased to 25 mg b.i.d. after at least 7 days, and again to 25 mg t.i.d. after an additional 7 days if necessary. Doses above 150 mg per day are not recommended. Consideration should be given to reducing ENKAID dosage if renal function deteriorates significantly.

Carcinogenesis, Mutagenesis, Impairment of Fertility
Carcinogenicity studies have been performed by the oral route in rats and mice at doses up to 30 mg/kg/day and 135 mg/kg/day, respectively. No drug-related increase in tumor incidence was observed. Bacterial and mammalian mutagenicity tests with encainide have been negative. No reduction in fertility occurred in rats at oral doses up to 14 mg/kg/day. Fertility was reduced when both male and female rats received oral doses of 28 mg/kg/day (approximately 13 times the average human dose) prior to mating; there was no reduction with treatment of each sex separately at the same dose.

Pregnancy Category B
Reproduction studies have been performed in rats and rabbits at doses up to 13 and 9 times the average human dose respectively and have revealed no evidence of harm to the fetus due to encainide. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers
Encainide is excreted in the milk of laboratory animals and has been reported to be present in human milk. Although no overt postnatal effects were observed in the postnatal phase of the rodent reproduction studies, other than decreased weight at the highest dose of 28 mg/kg/day (13 times human dose), the potential for serious adverse reactions in nursing infants from ENKAID is unknown. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use
The safety and effectiveness of ENKAID in children less than 18 years of age have not been established.

ADVERSE REACTIONS
The most serious adverse reactions reported for ENKAID are the provocation or aggravation of ventricular arrhythmias (See **WARNINGS**). These occurred during the course of the clinical research program in about 10% of the patients who received a wide range of doses under a variety of circumstances. In some cases this resulted in the development of sustained ventricular tachycardia or ventricular fibrillation.

Only 0.4% of patients discontinued ENKAID therapy due to congestive heart failure or related causes. Second- or third-degree AV block developed in 0.5% and 0.2% of the patients respectively. Sinus bradycardia, sinus pause or sinus arrest occurred in 1% of the patients. There have been rare reports of elevated serum liver enzymes (alkaline phosphatase, serum transaminases), hepatitis, and jaundice; in which a relation to encainide is possible and there has been one instance of a rechallenge-confirmed elevation of transaminases. There have also been rare reports of elevated blood glucose levels or of increased insulin requirements in diabetic patients. Although no cause and effect relationship has been established, caution is advised in patients who develop unexplained jaundice or signs of hepatic dysfunction or hyperglycemia and consideration should be given to discontinuing therapy.

In premarketing evaluations 2400 subjects were exposed to ENKAID, of whom more than 500 were maintained on drug for two years or longer. Adverse events were sufficiently troublesome to cause discontinuation in about 7% of the patients participating in premarketing clinical trials. The most frequently reported adverse events are dizziness, blurred or abnormal vision, and headache.

The most common adverse events reported by at least 3% of patients in controlled clinical trials, occurring at frequencies greater than those seen for patients on placebo, are chest pains, death, headache, lower extremity pain, proarrhythmia, abdominal pain, constipation, diarrhea, dry mouth, dyspepsia, nausea, dizziness, insomnia, somnolence, abnormal/blurred vision, and tinnitus.

OVERDOSAGE
Intentional or accidental overdosages with ENKAID have resulted in death.

Signs, Symptoms, and Laboratory Findings Associated with an Overdosage of the Drug
Overdosage with ENKAID may produce excessive widening of the QRS complex and QT interval and AV dissociation. Hypotension, bradycardia and finally asystole may develop. A variety of conduction disturbances may be observed. Convulsions have occurred in one case of intentional overdosage.

Oral LD_{50} of the Drug in Animals
The acute, oral LD_{50} values for encainide are estimated to be 80 mg/kg in the mouse and 59 mg/kg in the rat.

Recommended General Treatment Procedures
In the event of overdosage with ENKAID patients should be hospitalized and provided with cardiac monitoring and advanced life support systems. No specific antidote for ENKAID has been identified; however, one report has suggested hypertonic sodium bicarbonate may be useful in managing the cardiac toxicity associated with an ENKAID overdosage. Acute overdosages should be treated by gastric lavage followed by activated charcoal. Treatment of overdosage should be supportive.

DOSAGE AND ADMINISTRATION
As with other antiarrhythmic agents, ENKAID therapy in patients with sustained ventricular tachycardia should be initiated in a hospital setting with facilities for cardiac rhythm monitoring. Hospitalization is also recommended for patients with sinus node dysfunction or cardiomyopathy and/or congestive heart failure even if there is no history of sustained ventricular tachycardia, and at the time of a dose increase to 200 mg per day or above.

Dosages of ENKAID should be adjusted gradually allowing 3 to 5 days between dosing increments.

HOW SUPPLIED
Capsules, 25 mg, green and yellow hard gelatin capsule imprinted with ENKAID, 25 mg, Bristol and 732.

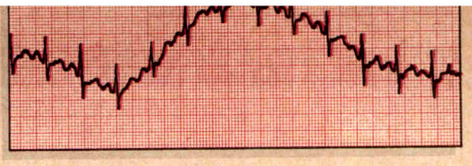
Evansville, Indiana 47721 U.S.A.
Made in U.S.A. #B-V-20 Revised June, 1987

preparation system Quik-Prep™ because it makes prepping the patient faster. But one look at the traces on the right will tell you we could have named it Stable Baseline Prep. Both traces were from the same patient, the same day, with the same equipment.

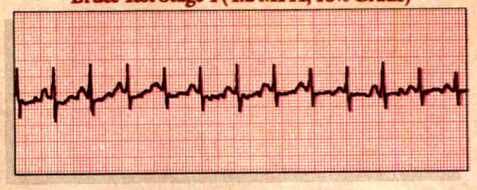
Consistently better ECG traces.

Proper skin preparation is the key to stable baselines. And Quik-Prep is the key to proper skin preparation.

Quik-Prep's patented applicator rotates the center of a special pre-gelled silver-silver chloride electrode. By measuring the electrical impedance of the skin electrode combination, it literally senses when the skin is properly prepared so you get stable ECG baselines, test after test.



Unprepped skin,
Bruce Test Stage 4 (4.2 MPH, 16% Grade)



Quik-Prepped Skin,
Bruce Test Stage 4 (4.2 MPH, 16% Grade)

What's more, Quik-Prep won't overabrade the skin, so your patients will have less pain, less anxiety, less trauma.

Like the name says, Quik-Prep's fast. In most cases, ten electrodes can be prepped in less than three minutes.

You save expensive technician time every test. And you won't waste either time or supplies repeating tests because the skin wasn't properly prepped. That gives Quik-Prep a lower cost-in-use than most standard electrodes.

We'd like to show you how Quik-Prep's skin preparation system can give you better ECG traces, more efficiently. For a free demonstration, call Quinton at 1-800-431-1114 or write us at 2121 Terry Ave., Seattle, WA 98121 • Telex 3794094.

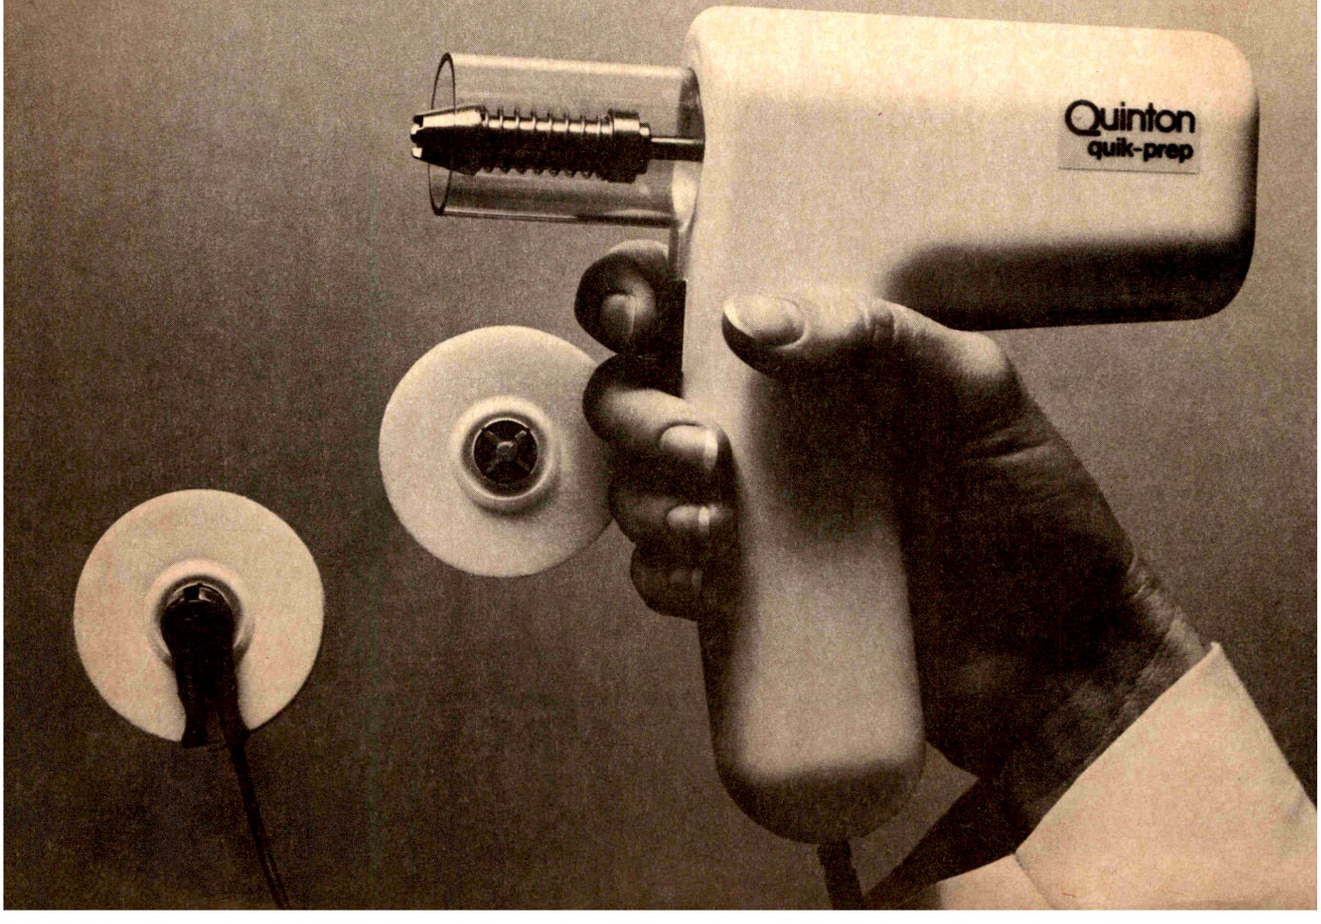
WE COULD HAVE CALLED IT "STABLE BASELINE PREP."



First-step protection for the hypertensive heart

Lopressor®
metoprolol tartrate USP

Tablets
Ampuls
Prefilled Syringes

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE INSERT)

CONTRAINDICATIONS
Hypertension and Angina
Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **WARNINGS**).
Myocardial Infarction
Lopressor is contraindicated in patients with a heart rate < 45 beats/min; second- and third-degree heart block; significant first-degree heart block (P-R interval ≥ 0.24 sec); systolic blood pressure < 100 mmHg; or moderate-to-severe cardiac failure (see **WARNINGS**).

WARNINGS
Hypertension and Angina
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive and angina patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and Lopressor slow AV conduction.
In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic. The response should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, Lopressor should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have occurred. When discontinuing chronically administered Lopressor, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of 1-2 weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Lopressor administration should be reinstated promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Lopressor therapy abruptly even in patients treated only for hypertension.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly, and the lowest possible dose of Lopressor should be used. In these circumstances it would be prudent initially to administer Lopressor in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See DOSAGE AND ADMINISTRATION.)**

Major Surgery: The necessity or desirability of withdrawing beta-blocking therapy prior to major surgery is controversial; the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Lopressor, like other beta blockers, is a competitive inhibitor of beta-receptor agonists, and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
Diabetes and Hypoglycemia: Lopressor should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected.
Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade, which might precipitate a thyroid storm.
Myocardial Infarction
Cardiac Failure: Sympathetic stimulation is a vital component supporting circulatory function, and beta blockade carries the potential hazard of depressing myocardial contractility and precipitating or exacerbating minimal cardiac failure.
During treatment with Lopressor, the hemodynamic status of the patient should be carefully monitored. If heart failure occurs or persists despite appropriate treatment, Lopressor should be discontinued.
Bradycardia: Lopressor produces a decrease in sinus heart rate in most patients; this decrease is greatest among patients with high initial heart rates and least among patients with low initial heart rates. Acute myocardial infarction (particularly inferior infarction) may in itself produce significant lowering of the sinus rate. If the sinus rate decreases to < 40 beats/min, particularly if associated with evidence of lowered cardiac output, atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, Lopressor should be discontinued, and cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.
AV Block: Lopressor slows AV conduction and may produce significant first- (P-R interval ≥0.26 sec), second-, or third-degree heart block. Acute myocardial infarction also produces heart block.
If heart block occurs, Lopressor should be discontinued and atropine (0.25-0.5 mg) should be administered intravenously. If treatment with atropine is not successful, cautious administration of isoproterenol or installation of a cardiac pacemaker should be considered.
Hypotension: If hypotension (systolic blood pressure ≤ 90 mmHg) occurs, Lopressor should be discontinued, and the hemodynamic status of the patient and the extent of myocardial damage carefully assessed. Invasive monitoring of central venous, pulmonary capillary wedge, and arterial pressures may be required. Appropriate therapy with fluids, positive inotropic agents, balloon counterpulsation, or other treatment modalities should be instituted. If hypotension is associated with sinus bradycardia or AV block, treatment should be directed at reversing these (see above).
Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, Lopressor may be used with extreme caution in patients with bronchospastic disease. Because it is unknown to what extent beta$_2$-stimulating agents may exacerbate myocardial ischemia and the extent of infarction, these agents should *not* be used prophylactically. If bronchospasm not related to congestive heart failure occurs, Lopressor should be discontinued. A theophylline derivative or a beta$_2$ agonist may be administered cautiously, depending on the clinical condition of the patient. Both theophylline derivatives and beta$_2$ agonists may produce serious cardiac arrhythmias.**

PRECAUTIONS
General
Lopressor should be used with caution in patients with impaired hepatic function.
Information for Patients
Patients should be advised to take Lopressor regularly and continuously, as directed, with or immediately following meals. If a dose should be missed, the patient should take only the next scheduled dose (without doubling it). Patients should not discontinue Lopressor without consulting the physician.
Patients should be advised (1) to avoid operating automobiles and machinery or engaging in other tasks requiring alertness until the patient's response to therapy with Lopressor has been determined; (2) to contact the physician if any difficulty in breathing occurs; (3) to inform the physician or dentist before any type of surgery that he or she is taking Lopressor.
Laboratory Tests
Clinical laboratory findings may include elevated levels of serum transaminase, alkaline phosphatase, and lactate dehydrogenase.
Drug Interactions
Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension or marked bradycardia, which may produce vertigo, syncope, or postural hypotension.
Carcinogenesis, Mutagenesis, Impairment of Fertility
Long-term studies in animals have been conducted to evaluate carcinogenic potential. In 2-year studies in rats at three oral dosage levels of up to 800 mg/kg per day, there was no increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes that appeared to be drug related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in Swiss albino mice at three oral dosage levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant or total (benign plus malignant) lung tumors, nor in the overall incidence of tumors or malignant tumors. This 21-month study was repeated in CD-1 mice, and no statistically or biologically significant differences were observed between treated and control mice of either sex for any type of tumor.
All mutagenicity tests performed (a dominant lethal study in mice, chromosome studies in somatic cells, a Salmonella/mammalian-microsome mutagenicity test, and a nucleus anomaly test in somatic interphase nuclei) were negative.
No evidence of impaired fertility due to Lopressor was observed in a study performed in rats at doses up to 55.5 times the maximum daily human dose of 450 mg.
Pregnancy Category C
Lopressor has been shown to increase postimplantation loss and decrease neonatal survival in rats at doses up to 55.5 times the maximum daily human dose of 450 mg. Distribution studies in mice confirm exposure of the fetus when Lopressor is administered to the pregnant animal. These studies have revealed no evidence of impaired fertility or teratogenicity. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers
Lopressor is excreted in breast milk in very small quantity. An infant consuming 1 liter of breast milk daily would receive a dose of less than 1 mg of the drug. Caution should be exercised when Lopressor is administered to a nursing woman.
Pediatric Use
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Hypertension and Angina
Most adverse effects have been mild and transient.
Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression has been reported in about 5 of 100 patients. Mental confusion and short-term memory loss have been reported. Headache, nightmares, and insomnia have also been reported.
Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations; congestive heart failure; peripheral edema; and hypotension have been reported in about 1 of 100 patients. (See **CONTRAINDICATIONS, WARNINGS,** and **PRECAUTIONS**.)
Respiratory: Wheezing (bronchospasm) and dyspnea have been reported in about 1 of 100 patients (see **WARNINGS**).
Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, dry mouth, gastric pain, constipation, flatulence, and heartburn have been reported in about 1 of 100 patients.
Hypersensitive Reactions: Pruritus or rash have occurred in about 5 of 100 patients. Worsening of psoriasis has also been reported.
Miscellaneous: Peyronie's disease has been reported in fewer than 1 of 100,000 patients. Musculoskeletal pain, blurred vision, and tinnitus have also been reported.
There have been rare reports of reversible alopecia, agranulocytosis, and dry eyes. Discontinuation of the drug should be considered if any such reaction is not otherwise explicable.
The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor.
Myocardial Infarction
Central Nervous System: Tiredness has been reported in about 1 of 100 patients. Vertigo, sleep disturbances, hallucinations, headache, dizziness, visual disturbances, confusion, and reduced libido have also been reported, but a drug relationship is not clear.
Cardiovascular: In the randomized comparison of Lopressor and placebo described in the **CLINICAL PHARMACOLOGY** section, the following adverse reactions were reported:

	Lopressor	*Placebo*
Hypotension (systolic BP < 90 mmHg)	27.4%	23.2%
Bradycardia (heart rate < 40 beats/min)	15.9%	6.7%
Second- or third-degree heart block	4.7%	4.7%
First-degree heart block (P-R ≥ 0.26 sec)	5.3%	1.9%
Heart failure	27.5%	29.6%

Respiratory: Dyspnea of pulmonary origin has been reported in fewer than 1 of 100 patients.
Gastrointestinal: Nausea and abdominal pain have been reported in fewer than 1 of 100 patients.
Dermatologic: Rash and worsened psoriasis have been reported, but a drug relationship is not clear.
Miscellaneous: Unstable diabetes and claudication have been reported, but a drug relationship is not clear.
Potential Adverse Reactions
A variety of adverse reactions not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse reactions to Lopressor.
Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.
Cardiovascular: Intensification of AV block (see **CONTRAINDICATIONS**).
Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.
Hypersensitive Reactions: Fever combined with aching and sore throat, laryngospasm, and respiratory distress.

OVERDOSAGE
Acute Toxicity
Several cases of overdosage have been reported, some leading to death.
Oral LD_{50}'s (mg/kg): mice, 1158-2460; rats, 3090-4670.
Signs and Symptoms
Potential signs and symptoms associated with overdosage with Lopressor are bradycardia, hypotension, bronchospasm, and cardiac failure.
Treatment
There is no specific antidote.
In general, patients with acute or recent myocardial infarction may be more hemodynamically unstable than other patients and should be treated accordingly (see **WARNINGS, Myocardial Infarction**).
On the basis of the pharmacologic actions of Lopressor, the following general measures should be employed:
Elimination of the Drug: Gastric lavage should be performed.
Bradycardia: Atropine should be administered. If there is no response to vagal blockade, isoproterenol should be administered cautiously.
Hypotension: A vasopressor should be administered, e.g., levarterenol or dopamine.
Bronchospasm: A beta$_2$-stimulating agent and/or a theophylline derivative should be administered.
Cardiac Failure: A digitalis glycoside and diuretic should be administered. In shock resulting from inadequate cardiac contractility, administration of dobutamine, isoproterenol, or glucagon may be considered.

24-hour security for the hypertensive heart

First-step cardiovascular protection

Reduces workload of the heart by reducing myocardial O_2 demand

Preserves K^+ balance

Normalizes stress-induced systolic peaks with cardioselective beta-one blockade

Contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet

Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR (procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

> The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: Hypersensitivity to procainamide is an absolute contraindication. In this connection, cross-sensitivity to procaine and related drugs must be borne in mind.

Procainamide should not be administered to patients with complete atrioventricular heart block. It is also contraindicated in cases of second degree and third degree A-V nodal block unless an electrical pacemaker is operative.

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis.

WARNINGS: Granulocytopenia may follow the use of procainamide, and deaths from sepsis have occurred. Leukocyte changes are most likely to occur during the first three months of therapy. During this time routine blood counts should be done at least every two weeks and thereafter at longer intervals throughout maintenance procainamide therapy. Complaints of malaise and aches (a flu-type syndrome) are often reported in association with the granulocyte depression.

Patients should be instructed to report such symptoms promptly, as well as any soreness of mouth, throat or gums, unexplained fever, or symptoms of an upper respiratory tract infection. If these should occur and a complete blood count indicates a granulocyte depression, procainamide therapy should be discontinued immediately and appropriate treatment instituted. Recovery of leukocyte count usually occurs within a few weeks.

The incidence of granulocytopenia appears to be higher with procainamide sustained-release tablets than with standard tablets.

PRECAUTIONS: General — During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgment of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Serious hypotension can result from peripheral vasodilation and from decreases in cardiac output. At high plasma levels, procainamide may produce sinus tachycardia due to reflex sympathetic response to its hypotensive effect. Large doses may increase cardiac automaticity and can induce complete atrioventricular block, cardiac standstill, or ventricular extrasystoles that may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram: a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged; and the QRS and T waves show some decrease in voltage.

Antinuclear antibodies (ANA) are often found in patients receiving long-term procainamide therapy. The induction of ANA appears to be independent of dosage. Patients with procainamide-induced increases in ANA titers may develop a syndrome resembling systemic lupus erythematosus (SLE). The mechanism of this syndrome is uncertain. Polyarthralgia, arthritic symptoms, and pleuritic pain are common symptoms; to a lesser extent fever, myalgia, skin lesions, pleural effusion, pericarditis, headache, fatigue, weakness, nausea and abdominal pain may occur. Rare cases of thrombocytopenia, Coombs' positive hemolytic anemia, increased SGOT, SGPT, and serum amylase have been reported which may be related to this SLE-like syndrome.

It is recommended that tests for systemic lupus erythematosus be carried out at regular intervals in patients receiving maintenance or prolonged procainamide therapy. The drug should be discontinued if there is a rising ANA titer or clinical symptoms of SLE appear. The SLE-like syndrome may be reversible upon discontinuation of the drug. If discontinuation does not cause remission of the symptoms, corticosteroid therapy may be effective. If the SLE-like syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, corticosteroid suppressive therapy may be used concomitantly with procainamide.

Information for Patient — Practitioners should give the following information and instructions to patients receiving Procan SR. 1. Do not crush or chew these tablets. Swallow them whole. 2. Take this medicine exactly as directed by your doctor. Do not miss any doses and do not take more medicine than ordered. Do not stop taking this medicine without first checking with your doctor. 3. If you miss a dose and remember within one hour or so, take it as soon as possible. Then go back to your regular dosing schedule. Do not take double doses. If you have any questions about this, check with your doctor. 4. Report to your doctor any flu-type symptoms, such as malaise and aches, as well as any soreness of the mouth, throat or gums, unexplained fever, skin rash, unusual bleeding or bruising, symptoms that resemble arthritis, or symptoms of an upper respiratory tract infection. 5. Do not be concerned if you occasionally notice in your stool something that looks like a tablet. In Procan SR (procainamide hydrochloride tablets), the drug is "held" in a wax core that has been specially designed to slowly release the drug for your body to absorb. When this process is completed the empty, nonabsorbable wax core, which looks nearly unchanged, is eliminated from your body. 6. Keep container tightly closed and store in a cool, dry place.

Laboratory Tests — Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals.

Routine blood counts are advisable during maintenance procainamide therapy. See WARNINGS for additional information.

Plasma concentrations of procainamide and NAPA should be monitored in patients with renal disease, hepatic disease, cardiac failure, or low cardiac output states.

Drug Interactions: 1. **Antiarrhythmics:** Concurrent use with procainamide may result in additive cardiac effects and/or additive toxic effects. 2. **Anticholinergics:** Procainamide enhances the anticholinergic effects. Extreme caution must be exercised with such a combination. 3. **Anticholinesterases:** Procainamide antagonizes the effect of anticholinesterases in myasthenia gravis, and paralysis returns. 4. **Antihypertensives:** Procainamide may potentiate the hypotensive effects of thiazide diuretics and other antihypertensive agents. Adjustment of dosage may be required. 5. **Histamine H_2-receptor antagonists:** It has been reported that histamine H_2-receptor antagonists such as cimetidine and ranitidine reduce renal clearance of procainamide and NAPA, resulting in higher plasma concentrations for longer durations. Caution should be exercised when administering these drugs concurrently, especially in the elderly, who have a reduced ability to clear all three. Dosage modification may be required. 6. **Neuromuscular Blocking Agents:** Procainamide potentiates the effects of skeletal muscle relaxants such as succinylcholine. It also may enhance or prolong the neuromuscular blocking activity of bacitracin, colistimethate, dihydrostreptomycin, gentamicin, gramicidin, kanamycin, neomycin, polymyxin B, streptomycin, and viomycin, producing respiratory depression.

Pregnancy — Pregnancy Category C. Animal reproduction studies have not been conducted with procainamide. It is also not known whether procainamide can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Procainamide should be given to a pregnant woman only if clearly needed.

Nursing Mothers — Procainamide and its major metabolite, NAPA, have been identified in breast milk. Caution should be exercised when procainamide is administered to a nursing woman.

ADVERSE REACTIONS: Most frequent, especially with large oral doses: 1. Anorexia; 2. Nausea; 3. Vomiting; 4. Diarrhea; 5. Urticaria; 6. Pruritus.

Less frequent: 1. Reactions in patients on long-term procainamide therapy: a. Antinuclear antibodies (ANA); b. Syndrome resembling systemic lupus erythematosus (SLE) (See PRECAUTIONS); 2. Hypersensitivity reactions: a. Angioneurotic edema; b. Maculopapular rash; c. Fever; d. Eosinophilia; e. Hypergammaglobulinemia.

Infrequent: 1. Granulocytopenia, sometimes resulting in death (See WARNINGS); 2. Convulsions; 3. Psychosis with hallucinations; 4. Confusion; 5. Mental depression; 6. Giddiness; 7. Lightheadedness; 8. Weakness; 9. Bitter taste.

Rare: 1. Hypotension; 2. A case was reported with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following a single dose of the drug.

OVERDOSAGE: Signs and Symptoms: Severe hypotension, ventricular fibrillation, widening of QRS complex, junctional tachycardia, intraventricular conduction delay, oliguria, lethargy, confusion, nausea, and vomiting.

Treatment: If ingestion is recent, emesis, activated charcoal, or gastric lavage may reduce absorption. Dopamine, phenylephrine, or levarterenol may be helpful in reversing severe hypotensive responses.

Management of overdosage includes symptomatic treatment with ECG and blood pressure monitoring. Procainamide toxicity can usually be treated, if necessary, by administering vasopressors after adequate fluid volume replacement. Intravenous infusion of 1/6 molar sodium lactate injection reportedly reduces the cardiotoxic effects of procainamide.

If procainamide toxicity causes severe hypotension and renal insufficiency, urinary elimination of procainamide and NAPA is decreased, and hemodialysis may be required. Hemodialysis significantly reduces the serum half-life of procainamide, and effectively removes procainamide and NAPA. Peritoneal dialysis is not effective.

It has been reported that one patient who ingested approximately 7 grams of procainamide hydrochloride recovered after treatment consisting of IV levarterenol, IV furosemide, attempted volume expansion with albumin, and hemodialysis. Also reported is the case of an elderly patient who recovered after ingestion of approximately 19 grams of procainamide hydrochloride. The patient was treated with IV isoproterenol and IV epinephrine. The latter report suggested that insertion of a ventricular pacing electrode is a reasonable precautionary measure in case high grade A-V block develops.

Storage Conditions: Protect from moisture. Store bottles below 30°C (86°F). Store unit-dose packages at controlled room temperature, 15°-30°C (59°-86°F).

Caution — Federal law prohibits dispensing without prescription. 0207G014

2nd edition just published

A Synopsis of Cancer Chemotherapy

Completely revised and updated to include the latest information on drug interactions in cancer chemotherapy

The reader can quickly find the following for both commercially available and investigational drugs:

- Structure
- Mechanism of Action
- Pharmacokinetics
- Toxicity
- Therapy
- Dosage forms

The chemotherapeutic agents in the main listing section cover these categories:

Alkylating Agents
Antimetabolites
Mitotic Inhibitors
Antibiotics
Miscellaneous (includes such drugs as Interferons, Mithramycin, Mitotane, etc.)

A new section in this second edition is a basic introduction for understanding principles of chemotherapy, "Synopsis of Cancer Growth Kinetics and Chemotherapy." Other new sections include "Hormonal Agents," "Treatment of Extravasation," "Safe Handling of Parenteral Chemotherapy Agents," and an updated listing of the more commonly used combination chemotherapy regimens. Finally, a section on "Interferons."

Written by three leading authorities on the use of chemotherapeutic agents

Richard T. Silver, M.D.
Chief, Section of Oncology, Chemotherapy Research
Division of Hematology-Oncology
Former Vice-Chairman, Cancer and Leukemia Group B.
Clinical Professor of Medicine, Cornell University Medical College
Attending Physician, The New York Hospital

R. David Lauper, Pharm.D.
Associate Director Professional Services, Cetus Corporation

Charles I. Jarowski, M.D.
Clinical Assistant Professor of Medicine, Cornell University Medical College
Assistant Attending Physician, The New York Hospital

With an introduction by:
Larry Norton, M.D.
Associate Professor of Neoplastic Diseases, Mount Sinai School of Medicine
Associate Attending Physician, Mount Sinai Hospital

Continuing developments in clinical chemotherapy since 1977 have encouraged us to prepare this second edition.

The need for a book of this kind has increased because of the larger number of oncologists, general internists, nurse oncologists, clinical pharmacists, surgeons, students and allied health personnel interested in a concise and accurate guide to cancer chemotherapeutic drugs.

USE IT FOR 30 DAYS—FREE

Refer to it for chemotherapeutic information for a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

Butterworths, 80 Montvale Ave., Stoneham, MA 02180

CONSIDER THE ENTIRE CARDIOVASCULAR STATUS...

AVAILABLE IN 40-mg TITRADOSE® TABLETS

In routine angina...
In angina with concurrent congestive heart failure...

ISORDIL®
(isosorbide dinitrate)

- Relieves the myocardial pain
- Decreases preload—dilates large veins to reduce venous return to the heart
- Decreases afterload—arteriolar relaxation lowers systemic vascular resistance and arterial pressure

CONSIDER THE COMPLEXITIES...ACCEPT NO SUBSTITUTES.

ISORDIL®
(isosorbide dinitrate)

Contraindications: Hypersensitivity or idiosyncrasy to this drug or other nitrates or nitrites.

Warnings: Benefits of use during early days of acute myocardial infarction have not been established; if used in early infarction, hemodynamic monitoring and frequent clinical assessment should be made because of potential deleterious effects of hypotension.

Precautions: *General.* Severe hypotensive response, particularly with upright posture, may occur even with small doses; therefore use caution in subjects with blood volume depletion from diuretic therapy or with low systolic blood pressure (eg, below 90 mm Hg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrates may aggravate angina caused by hypertrophic cardiomyopathy. Tolerance to this drug and cross-tolerance to other nitrates and nitrites and physical dependence may occur. Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination; dose adjustment of either class of agents may be necessary. There are reports of anginal attacks being more easily provoked and of rebound in hemodynamic effects soon after nitrate withdrawal; when therapy is being terminated, withdraw the drug gradually rather than stopping it abruptly.

Information for Patients. Headache may occur during initial therapy, is usually relieved by standard headache remedies or by lowering dose, and tends to disappear after first week or two.

Drug Interactions. Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates. Isosorbide dinitrate acts directly on vascular smooth muscle; therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect, depending on the agent.

Carcinogenesis, Mutagenesis, Impairment of Fertility. No long-term studies in animals have been performed.

Pregnancy Category C. Use during pregnancy only if the potential benefit justifies the potential risk to the fetus. There are no adequate and well-controlled studies in pregnant women.

Nursing Mothers. It is not known whether this drug is excreted in human milk; because many drugs are excreted in human milk, caution should be exercised in nursing women.

Pediatric Use. Safety and effectiveness in children have not been established.

Adverse Reactions, particularly headache and hypotension, are dose related. At various doses, the following have been observed: Headache is the most common (average occurrence about 25%) and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to hypotensive effects of nitrates; severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear uncommon.

Overdosage: *Treatment.* Prompt removal of the ingested material by gastric lavage is reasonable but not documented to be useful. Keep the patient recumbent in a shock position and comfortably warm. Passive movements of the extremities may aid venous return. Administer oxygen and artificial respiration if necessary. Conventional doses of organic nitrates could produce harmful concentrations of methemoglobin. If methemoglobinemia is present, administer methylene blue (1% solution), 1 to 2 mg/kg intravenously. WARNING: Epinephrine is ineffective in reversing the severe hypotensive events associated with overdose. It and related compounds are contraindicated in this situation.

Consult package insert before prescribing.

ABC

Contents in Brief

APRIL 15, 1988
VOLUME 61
NUMBER 11

MISCELLANEOUS TOPICS

875
Left Ventricular Dysfunction After Prolonged Strenuous Exercise in Healthy Subjects.
Douglas R. Seals, Marc A. Rogers, James M. Hagberg, Chikashi Yamamoto, Philip E. Cryer, and Ali A. Ehsani

880
The 24-Hour Heart Rate Behavior in Long-Term Survivors of Cardiac Transplantation.
Dimitrios Alexopoulos, Salim Yusuf, Jim A. Johnston, Julian Bostock, Peter Sleight and Magdi H. Yacoub

METHODS

885
Optimal Lead Subsets for Reconstruction of QRS and ST-T in 35-Lead Precordial Maps.
Christopher D. McManus, Alan S. Berson, Jorge C. Rios, Emigdio A. Lopez, and Hubert V. Pipberger

891
Limits of Reproducibility of Mitral Pulsed Doppler Spectra.
Jules Fast, Ina Van Dam, Anco Heringa, Theo De Boo, Jos Alsters, Jeroen Hopman, Otto Daniels, and Lambert Van Den Merkhof

HISTORICAL STUDIES

895
From Irritable Heart to Mitral Valve Prolapse: World War I—The U.S. Experience and the Prevalence of Apical Systolic Murmurs and Mitral Regurgitation in Drafted Men Compared with Present Day Mitral Valve Prolapse Studies.
Charles F. Wooley and Harisios Boudoulas

900
Lewis A. Conner, MD (1867–1950), and Lessons Learned from Examining Four Million Young Men in World War I.
Charles F. Wooley

BRIEF REPORTS

904
Low Dose Aspirin After Early Thrombolysis in Anterior Wall Acute Myocardial Infarction.
Freek W.A. Verheugt, Albert J. Funke Küpper, Tjebbe W. Galema, and Jan P. Roos

906
Treatment of Recurrent Restenosis with Repeat Percutaneous Transluminal Coronary Angioplasty.
Patrick Joly, Raoul Bonan, Donald Palisaitis, Angel Cequier, Jacques Crépeau, Gilles Coté, Pierre De Guise, and David D. Waters

908
Effect of Nifedipine on Out-of-Hospital Silent Myocardial Ischemia in Asymptomatic Men with Coronary Artery Disease.
Peter F. Cohn and William E. Lawson, with the technical assistance of Virginia Gennaro and Dorothy Brady

910
Relation of Left Ventricular Free Wall Rupture in Acute Myocardial Infarction to Forced Immobilization.
Christian Torp-Pedersen, Frank Steensgaard Hansen, and Asger Pedersen

912
Assessment of Left Ventricular Volume Changes During Exercise Radionuclide Angiography in Coronary Artery Disease.
Pierce J. Vatterott, Raymond J. Gibbons, David C.K. Hu, Manuel L. Brown, and Ian P. Clements

914
Propafenone for Prevention of Recurrent Atrial Fibrillation.
Charles R. Kerr, George J. Klein, James E. Axelson, and Jocelyn C. Cooper

916
Ventriculoatrial Conduction and Atrial Activation During Ventricular Flutter and Fibrillation.
Guido Capella, Pedro Brugada, and Hein J.J. Wellens

919
Fatal and Nonfatal Cardiac Arrest in Patients with an Implanted Antitachycardia Device for the Treatment of Supraventricular Tachycardia.
Chu Pak Lau, Elizabeth Cornu, and A. John Camm

922
Analysis of Antiarrhythmic Drug Concentrations Determined During Electrophysiologic Drug Testing in Patients with Inducible Tachycardias.
Nada S. Berry, Jerry L. Bauman, Jose L. Gallastegui, Wayne Bauma, Karen J. Beckman, and Robert J. Hariman

925
Acute Termination of Supraventricular Tachyarrhythmias in Children by Transesophageal Atrial Pacing.
Macdonald Dick II, William A. Scott, Gerald S. Serwer, Burt I. Bromberg, Robert H. Beekman, Albert P. Rocchini, A. Rebecca Snider, Dennis C. Crowley, and Amnon Rosenthal

928
Color and Pulsed-Wave Doppler Study of Aortic Regurgitation in Systemic Hypertension.
Carlo Vigna, Aldo Russo, Mauro Pellegrino Salvatori, Francesco Laurenzi, Gianpiero Perna, Alessandro Villella, Tommaso Langialonga, Raffaele Fanelli, and Francesco Loperfido

930
Early Results of Balloon Angioplasty of Native Aortic Coarctation in Young Adults.
Ihab M. Attia and Zuhdi A. Lababidi

932
Effects of Repeated Increments in Right Atrial Pressure on Secretion of Atrial Natriuretic Factor.
Mathias C. Haufe, Jochen Weil, Rupert Gerzer, Johanna E. Ernst, and Karl Theisen

934
Lipoprotein Profiles of Elite Veteran Endurance Athletes.
Robin J. Northcote, Gordon C. Canning, Iain C. Todd, and David Ballantyne

936
Idioventricular Rates in Early and Late Phases of Acute Myocardial Infarction.
Jaok Han, Myung S. Yoon, and George H. Dersham

INSTRUCTIONS TO AUTHORS
on page 957

ADD CAPTEN® SOONER*...

(captopril tablets)

SQUIBB

COMPLETE THE JOB YOUR LOOP DIURETIC STARTED

In patients symptomatic on diuretic and digitalis

- ☐ Adding CAPOTEN enhances the diuretic effect of furosemide
  - —Disappearance of edema in 55% of a subgroup of patients after adding CAPOTEN to furosemide†[1]
- ☐ Adding CAPOTEN improves exercise tolerance times in mild, moderate, and severe heart failure patients[2]

IN MILD, MODERATE, AND SEVERE HEART FAILURE (NYHA Class II, III, and IV)

CAPOTEN®

(captopril tablets)

CLOSING THE LOOP IN HEART FAILURE THERAPY

*CAPOTEN is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis. In using CAPOTEN, consideration should be given to the risk of neutropenia/agranulocytosis. Use special precautions in patients with impaired renal function, collagen vascular disorders, or those exposed to other drugs known to affect the white cells or immune response. Evaluation of heart failure patients should always include assessment of renal function. See INDICATIONS AND USAGE, CONTRAINDICATIONS, WARNINGS, and ADVERSE REACTIONS in the brief summary of prescribing information on adjacent page.

†Patients for whom data were available for two months. Patients were NYHA Class II, III, or IV receiving concomitant diuretic and digitalis therapy.

CLOSING THE LOOP IN HEART FAILURE THERAPY

SQUIBB

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension – CAPOTEN (captopril) is indicated for the treatment of hypertension. Consideration should be given to the risk of neutropenia/agranulocytosis (see WARNINGS). CAPOTEN may be used as initial therapy for patients with normal renal function, in whom the risk is relatively low. In patients with impaired renal function, particularly those with collagen vascular disease, captopril should be reserved for those who have either developed unacceptable side effects on other drugs, or have failed to respond satisfactorily to drug combinations. CAPOTEN is effective alone and in combination with other antihypertensive agents, especially thiazide-type diuretics.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

CONTRAINDICATIONS: CAPOTEN is contraindicated in patients who are hypersensitive to this product.

WARNINGS: Neutropenia/Agranulocytosis – Neutropenia ($<1000/mm^3$) with myeloid hypoplasia has resulted from use of captopril. About half of the neutropenic patients developed systemic or oral cavity infections or other features of the syndrome of agranulocytosis. The risk of neutropenia is dependent on the clinical status of the patient:

In clinical trials in patients with hypertension who have normal renal function (serum creatinine less than 1.6 mg/dL and no collagen vascular disease), neutropenia has been seen in one patient out of over 8,600 exposed. In patients with some degree of renal failure (serum creatinine at least 1.6 mg/dL) but no collagen vascular disease, the risk in clinical trials was about 1 per 500. Doses were relatively high in these patients, particularly in view of their diminished renal function. In patients with collagen vascular diseases (e.g., systemic lupus erythematosus, scleroderma) and impaired renal function, neutropenia occurred in 3.7% of patients in clinical trials. While none of the over 750 patients in formal clinical trials of heart failure developed neutropenia, it has occurred during the subsequent clinical experience. Of reported cases, about half had serum creatinine ≥ 1.6 mg/dL and more than 75% received procainamide. In heart failure, it appears that the same risk factors for neutropenia are present.

Neutropenia has appeared usually within 3 months after starting therapy, associated with myeloid hypoplasia and frequently accompanied by erythroid hypoplasia and decreased numbers of megakaryocytes (e.g., hypoplastic bone marrow and pancytopenia); anemia and thrombocytopenia were sometimes seen. Neutrophils generally returned to normal in about 2 weeks after captopril was discontinued, and serious infections were limited to clinically complex patients. About 13% of the cases of neutropenia have ended fatally, but almost all fatalities were in patients with serious illness, having collagen vascular disease, renal failure, heart failure or immunosuppressant therapy, or a combination of these complicating factors. **Evaluation of the hypertensive or heart failure patient should always include assessment of renal function.** If captopril is used in patients with impaired renal function, white blood cell and differential counts should be evaluated prior to starting treatment and at approximately 2-week intervals for about 3 months, then periodically. In patients with collagen vascular disease or who are exposed to other drugs known to affect the white cells or immune response, particularly when there is impaired renal function, captopril should be used only after an assessment of benefit and risk, and then with caution. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat, fever). If infection is suspected, perform white cell counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count $<1000/mm^3$) withdraw captopril and closely follow the patient's course.

Proteinuria: Total urinary proteins >1 g per day were seen in about 0.7% of patients on captopril. About 90% of affected patients had evidence of prior renal disease or received high doses (>150 mg/day), or both. The nephrotic syndrome occurred in about one-fifth of proteinuric patients. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients. Since most cases of proteinuria occurred by the 8th month of therapy with captopril, patients with prior renal disease or those receiving captopril at doses >150 mg per day, should have urinary protein estimates (dip-stick on 1st morning urine) before therapy, and periodically thereafter.

Hypotension: Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]). In heart failure, where the blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function* – Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis due to decreased afterload reduction. *Surgery/Anesthesia* – If hypotension occurs during surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension – Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the 1st hour after administration of the initial of captopril dose in patients on diuretics, especially those recently placed on diuretics, and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy or by initiating therapy with small doses (6.25 or 12.5 mg). Alternatively, provide medical supervision for at least 1 hour after the initial dose.

Agents Having Vasodilator Activity – In heart failure patients, vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. Use potassium-containing salt substitutes with caution.

Inhibitors of Endogenous Prostaglandin Synthesis – Indomethacin and other nonsteroidal anti-inflammatory agents may reduce the antihypertensive effect of captopril, especially in low renin hypertension.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Pregnancy: Category C: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects and craniofacial malformations were observed in rabbits. Therefore, captopril should be used during pregnancy, or for patients likely to become pregnant, only if the potential benefit outweighs the potential risk to the fetus. Captopril crosses the human placenta.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. CAPOTEN (captopril) should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 7000 patients.

Renal – About 1 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic – Neutropenia/agranulocytosis has occurred (see WARNINGS). Anemia, thrombocytopenia, and pancytopenia have been reported.

Dermatologic – Rash, (usually maculopapular, rarely urticarial), often with pruritus, and sometimes with fever and eosinophilia, in about 4 to 7 of 100 patients (depending on renal status and dose), usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity, have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 1000 patients – reversible on discontinuance of captopril therapy. One case of laryngeal edema has been reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular – Hypotension may occur; see WARNINGS and PRECAUTIONS [Drug Interactions] for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia – Approximately 2 to 4 (depending on renal status and dose) of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, cough, alopecia, paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice, and hepatocellular injury with or without secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertension patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg and 50 mg also available in bottles of 1000), and in UNIMATIC® unit-dose packs of 100 tablets. (J3-658J)

IN CERTAIN DYSLIPIDEMIAS

A Desirable Balance of Efficac

LOPID® *300 mg*
(gemfibrozil capsules, USP)

Lopid is indicated for treatment of adult patients with very high serum triglyceride levels in hyperlipoproteinem other than type I who present a risk of pancreatitis and who do not respond adequately to diet.

© 1987 Warner-Lambert Company

with Patient Acceptance

Efficacy Lopid reduces synthesis[1-3] and increases clearance of triglyceride-rich VLDL.[2,3]

Patient acceptance Lopid has a very low order of side effects and has demonstrated limited effects on clinical and laboratory evaluations.[4]

Convenient BID dosage Two 300-mg capsules taken 30 minutes before morning and evening meals help ensure patient compliance.

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

PARKE-DAVIS

Please see next page for references and a brief summary of prescribing information.

LOPID®
(gemfibrozil capsules, USP) 300 mg

Before prescribing, please see full prescribing information. A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. It has been reported that LOPID may increase levels of high density lipoprotein (HDL) subfractions, HDL_2 and HDL_3 as well as apolipoproteins AI and AII. Epidemiological studies have shown that both low HDL-cholesterol and high LDL-cholesterol are independent risk factors for coronary heart disease. It is not yet known whether pharmacological interventions designed to raise HDL-cholesterol alter morbidity or mortality due to coronary heart disease.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID inhibits synthesis and increases clearance of VLDL carrier apolipoprotein B, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, mostly as the glucuronide conjugate, with less than 2% excreted as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. The initial treatment for hyperlipidemia is dietary therapy specific for the type of hyperlipoproteinemia. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV or type V hyperlipoproteinemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk. LOPID has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of gemfibrozil-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies – Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID (gemfibrozil capsules, USP) administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis – LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants – Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy** – Before instituting LOPID therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy** – Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Impairment of Fertility** – Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

4. **Pregnancy Category B** – Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

5. **Nursing Mothers** – Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

6. **Hematologic Changes** – Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

7. **Liver Function** – Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

8. **Use in Children** – Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints, myositis

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope, alopecia

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

Caution – Federal law prohibits dispensing without prescription.

MISCELLANEOUS TOPICS

875 **Left Ventricular Dysfunction After Prolonged Strenuous Exercise in Healthy Subjects**

Douglas R. Seals, Marc A. Rogers, James M. Hagberg, Chikashi Yamamoto, Philip E. Cryer, and Ali A. Ehsani

To examine whether left ventricular dysfunction can occur following prolonged strenuous exercise in healthy subjects, 12 young men were studied before and after 170 ± 10 minutes of exercise at an intensity of 70% of their maximal aerobic capacity. Ejection phase indexes of left ventricular function, assessed by echocardiography, decreased after exhausting exercise despite a lower end-systolic wall stress. Plasma free fatty acids increased after exhausting exercise. The data suggest that exhausting exercise can result in impaired left ventricular function in healthy young subjects.

880 **The 24-Hour Heart Rate Behavior in Long-Term Survivors of Cardiac Transplantation**

Dimitrios Alexopoulos, Salim Yusuf, Jim A. Johnston, Julian Bostock, Peter Sleight, and Magdi H. Yacoub

Ambulatory monitoring of heart rate (HR) was performed in 19 long-term survivors of cardiac transplantation (12 orthotopic, 7 heterotopic) and in 10 normal volunteers. The transplanted denervated and the recipient innervated hearts in the heterotopic group showed higher than normal average HRs over 24 hours, waking and sleeping periods. Maximal HR was similar in the 3 groups, but the minimal HR was lower in normal hearts than in the denervated and recipient hearts. The 24-hour HR variability was reduced in the denervated hearts. During arousal from sleep, HR changes were smaller in the denervated and recipient hearts compared with normal hearts. The denervated heart can show significant HR variations, but to a lesser extent than normal. In heterotopic transplant recipients, the patients' own HR changes also are significantly blunted.

METHODS

885 **Optimal Lead Subsets for Reconstruction of QRS and ST-T in 35-Lead Precordial Maps**

Christopher D. McManus, Alan S. Berson, Jorge C. Rios, Emigdio A. Lopez, and Hubert V. Pipberger

Precordial maps have been used for 15 years to estimate extent of myocardial injury in patients with acute anterior or lateral wall infarction. Application of the electrodes, commonly 35, is cumbersome and time-consum-

ing with the critically ill. A subset of only 5 or 7 selected leads can be applied instead, and the remaining leads calculated from the subset with minimal loss of QRS and ST-T information. Maps were recorded from 100 patients within 72 hours of onset of infarct. Optimal subsets numbering between 2 and 15 leads were derived, with their lead-transform coefficients, by the sequential selection method of Lux. Reconstruction from a 7-lead subset had a mean 0.92 correlation with ST-T in the original leads and root-mean-square error of only 0.04 mV. Sum of ST elevation differed by only 2% between original leads and reconstructions based on 5 or more leads.

891 Limits of Reproducibility of Mitral Pulsed Doppler Spectra

Jules Fast, Ina Van Dam, Anco Heringa, Theo De Boo, Jos Alsters, Jeroen Hopman, Otto Daniels, and Lambert Van Den Merkhof

In this study we evaluated the total intrinsic variability of pulsed Doppler spectra of mitral blood flow. Doppler examinations were performed in 10 normal volunteers (7 men, 3 women), ages 29 to 57 years with an interval period of 3 months. The recordings were made in the apical 4-chamber view. The sample was placed approximately 1 cm proximal (left atrium) and 1 cm distal (left ventricle) of the middle of the anulus of the mitral valve at the onset of diastole. Mitral peak velocities, accelerations and spectral widths were measured in early diastole and late diastole. From the parameters under investigation, maximal velocities showed the best reproducibility with a range of coefficients of variation of 9 to 13%. Peak acceleration in early diastole and spectral widths showed rather large coefficients of variation, ranging from 19 to 30 and 14 to 24%, respectively. Mitral pulsed Doppler spectra in the left atrium were more reproducible than in the left ventricle.

CARDIZEM® FEW SIDE EFFECTS IN ANTIANGINAL THERAPY

diltiazem HCl/Marion

60 mg tid or qid

BRIEF SUMMARY
Professional Use Information

CARDIZEM®
(diltiazem HCl)
30 mg, 60 mg, 90 mg, and 120 mg Tablets

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, (3) patients with hypotension (less than 90 mm Hg systolic), and (4) patients who have demonstrated hypersensitivity to the drug.

WARNINGS

1. ***Cardiac Conduction.*** *CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1,243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.*
2. ***Congestive Heart Failure.*** *Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.*
3. ***Hypotension.*** *Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.*
4. ***Acute Hepatic Injury.*** *In rare instances, significant elevations in enzymes such as alkaline phosphatase, LDH, SGOT, SGPT, and other phenomena consistent with acute hepatic injury have been noted. These reactions have been reversible upon discontinuation of drug therapy. The relationship to CARDIZEM is uncertain in most cases, but probable in some. (See PRECAUTIONS.)*

PRECAUTIONS

General. *CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.*

Dermatological events (see ADVERSE REACTIONS section) may be transient and may disappear despite continued use of CARDIZEM. However, skin eruptions progressing to erythema multiforme and/or exfoliative dermatitis have also been infrequently reported. Should a dermatologic reaction persist, the drug should be discontinued.

Drug Interaction. *Due to the potential for additive effects, caution and careful titration are warranted in patients receiving CARDIZEM concomitantly with any agents known to affect cardiac contractility and/or conduction. (See WARNINGS.)*

Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

As with all drugs, care should be exercised when treating patients with multiple medications. CARDIZEM undergoes biotransformation by cytochrome P-450 mixed function oxidase. Coadministration of CARDIZEM with other agents which follow the same route of biotransformation may result in the competitive inhibition of metabolism. Dosages of similarly metabolized drugs, particularly those of low therapeutic ratio or in patients with renal and/or hepatic impairment, may require adjustment when starting or stopping concomitantly administered CARDIZEM to maintain optimum therapeutic blood levels.

Beta-blockers: *Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities.*

Administration of CARDIZEM (diltiazem hydrochloride) concomitantly with propranolol in five normal volunteers resulted in increased propranolol levels in all subjects and bioavailability of propranolol was increased approximately 50%. If combination therapy is initiated or withdrawn in conjunction with propranolol, an adjustment in the propranolol dose may be warranted. (See WARNINGS.)

Cimetidine: *A study in six healthy volunteers has shown a significant increase in peak diltiazem plasma levels (58%) and area-under-the-curve (53%) after a one-week course of cimetidine at 1,200 mg per day and diltiazem 60 mg per day. Ranitidine produced smaller, nonsignificant increases. The effect may be mediated by cimetidine's known inhibition of hepatic cytochrome P-450, the enzyme system probably responsible for the first-pass metabolism of diltiazem. Patients currently receiving diltiazem therapy should be carefully monitored for a change in pharmacological effect when initiating and discontinuing therapy with cimetidine. An adjustment in the diltiazem dose may be warranted.*

Digitalis: *Administration of CARDIZEM with digoxin in 24 healthy male subjects increased plasma digoxin concentrations approximately 20%. Another investigator found no increase in digoxin levels in 12 patients with coronary artery disease. Since there have been conflicting results regarding the effect of digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing CARDIZEM therapy to avoid possible over- or under-digitalization. (See WARNINGS.)*

Carcinogenesis, Mutagenesis, Impairment of Fertility. *A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.*

Pregnancy. *Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/ postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.*

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. *Diltiazem is excreted in human milk. One report suggests that concentrations in breast milk may approximate serum levels. If use of CARDIZEM is deemed essential, an alternative method of infant feeding should be instituted.*

Pediatric Use. *Safety and effectiveness in children have not been established.*

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences as well as their frequency of presentation are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%). In addition, the following events were reported infrequently (less than 1%):

Cardiovascular:	*Angina, arrhythmia, AV block (first degree), AV block (second or third degree—see conduction warning), bradycardia, congestive heart failure, flushing, hypotension, palpitations, syncope.*
Nervous System:	*Amnesia, depression, gait abnormality, hallucinations, insomnia, nervousness, paresthesia, personality change, somnolence, tinnitus, tremor.*
Gastrointestinal:	*Anorexia, constipation, diarrhea, dysgeusia, dyspepsia, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH (see hepatic warnings), vomiting, weight increase.*
Dermatologic:	*Petechiae, pruritus, photosensitivity, urticaria.*
Other:	*Amblyopia, CPK elevation, dyspnea, epistaxis, eye irritation, hyperglycemia, nasal congestion, nocturia, osteoarticular pain, polyuria, sexual difficulties.*

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: alopecia, gingival hyperplasia, erythema multiforme, and leukopenia. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established. *Issued 6/87*

INFECTIOUS COMPLICATIONS OF NEOPLASTIC DISEASE

Controversies in Management

Edited by Arthur E. Brown, MD, and Donald Armstrong, MD
0-914316-43-5, approx. 400 pp., Oct. 1984, $40.00 casebound

About the book

Derived from a symposium sponsored by the Infectious Disease Service, Department of Medicine and the Department of Pediatrics, Memorial Sloan-Kettering Cancer Center, New York City, and Cornell University Medical College, New York City, this book presents the latest thinking by international authorities, all of whom were invited to present findings in their area of expertise on the diagnosis, treatment, and prevention of various bacterial, fungal, viral, and parasitic infections presenting in patients with neoplastic disease.

This is not just another "proceedings" volume. Rather it is an edited work, with papers by investigators who submitted definitive preparations for publication. Furthermore, the authors take a strong position on their topics, ask probing questions and promote a stimulating forum of controversy.

The result is a concise, dynamic study that belongs in the professional library of every physician treating patients with neoplastic disease.

About the Editors

Arthur E. Brown, MD, is Assistant Attending Physician, Memorial Sloan-Kettering Cancer Center, and Assistant Professor of Medicine and Pediatrics, Cornell University Medical College.

Donald Armstrong, MD, is Attending Physician; Chief of Service; Director, Microbiology Laboratory, Memorial Sloan-Kettering Cancer Center, and Professor of Medicine, Cornell University Medical College

Table of Contents

PART I. DIAGNOSIS AND TREATMENT

Introduction and epidemiology
Neutropenia, fever, and infection
Significance of serum bactericidal activity in gram-negative bacillary bacteremia in patients with and without granulocytopenia
Approaching the controversies in antibacterial management of cancer patients
Can antibacterial therapy be discontinued in persistently febrile granulocytopenic cancer patients?
Quantitative blood cultures: a review of 52 years
Opportunistic fungal infections in patients with neoplastic disease
Chemotherapy of Systemic Mycoses
Viral infections in patients with neoplastic disease: diagnosis and therapy
Parasitic diseases in immunocompromised hosts

PART II. AIDS

Cluster of cases of the acquired immune deficiency syndrome: patients linked by sexual contact
Model-based approach to an analysis of a cluster pattern
Association between acquired immune deficiency syndrome and sexual contact: an analysis of the incidence pattern
Acquired immune deficiency syndrome (AIDS) trends in the United States
Assessment of therapy for Pneumocystis carinii pneumonia PCP Therapy Project Group

PART III. PREVENTION

Granulocyte transfusions
Leukocyte transfusions: thinking twice
Chemoprophylaxis of bacterial infections in granulocytopenic patients
Chemoprophylaxis of fungal infections
Legionnaires' Disease: aspects of nosocomial infection
Immunoprophylaxis and serotherapy of bacterial infections

ONCE-A-DAY
Calan® SR
(verapamil HCl) 240mg
SUSTAINED-RELEASE CAPLETS

- **Convenient one-caplet, once-a-day dosing regimen:* Start with one 240—mg caplet in the morning with food. (Starting dosages of 120 mg/day, ½ caplet, may be suitable for the elderly or those of small stature.)**
- **Favorably priced—similar in cost to beta blockers**

*Some patients may require *b.i.d.* dosing.

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with significant ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan SR is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.

Adverse Reactions— oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, cerebrovascular accident, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation.

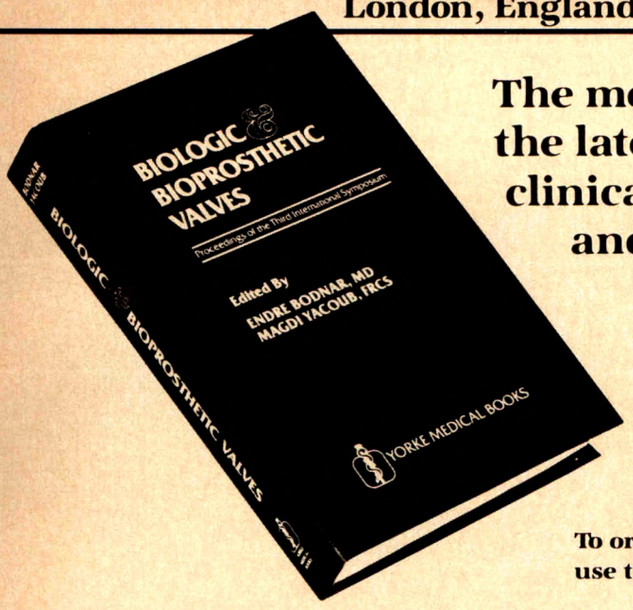
Biologic & Bioprosthetic Valves

Proceedings of the Third International Symposium London, England, May 21-23, 1985



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

edited by Endre Bodnar, MD, and Magdi Yacoub, FRCS
ISBN 0-914316-49-4, 920 pp., May, 1986, $125.00

To order your copy of this important new book use the order form below.

The Third International Symposium on Cardiac Bioprostheses was held May 21-23, 1985, at the Grosvenor House Hotel, London. Six years have passed since the first meeting of this kind was held in Munich and 3 years since the second conference in Rome. The reassessment of the state of the art with biologic and bioprosthetic valves seems to have become a regular 3-yearly fixture reflecting the fast development of these devices, as well as the desire of surgeons and academics working in this field to share experiences, exchange ideas, and to resolve problems together.

The London meeting brought together surgeons, cardiologists, pathologists, engineers, and basic scientists, and the 3-day program accommodated 96 formal presentations with nearly 7 hours of discussion. It is a credit to the session chairmen and participants that the discussions were frank, outspoken, but fair and always to the point, and they have been added to this volume, and they certainly enhance its value.

This volume incorporates the work of the best specialists in the field, and should not be missing from your own professional library.

The Editors are eminently qualified to do this book, Dr. Bodnar is with the Cardiothoracic Institute, London, England, and Mr. Yacoub is with Harefield Hospital, Middlesex, England.

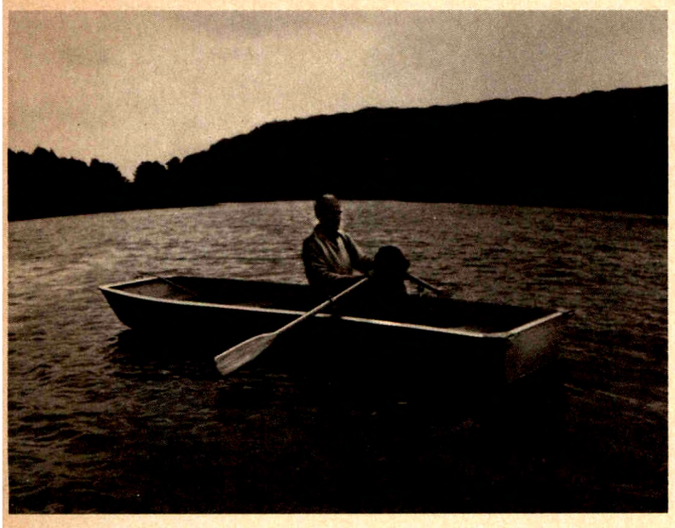
Now Available in 20mg Capsules
FOR GREATER DOSING CONVENIENCE
TO A "DOER"
Your mixed angina patients can become more active...with PROCARDIA® (nifedipine) protection. They'll be pain-free more of the time and find their need for nitroglycerin greatly reduced.[1] They'll be able to work harder, exercise more.[2] And be more active participants in their own lives once again.
feeling better...doing more
PROCARDIA®
(NIFEDIPINE) Capsules 10 mg and 20 mg
Protection in Mixed Angina
Please see PROCARDIA® (nifedipine) brief summary on next page.

feeling better...doing more



PROCARDIA®
(NIFEDIPINE)

Capsules 10 mg and 20 mg

–Effective dosage range is 30-120 mg/day

For most patients, start with 10 mg *t.i.d.*, and titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because PROCARDIA decreases peripheral vascular resistance (occasional patients have had excessive hypotension), careful monitoring of blood pressure during initial administration and upward dosage titration is suggested, especially for patients taking other drugs known to lower blood pressure. Occasional patients have developed increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases.

–Offers a favorable safety profile

Most frequently reported side effects associated with PROCARDIA therapy, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients; transient hypotension in about 5%; palpitation in about 2%; syncope in about 0.5%.

Brief Summary

PROCARDIA® (nifedipine) Capsules For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See WARNINGS.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina and/or Myocardial Infarction: Rarely, patients, particularly those who have severe obstructive coronary artery disease, have developed well documented increased frequency, duration and/or severity of angina or acute myocardial infarction on starting PROCARDIA or at the time of dosage increase. The mechanism of this effect is not established.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See WARNINGS.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Laboratory tests: Rare, usually transient, but occasionally significant elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT and SGPT have been noted. The relationship to PROCARDIA therapy is uncertain in most cases, but probable in some. These laboratory abnormalities have rarely been associated with clinical symptoms, however, cholestasis with or without jaundice has been reported. Rare instances of allergic hepatitis have been reported.

Limited clinical studies have demonstrated a moderate but statistically significant decrease in platelet aggregation and increase in bleeding time in some PROCARDIA (nifedipine) patients. No clinical significance for these findings has been demonstrated. Positive direct Coombs test with/without hemolytic anemia has been reported.

Although PROCARDIA has been used safely in patients with renal dysfunction and has been reported to exert a beneficial effect in certain cases, rare, reversible elevations in BUN and serum creatinine have been reported in patients with pre-existing chronic renal insufficiency. The relationship to PROCARDIA therapy is uncertain in most cases but probable in some.

Drug interactions: Beta-adrenergic blocking agents: (See INDICATIONS AND WARNINGS.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Coumarin anticoagulants: There have been rare reports of increased prothrombin time in patients taking coumarin anticoagulants to whom PROCARDIA was administered.

Cimetidine: A study in six healthy volunteers has shown a significant increase in peak nifedipine plasma levels (80%) and area-under-the-curve (74%) after a one week course of cimetidine at 1000 mg per day and nifedipine at 40 mg per day. Ranitidine produced smaller, non-significant increases. If nifedipine therapy is initiated in a patient currently receiving cimetidine, cautious titration is advised.

Carcinogenesis, mutagenesis, impairment of fertility: Nifedipine was administered orally to rats for two years and was not shown to be carcinogenic. When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose. *In vivo* mutagenicity studies were negative.

Pregnancy: Pregnancy Category C. Nifedipine has been shown to be teratogenic in rats and embryotoxic in rats, mice and rabbits. There are no adequate and well controlled studies in pregnant women. PROCARDIA should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: The most common adverse events include dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, shortness of breath, diarrhea, constipation, gastrointestinal cramps, flatulence, inflammation, joint stiffness, shakiness, jitteriness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, sexual difficulties, thrombocytopenia, anemia, leukopenia, purpura, allergic hepatitis, gingival hyperplasia, depression, paranoid syndrome, transient blindness at the peak of plasma level, erythromelalgia, and arthritis with ANA (+). Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

HOW SUPPLIED: PROCARDIA soft gelatin capsules are supplied in:
Bottles of 100: 10 mg (NDC 0069-2600-66) orange #260; 20 mg (NDC 0069-2610-66) orange and light brown #261. Bottles of 300: 10 mg (NDC 0069-2600-72) orange #260; 20 mg (NDC 0069-2610-72) orange and light brown #261. Unit dose packages of 100: 10 mg (NDC 0069-2600-41) orange #260; 20 mg (NDC 0069-2610-41) orange and light brown #261.

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Vaseretic®

(Enalapril Maleate-Hydrochlorothiazide|MSD)

For added hypertension control

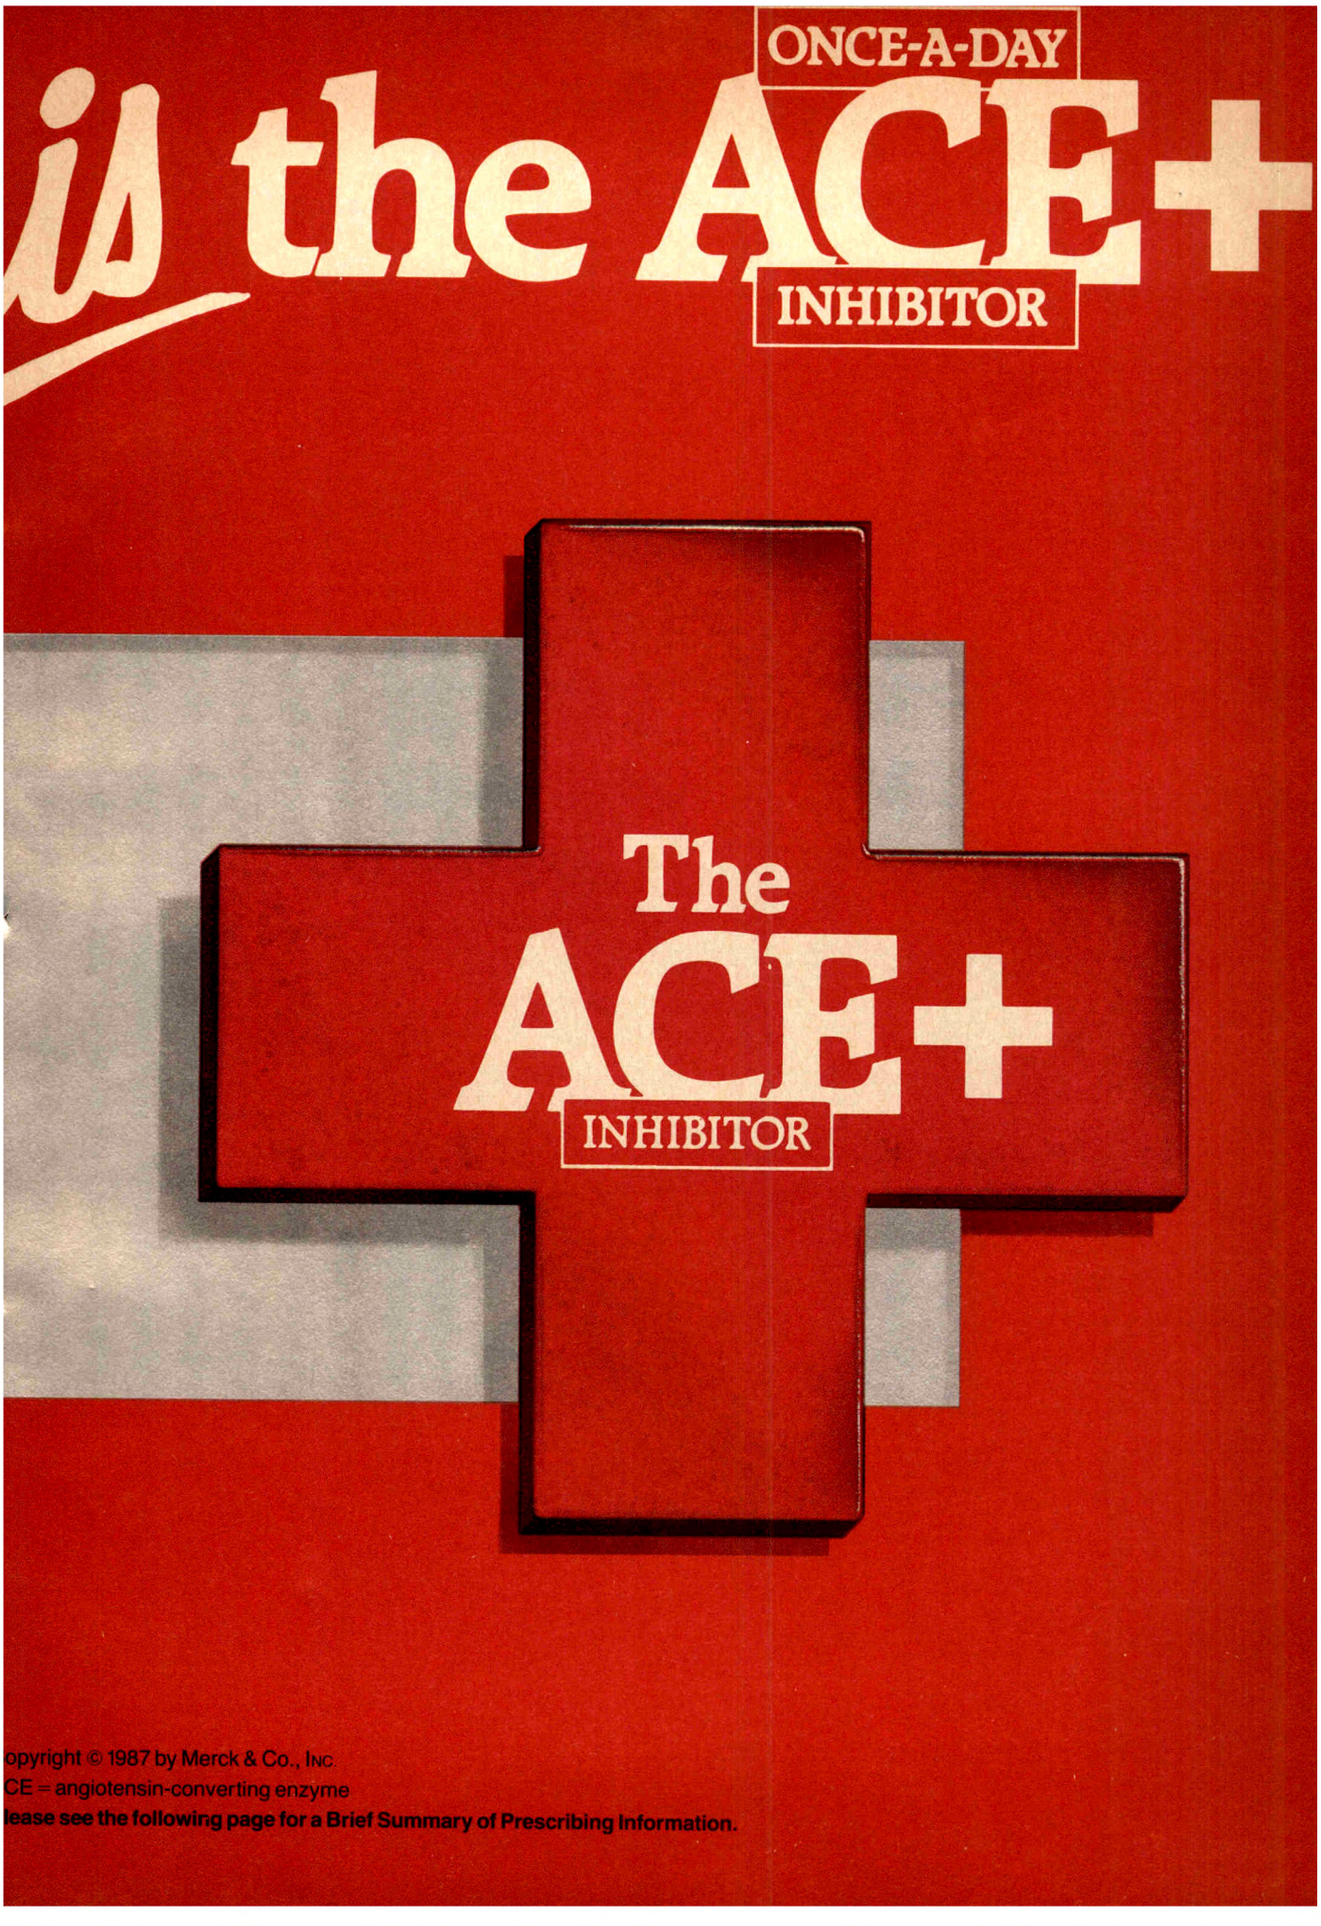
- **Hydrochlorothiazide** augments the antihypertensive effect of enalapril.
- **Enalapril** tends to reverse the potassium loss often associated with hydrochlorothiazide.
- Highly effective in adults, regardless of age or race.*

This fixed-dose combination is not indicated for initial therapy. Patients already receiving a diuretic when enalapril is initiated or given a diuretic and enalapril simultaneously can develop symptomatic hypotension. In the initial titration of the individual entities, it is important, if possible, to stop the diuretic for several days before starting enalapril or, if this is not possible, to begin enalapri at a low initial dose (2.5 mg; see DOSAGE AND ADMINISTRATION). This fixed-dose combination is not suitable for titration but may be substituted for the individual components if the titrated doses are the same as those in the combination.

VASERETIC, containing 10 mg enalapril maleate and 25 mg hydrochlorothiazide, is contraindicated in patients who are hypersensitive to any component of this product. Because of the hydrochlorothiazide component, this product is contraindicated in patients with anuria or hypersensitivity to other sulfonamide-derived drugs.

Evaluation of the hypertensive patient should always include assessment of renal function.

*Although enalapril was antihypertensive in all races studied, black hypertensive patients (usually a low-renin hypertensive population) had a smaller average response to enalapril maleate monotherapy than non-black patients. In contrast, hydrochlorothiazide was more effective in black patients than enalapril. Concomitant administration of enalapril maleate and hydrochlorothiazide was equally effective in black and non-black patients.

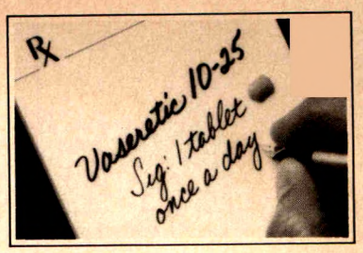


opyright © 1987 by Merck & Co., Inc.

CE = angiotensin-converting enzyme

lease see the following page for a Brief Summary of Prescribing Information.

Once-A-Day
Vaseretic®
(Enalapril Maleate-Hydrochlorothiazide|MSD)



This fixed-dose combination is not indicated for initial therapy. Patients already receiving a diuretic when enalapril is initiated, or given a diuretic and enalapril simultaneously, can develop symptomatic hypotension. In the initial titration of the individual entities, it is important, if possible, to stop the diuretic for several days before starting enalapril or, if this is not possible, begin enalapril at a low initial dose (see DOSAGE AND ADMINISTRATION in complete Prescribing Information). This fixed-dose combination is not suitable for titration but may be substituted for the individual components if the titrated doses are the same as those in the combination.

CONTRAINDICATIONS

VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) is contraindicated in patients who are hypersensitive to any component of this product. Because of the hydrochlorothiazide component, this product is contraindicated in patients with anuria or hypersensitivity to other sulfonamide-derived drugs.

WARNINGS

Hypotension: Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of enalapril use in severely salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. Syncope has been reported in 1.3% of patients receiving VASERETIC. In patients receiving enalapril alone, the incidence of syncope is 0.5%. The overall incidence of syncope may be reduced by proper titration of the individual components (see PRECAUTIONS, Drug Interactions; ADVERSE REACTIONS; and DOSAGE AND ADMINISTRATION in complete Prescribing Information). In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of enalapril and/or diuretic is increased.

If hypotension occurs, the patient should be placed in a supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses, which usually can be given without difficulty once the blood pressure has increased after volume expansion.

Angioedema: Angioedema of the face, extremities, lips, tongue, glottis, and/or larynx has been reported in patients treated with angiotensin-converting-enzyme inhibitors, including enalapril. In such cases, VASERETIC should be promptly discontinued and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis, or larynx, likely to cause airway obstruction, appropriate therapy, e.g., subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL) should be promptly administered** (see ADVERSE REACTIONS).

Neutropenia/Agranulocytosis: Another angiotensin-converting-enzyme inhibitor has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment, especially if they also have a collagen vascular disease. Available data from clinical trials of enalapril are insufficient to show that enalapril does not cause agranulocytosis at similar rates. Foreign marketing experience has revealed several cases of neutropenia or agranulocytosis in which a causal relationship to enalapril cannot be excluded. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered.

Hydrochlorothiazide: Thiazides should be used with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects of the drug may develop in patients with impaired renal function.

Thiazides should be used with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma.

Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Lithium generally should not be given with thiazides (see PRECAUTIONS, Drug Interactions: Hydrochlorothiazide).

PRECAUTIONS

General: ***Enalapril Maleate:*** *Impaired Renal Function:* As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin-converting-enzyme inhibitors, including enalapril, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death.

In clinical studies in hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine were observed in 20% of patients. These increases were almost always reversible upon discontinuation of enalapril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy.

Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea and serum creatinine, usually minor and transient, especially when enalapril has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of enalapril and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function.**

Hyperkalemia: Elevated serum potassium (greater than 5.7 mEq/L) was observed in approximately 1% of hypertensive patients in clinical trials treated with enalapril alone. In most cases, these were isolated values which resolved despite continued therapy, although hyperkalemia was a cause of discontinuation of therapy in 0.28% of hypertensive patients. Hyperkalemia was less frequent (approximately 0.1%) in patients treated with enalapril plus hydrochlorothiazide. Risk factors for the development of hyperkalemia may include renal insufficiency, diabetes mellitus, and the concomitant use of agents to treat hypokalemia (see Drug Interactions).

Surgery/Anesthesia: In patients undergoing major surgery or during anesthesia with agents that produce hypotension, enalapril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion.

Hydrochlorothiazide: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving thiazide therapy should be observed for clinical signs of fluid or electrolyte imbalance: namely hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance, irrespective of cause, include dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting.

Hypokalemia may develop, especially with brisk diuresis, when severe cirrhosis is present or after prolonged therapy. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Hypokalemia can sensitize or exaggerate the response of the heart to the toxic effects of digitalis (e.g., increased ventricular irritability). Because enalapril reduces the production of aldosterone, concomitant therapy with enalapril attenuates the diuretic-induced potassium loss (see Drug Interactions: Agents Increasing Serum Potassium).

Although any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease), chloride replacement may be required in the treatment of metabolic alkalosis.

Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction rather than administration of salt except in rare instances when the hyponatremia is life-threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or frank gout may be precipitated in certain patients receiving thiazide therapy.

In diabetic patients, dosage adjustments of insulin or oral hypoglycemic agents may be required. Hyperglycemia may occur with thiazide diuretics. Thus, latent diabetes mellitus may become manifest during thiazide therapy.

The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient.

If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy.

Thiazides have been shown to increase the urinary excretion of magnesium; this may result in hypomagnesemia.

Thiazides may decrease urinary calcium excretion. Thiazides may cause intermittent and slight elevation of serum calcium in the absence of known disorders of calcium metabolism. Marked hypercalcemia may be evidence of hidden hyperparathyroidism. Thiazides should be discontinued before carrying out tests for parathyroid function.

Information for Patients: *Angioedema:* Angioedema, including laryngeal edema, may occur especially following the first dose of enalapril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue and/or difficulty in breathing) and to take no more drug until they have consulted with the prescribing physician.

Hypotension: Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, patients should be told to discontinue the drug until they have consulted with the prescribing physician.

All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with the physician.

Hyperkalemia: Patients should be told not to use salt substitutes containing potassium without consulting their physician.

Neutropenia: Patients should be told to report promptly any indication of infection (e.g., sore throat, fever) which may be a sign of neutropenia.

NOTE: As with many other drugs, certain advice to patients being treated with VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects.

Drug Interactions: ***Enalapril Maleate:*** *Hypotension—Patients on Diuretic Therapy:* Patients on diuretics and especially those in whom diuretic therapy was recently instituted may occasionally experience an excessive reduction of blood pressure after initiation of therapy with enalapril. The possibility of hypotensive effects with enalapril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with enalapril. If it is necessary to continue the diuretic, provide medical supervision for at least one hour after the initial dose (see WARNINGS and DOSAGE AND ADMINISTRATION). *Agents Causing Renin Release:* The antihypertensive effect of enalapril is augmented by antihypertensive agents that cause renin release (e.g., diuretics). *Other Cardiovascular Agents:* Enalapril has been used concomitantly with beta-adrenergic-blocking agents, methyldopa, nitrates, calcium-blocking agents, hydralazine, and prazosin without evidence of clinically significant adverse interactions. *Agents Increasing Serum Potassium:* Enalapril attenuates diuretic-induced potassium loss. Potassium-sparing diuretics (e.g., spironolactone, triamterene, or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated, they should be used with caution and with frequent monitoring of serum potassium.

Hydrochlorothiazide: When administered concurrently, the following drugs may interact with thiazide diuretics. *Alcohol, barbiturates, or narcotics*—potentiation of orthostatic hypotension may occur. *Antidiabetic drugs (oral agents and insulin)*—dosage adjustment of the antidiabetic drug may be required. *Other antihypertensive drugs*—additive effect or potentiation. *Corticosteroids, ACTH*—intensified electrolyte depletion, particularly hypokalemia. *Pressor amines (e.g., norepinephrine)*—possible decreased response to pressor amines but not sufficient to preclude their use. *Skeletal muscle relaxants, nondepolarizing (e.g., tubocurarine)*—possible increased responsiveness to the muscle relaxant. *Lithium*—should not generally be given with diuretics. Diuretic agents reduce the renal clearance of lithium and add a high risk of lithium toxicity. Refer to the package insert for lithium preparations before use of such preparations with VASERETIC. *Nonsteroidal anti-inflammatory drugs*—In some patients, the administration of a nonsteroidal anti-inflammatory agent can reduce the diuretic, natriuretic, and antihypertensive effects of loop, potassium-sparing, and thiazide diuretics. Therefore, when VASERETIC and nonsteroidal anti-inflammatory agents are used concomitantly, the patient should be observed closely to determine if the desired effect of the diuretic is obtained.

Pregnancy: ***Enalapril Maleate-Hydrochlorothiazide:*** *Pregnancy Category C.* There was no teratogenicity in rats given up to 90 mg/kg/day of enalapril (150 times the maximum human dose) in combination with 10 mg/kg/day of hydrochlorothiazide (2-1/2 times the maximum human dose) or in mice given up to 30 mg/kg/day of enalapril (50 times the maximum human dose) in combination with 10 mg/kg/day of hydrochlorothiazide (2-1/2 times the maximum human dose). At these doses, fetotoxicity expressed as a decrease in average fetal weight occurred in both species. No fetotoxicity occurred at lower doses: 30/10 mg/kg/day of enalapril-hydrochlorothiazide in rats and 10/10 mg/kg/day of enalapril-hydrochlorothiazide in mice.

There are no adequate and well-controlled studies in pregnant women. VASERETIC® (Enalapril Maleate-Hydrochlorothiazide, MSD) should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Hydrochlorothiazide: Thiazides cross the placental barrier and appear in cord blood. *Nonteratogenic Effects:* These may include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult.

Nursing Mothers: It is not known whether enalapril is secreted in human milk, however, thiazides do appear in human milk. Because of the potential for serious reactions in nursing infants from hydrochlorothiazide, a decision should be made whether to discontinue nursing or to discontinue VASERETIC, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

VASERETIC has been evaluated for safety in more than 1,500 patients, including over 300 patients treated for one year or more.

In clinical trials with VASERETIC, no adverse experiences peculiar to this combination drug have been observed. Adverse experiences that have occurred have been limited to those that have been previously reported with enalapril or hydrochlorothiazide.

The most frequent clinical adverse experiences in controlled trials were: dizziness (8.6%), headache (5.5%), fatigue (3.9%), and cough (3.5%). Generally, adverse experiences were mild and transient in nature.

Adverse experiences occurring in greater than 2% of patients treated with VASERETIC in controlled clinical trials are shown below:

	Percent of Patients in Controlled Studies	
	VASERETIC (n = 1,580) Incidence (discontinuation)	Placebo (n = 230) Incidence
Dizziness	8.6(0.7)	4.3
Headache	5.5(0.4)	9.1
Fatigue	3.9(0.8)	2.6
Cough	3.5(0.4)	0.9
Muscle Cramps	2.7(0.2)	0.9
Nausea	2.5(0.4)	1.7
Asthenia	2.4(0.3)	0.9
Orthostatic Effects	2.3(<0.1)	0.0
Impotence	2.2(0.5)	0.5
Diarrhea	2.1(<0.1)	1.7

Clinical adverse experiences occurring in 0.5% to 2.0% of patients in controlled trials included: *Cardiovascular:* Syncope, orthostatic hypotension, palpitations, chest pain, tachycardia. *Nervous System:* Insomnia, nervousness, paresthesia, somnolence, vertigo. *Gastrointestinal System:* Abdominal pain, vomiting, dyspepsia, constipation, flatulence, dry mouth. *Other:* Dyspnea, gout, back pain, arthralgia, hyperhidrosis, pruritus, decreased libido, rash, tinnitus, urinary tract infection. *Angioedema:* Angioedema has been reported in patients receiving VASERETIC (0.6%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis, and/or larynx occurs, treatment with VASERETIC should be discontinued and appropriate therapy instituted immediately (see WARNINGS). *Hypotension:* In clinical trials, adverse effects relating to hypotension occurred as follows: hypotension (0.9%), orthostatic hypotension (1.5%), other orthostatic effects (2.3%). In addition, syncope occurred in 1.3% of patients (see WARNINGS).

Clinical Laboratory Test Findings: *Serum Electrolytes:* See PRECAUTIONS. *Creatinine, Blood Urea Nitrogen:* In controlled clinical trials, minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 0.6% of patients with essential hypertension treated with VASERETIC. More marked increases have been reported in other enalapril experience. Increases are more likely to occur in patients with renal artery stenosis (see PRECAUTIONS). *Serum Uric Acid, Glucose, Magnesium, and Calcium:* See PRECAUTIONS. *Hemoglobin and Hematocrit:* Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.3 g % and 1.0 vol %, respectively) occur frequently in hypertensive patients treated with VASERETIC but are rarely of clinical importance unless another cause of anemia coexists. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia. *Other (Causal Relationship Unknown):* Rarely, elevations of liver enzymes and/or serum bilirubin have occurred.

Other adverse reactions that have been reported with the individual components are listed below: *Enalapril Maleate*—Enalapril has been evaluated for safety in more than 10,000 patients. In clinical trials, adverse reactions which occurred with enalapril were also seen with VASERETIC. However, since enalapril has been marketed, the following adverse reactions have been reported: *Renal:* Renal dysfunction, renal failure, oliguria; *Hematologic:* Rare cases of neutropenia, thrombocytopenia, and bone marrow depression have been reported in which a causal relationship to enalapril cannot be excluded. *Hydrochlorothiazide—Body as a Whole:* Weakness; *Digestive:* Anorexia, gastric irritation, cramping, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis; *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia; *Musculoskeletal:* Muscle spasm; *Nervous System/Psychiatric:* Restlessness; *Special Senses:* Transient blurred vision, xanthopsia; *Hypersensitivity:* Purpura, photosensitivity, urticaria, necrotizing angiitis (vasculitis and cutaneous vasculitis), fever, respiratory distress including pneumonitis and pulmonary edema, anaphylactic reactions.

HOW SUPPLIED

No. 3418—Tablets VASERETIC 10-25, are red, squared capsule-shaped, compressed tablets, coded MSD 720 on one side and VASERETIC on the other. Each tablet contains 10 mg enalapril maleate and 25 mg hydrochlorothiazide. They are supplied as follows:

NDC 0006-0720-68 bottles of 100 (with desiccant).

Left Ventricular Dysfunction After Prolonged Strenuous Exercise in Healthy Subjects

DOUGLAS R. SEALS, PhD, MARC A. ROGERS, PhD, JAMES M. HAGBERG, PhD, CHIKASHI YAMAMOTO, MS, PHILIP E. CRYER, MD, and ALI A. EHSANI, MD

To determine whether depressed left ventricular (LV) contractile function can occur after prolonged and strenuous exercise, 12 healthy men, 26 ± 1 years old (mean ± standard error of the mean) were studied. The subjects exercised on a treadmill at 69 ± 1% of maximal O_2 uptake until exhaustion (170 ± 10 minutes). Hemodynamic variables were measured before and 10 minutes aftere exhausting exercise. Baseline systolic blood pressure decreased from 124 ± 2 to 113 ± 3 mm Hg ($p < 0.001$) after exhausting exercise. LV end-diastolic diameter, measured by echocardiography, decreased from 51 ± 1.0 to 47 ± 1.0 mm ($p < 0.005$) but LV end-systolic diameter did not change (34 ± 1.0 vs 34 ± 1.0 mm). Both LV fractional shortening and the mean velocity of circumferential fiber shortening decreased (33 ± 1 vs 28 ± 1%; $p < 0.01$ and 1.09 ± 0.4 vs 0.97 ± 0.05 circ/s; $p < 0.025$) despite a lower end-systolic wall stress (σ_{es} = 88 ± 4 vs 82 ± 5, × 10^3 dynes/cm^2; $p < 0.05$) after prolonged exhausting exercise. A repeat bout of exercise of the same intensity but brief in duration (10 minutes) resulted in increases in LV fractional shortening ($p < 0.001$) and mean velocity of circumferential fiber shortening ($p < 0.001$), and a decrease in LV end-diastolic diameter (50 ± 1.0 to 48 ± 1.0 mm; $p < 0.05$) at heart rates comparable to those attained after prolonged exhausting exercise. The results suggest that prolonged strenuous exercise may result in impaired LV function in healthy young subjects.

(Am J Cardiol 1988;61:875–879)

Controversy exists regarding whether strenuous exercise can cause left ventricular (LV) dysfunction in healthy subjects. Earlier studies suggested that impaired LV function might account for the decrease in blood pressure and stroke volume, and inappropriate tachycardia induced by exhausting exercise.[1,2] However, these changes were subsequently attributed to the compensatory thermoregulatory mechanisms that result in a lower effective blood volume which, in turn, can decrease venous return and stroke volume.[3] Some experimental studies also failed to show any evidence for impairment of LV contractile function.[4] On the other hand, there have been reports of depressed LV function after exhausting exercise in rats[5] and a recent study suggested that impaired LV function may occur in well-trained athletes after an ultramarathon (100 km) race.[6] Thus, it is still unclear whether or not strenuous exercise can cause impairment of LV performance. Accordingly, this study examines whether LV dysfunction can occur after prolonged exhausting exercise in young healthy subjects and characterizes the metabolic and hormonal changes concurrent with alterations in LV function.

From the Section of Applied Physiology, Cardiovascular and Metabolism Divisions, Department of Medicine, and the Irene Walter Johnson Institute of Rehabilitation, Washington University School of Medicine, St. Louis, Missouri. This study was supported in part by grant GCRC-RR00036 from the National Institutes of Health, Bethesda, Maryland. Dr. Seals was a postdoctoral Research Trainee supported by Institutional National Service Award AG-00078; Dr. Rogers was a postdoctoral Research Trainee supported by Institutional National Research Service Award HL07456. Manuscript received August 3, 1987; revised manuscript received November 30, 1987, and accepted December 4.

Dr. Seals's current address: Department of Exercise and Sport Sciences, McKale Center, University of Arizona, Tucson, Arizona.

Address for reprints: Ali A. Ehsani, MD, Department of Medicine, Washington University School of Medicine, 4566 Scott Avenue, St. Louis, Missouri 63110.

Methods

Subjects: Twelve male subjects 26 ± 1 years old (mean ± standard error of the mean) volunteered for

the study. They were asymptomatic, had no history of cardiopulmonary disease and their cardiac examination, including 12-lead electrocardiogram and echocardiogram, was normal. None was performing regular endurance exercise. All gave a written informed consent and the study was approved by the Human Studies Committee of the Washington University School of Medicine.

Measurement of maximal O_2 uptake ($\dot{V}O_2$max): A graded treadmill running protocol was used to determine $\dot{V}O_2$max as described by Costill and Fox.[7] $\dot{V}O_2$max was defined as the attainment of a plateau of O_2 uptake with increasing work rates (levelling-off criterion). $\dot{V}O_2$ was measured using an open-circuit gas collection system with a Daniel's breathing valve and neoprene meteorologic balloons. Gas samples were analyzed for O_2 and CO_2 with a Perkin-Elmer MGA-1100 mass spectrometer and the volume of the expired air was measured with a Tissot spirometer as described previously.[8]

Prolonged exercise to exhaustion: The subjects were tested in the morning, 2.5 to 3 hours after a breakfast containing approximately 500 Kcal. A catheter was placed in an antecubital vein and, after 15 minutes of rest, blood was drawn for determination of free fatty acids, catecholamines, lactate and glucose concentrations. Subsequently, an M-mode echocardiogram with simultaneous recording of carotid pulse tracing and measurement of blood pressure using the cuff method was obtained. The subjects walked for 20 minutes on a treadmill at a speed of 3.75 mph and with the grade set to elicit 70% of their $\dot{V}O_2$max. The exercise intensity was then reduced to a speed of 2 mph and 0% grade for 2 minutes. The exercise intensity was then raised to the previous level (70% of $\dot{V}O_2$max) for 18 minutes followed by a 2-minute exercise of reduced intensity. This sequence was repeated for as long as possible. When the subjects were no longer capable of maintaining the initial work rate of 70% of $\dot{V}O_2$max, the exercise intensity was reduced in 0.25 mph and 1% grade decrements and they were asked to continue exercising for at least 10 minutes at each reduced work rate. The onset of fatigue was defined as the time at which the work rate had to be reduced below the initial work rate by 10% of $\dot{V}O_2$max. At that time the exercise was terminated because of exhaustion and the elapsed time was taken as the subjects' endurance time. All subjects were then assisted from the treadmill and placed in a supine position.

The subjects were given water to drink ad libitum throughout the exhausting exercise. $\dot{V}O_2$, heart rate and blood pressure were measured during the last 2 minutes of each 18-minute bout of high intensity exercise. $\dot{V}O_2$ was measured to adjust the work rate to maintain the desired intensity. A repeat echocardiogram and blood samples were obtained 10 minutes after completion of the exhausting exercise.

Brief exercise: Eleven of the 12 subjects returned several weeks later for a repeat treadmill test (the remaining subject was unavailable). The exercise duration was 10 minutes at the same intensity used during the prolonged exercise, that is, 70% of $\dot{V}O_2$max. Blood samples were obtained and echocardiograms recorded before and approximately 5 minutes after the completion of the 10-minute exercise bout. The reason we waited 5 minutes to obtain echocardiograms and plasma samples was that heart rates at that time were comparable to those attained 10 minutes after prolonged exhausting exercise. The brief exercise was performed to determine whether exercise of the same intensity but brief in duration can produce similar hemodynamic and metabolic responses compared with the prolonged exhausting exercise. No complications occurred during or after the 2 bouts of exercise.

Echocardiogram: M-mode echocardiogram and carotid pulse tracings were obtained with a Smith Klein echocardiograph interfaced with a Cambridge strip-chart recorder using the standard approach described previously.[9] The standard landmarks were used for measurements of LV end-diastolic diameter, end-systolic diameter, posterior wall thickness and ejection time (carotid pulse tracing).[9] The same body position and the intercostal space were used for each subject in the 2 trials.

The following parameters were used to examine LV systolic function: (1) end-systolic stress-length relation; (2) LV fractional shortening and (3) mean velocity of circumferential fiber shortening as previously described.[9] Because LV fractional shortening and mean velocity of circumferential fiber shortening are affected by cardiac loading conditions,[10,11] the changes in these variables were examined as a function of estimated end-systolic wall stress. An inverse linear relationship between end-systolic wall stress (σ_{es}) and mean velocity of circumferential fiber shortening has been reported[11] and is considered to be a sensitive index of inotropic state.[11] The meridional end-systolic wall stress was estimated using the following equation: $\sigma = PR/[2h(1 + h/2R)]$, where σ = wall stress; P = systolic blood pressure in grams; h = end-systolic posterior wall thickness; R = LV end-systolic diameter/2.

Assay procedures: One ml of blood was deproteinized in chilled 10% perchloric acid and the neutralized supernatant was assayed for lactate.[12] Plasma glucose was measured using the glucose oxidase method.[13] Three ml of blood was drawn for assay of plasma free fatty acid concentration using the colorimetric method.[14] Four ml of blood was placed in chilled tubes containing 4.5 mg of reduced glutathione, 0.1 ml pargyline and 50 U sodium heparin; the plasma was separated by centrifugation at 4°C and used for determination of norepinephrine and epinephrine by the single-isotope derivative technique.[15] Lactate and glucose concentrations were measured only after the 2.8-hour exercise bout.

Statistics: Student *t* tests for paired observation were used to compare the rest with postexercise data for each exercise protocol. Data are mean ± standard error of the mean.

Results

The subjects' maximal O_2 uptake averaged 3.76 ± 0.12 liter/min (50.1 ± 1 ml/kg/min). $\dot{V}O_2$ during the prolonged strenuous exercise averaged 2.57 ± 0.10 li-

ters/min, which was equivalent to 69 ± 1% $\dot{V}O_2$max. The duration of exercise was 170 ± 10 minutes.

Heart rate and systolic blood pressure: Heart rate during maximal treadmill exercise was 201 ± 3 beats/min. The peak heart rates attained during the prolonged exhausting exercise and the 10-minute exercise were 175 ± 3 and 155 ± 4 beats/min, respectively. Heart rates at rest before the 2 modes of exercise were similar (59 ± 3 and 59 ± 4 beats/min, respectively). The heart rate recorded 10 minutes after the 2.8-hour exhausting exercise was 89 ± 4 beats/min ($p < 0.001$, postexercise vs baseline heart rate). The heart rate 5 minutes after the brief exercise bout was 85 ± 4 beats/min ($p < 0.001$, postexercise vs baseline heart rate). Systolic blood pressure decreased from 124 ± 2 to 113 ± 3 mm Hg ($p < 0.0001$), 10 minutes after the 2.8-hour exercise. In contrast, systolic blood pressure increased from 124 ± 2 to 145 ± 4 mm Hg ($p < 0.001$) after the brief exercise bout.

Changes in left ventricular function and size: Baseline LV fractional shortening was 33 ± 1 and 34 ± 1% before the 2 bouts of exercise. LV fractional shortening was significantly reduced to 28 ± 1% ($p < 0.01$), 10 minutes after exhausting exercise. In contrast, at heart rates comparable to those attained after prolonged exercise, the LV fractional shortening increased to 41 ± 2% ($p < 0.001$) after the brief exercise. Baseline values for mean velocity of circumferential fiber shortening obtained several weeks apart were identical (Figure 1A). It decreased ($p < 0.025$) after the 2.8-hour exhausting exercise but increased ($p < 0.001$) after the brief exercise at comparable heart rates. The decline in LV systolic function following the 2.8-hour exhausting exercise occurred despite a lower average end-systolic wall stress compared with baseline values. The increase in LV systolic function after the short-term exercise was evident even though the average LV end-systolic wall stress was unchanged (Figure 1A). The end-systolic stress-length relation was shifted downward, with a significantly lower end-systolic wall stress and no change in LV end-systolic diameter after exhausting exercise (Figure 2A). In contrast, 10 minutes of exercise at the same intensity shifted this relation to the left with a significantly smaller LV end-systolic diameter (Figure 2A).

Baseline values for LV end-diastolic diameter before the 2 bouts of exercise were 51 ± 1.0 and 50 ± 1.0 mm measured several weeks apart. Ten minutes after the long exhausting exercise, LV end-diastolic diameter decreased to 47 ± 1.0 mm ($p < 0.005$, Figure 1B). Brief exercise resulted in a comparable decrease in this variable, to 48 ± 1.0 mm ($p < 0.05$, Figure 1B) at similar heart rates. LV end-systolic diameter did not change after the 2.8-hour exhausting exercise but decreased significantly after brief exercise (Figure 2). The baseline values for average end-systolic wall stress were similar. However, end-systolic wall stress decreased slightly ($p < 0.05$) after the exhausting exercise but did not change after the 10-minute exercise at comparable heart rate (Figures 1 and 2).

Hormonal and metabolic changes: The increase in plasma norepinephrine concentrations was greater after prolonged exhausting exercise when compared with those following the brief exercise (Table I). There was almost a 4-fold increase from the resting level ($p < 0.01$) in plasma epinephrine concentration after exhausting exercise, compared with only a modest (1.5-fold) increase after the brief exercise ($p < 0.001$).

There was a modest and physiologically insignificant rise in plasma free fatty acids after the brief exercise but a 5-fold increase ($p < 0.001$) after the prolonged exhausting exercise (Table I). Venous plasma lactate was 1.62 ± 0.06 mM after the prolonged exhausting exercise. Plasma glucose concentrations decreased slightly but significantly following the 2.8-hour exer-

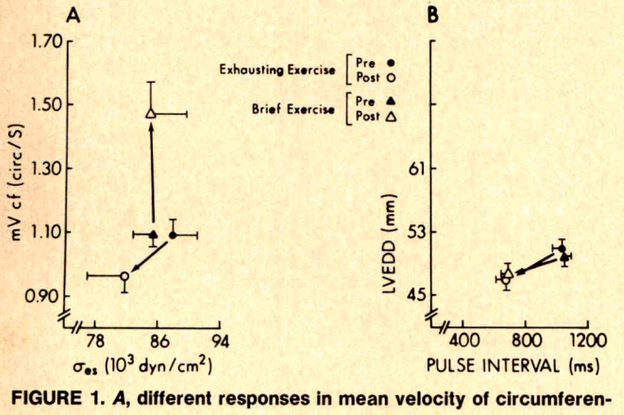

FIGURE 1. *A*, different responses in mean velocity of circumferential fiber shortening (mVcf) after prolonged exhausting and brief exercise at comparable heart rates. Despite a lower end-systolic wall stress, mVcf decreased after strenuous exercise to exhaustion (consistent with depressed contractile state). In contrast, the contractile state was enhanced after brief exercise of the same intensity (relative to $\dot{V}O_2$max), characterized by a large increase in mVcf at comparable levels of wall stress. *B*, at comparable heart rates (pulse interval), the changes in left ventricular end-diastolic dimension (LVEDD) were similar between the 2 bouts of exercise.

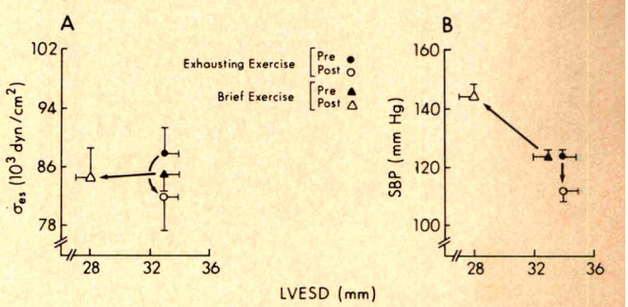

FIGURE 2. *A*, relation between left ventricular end-systolic diameter (LVESD) and end-systolic wall stress (σ_{es}). Prolonged strenuous exercise to exhaustion resulted in a decrease in LVESD with no change in σ_{es}, suggestive of depressed contractile state. Brief exercise of the same relative intensity increased σ_{es} with no change in LVESD, compatible with enhancement of inotropic state. *B*, systolic blood pressure (SBP) decreased following exhausting exercise with no change in LVESD. In contrast, SBP increased ($p < 0.01$) and LVESD decreased ($p < 0.01$) after the brief bout of exercise.

TABLE I Metabolic and Hormonal Changes in Plasma

	Prolonged Exhausting Exercise		Brief Exercise	
	Before	After	Before	After
Norepinephrine (pg/ml)	462 ± 75	726 ± 110 *	202 ± 71	369 ± 99*
Epinephrine (pg/ml)	61 ± 14	233 ± 32*	45 ± 9	65 ± 14*
Free fatty acids (mM)	0.467 ± 0.03	2.449 ± 0.08†	0.420 ± 0.03	0.558 ± 0.04*

* $p < 0.01$ (before versus after); † $p < 0.001$ (before versus after).

cise (83 ± 4 vs 71 ± 2 mM; $p < 0.05$). The hematocrit was virtually identical before and after the exhausting exercise (47.6 ± 0.1 vs 47.6 ± 0.1).

Discussion

The results show that prolonged strenuous exercise leading to exhaustion results in LV dysfunction among healthy young untrained subjects. Ejection phase indexes of contractility are sensitive both to changes in contractility and cardiac loading conditions. Therefore, the lower LV fractional shortening and mean velocity of circumferential fiber shortening observed after prolonged exhausting exercise may result from reduced preload or increased afterload, or both.[10] A decrease in left ventricular end-diastolic diameter in our subjects, therefore, could have accounted for the lower ejection phase indexes of LV function after exhausting exercise. However, the mean velocity of circumferential fiber shortening declined despite a lower end-systolic wall stress reflecting a depressed inotropic state.[11] The changes in end-systolic stress-length relation (lower end-systolic wall stress and no change in end-systolic diameter) were consistent with a decline in LV function.[10,11] Furthermore, the 10-minute bout of exercise that resulted in a comparable decrease in left ventricular end-diastolic diameter caused a marked increase in the ejection phase indexes at heart rates similar to those attained after exhausting exercise. Therefore, our findings are compatible with the interpretation of depressed inotropic state following prolonged exhausting exercise.

The limitations of the M-mode echocardiogram are well recognized. The changes in the LV fractional shortening may not necessarily be representative of global LV function. However, because the subjects were free of cardiac disease and had no chamber enlargement or altered geometry, these limitations should not pose a major problem in the interpretation of our results. The values for end-systolic wall stress should be considered only as estimates because of those known limitations, including the use of peak systolic instead of end-systolic blood pressure. The reproducibility of echocardiographic measurements has been reported previously.[9]

There are several conflicting reports concerning the development of LV dysfunction following strenuous exercise. Sugimoto et al[4] were not able to show depression of LV function. However, Maher et al[5] reported an abnormal force-velocity relation in exhausted rat heart. McKechnie et al[16] reported pulmonary edema in 2 long-distance runners after they participated in an ultramarathon race (100 km). The LV function and coronary angiogram results were normal in both runners. Niemela et al[6] recently found reversible abnormal left ventricular function in competitive runners after an ultramarathon race. The mechanisms underlying left ventricular dysfunction after prolonged exhausting exercise are not clear. Because large concentrations of free fatty acids can cause depression of the inotropic state,[17] impairment of LV function may have resulted, in part, from elevated free fatty acids following prolonged strenuous exercise. The decline in plasma glucose level was too small to account for LV dysfunction. Furthermore, the preferred substrates for oxidative metabolism of the heart are fatty acids.[18] Although plasma norepinephrine concentrations may not necessarily reflect those in the myocardium, impairment of LV function occurred despite higher concentrations of plasma norepinephrine after prolonged (compared with brief) exercise, which may reflect altered sensitivity of LV function to catecholamines.

Although the effects of prolonged strenuous exercise in patients with underlying cardiac disease have not been evaluated, it is possible that exhausting exercise lasting several hours may pose serious potential risks to patients with coronary artery disease. Therefore, engagement in prolonged strenuous exercise without supervision is not advisable in the high-risk population.

The 24-Hour Heart Rate Behavior in Long-Term Survivors of Cardiac Transplantation

DIMITRIOS ALEXOPOULOS, MD, SALIM YUSUF, MD, DPhil, JIM A. JOHNSTON, BSc, JULIAN BOSTOCK, BSc, PETER SLEIGHT, MD, and MAGDI H. YACOUB, MD

A detailed computerized analysis of heart rate (HR) behavior during ambulatory monitoring was performed in 19 long-term survivors of cardiac transplantation (12 orthotopic, 7 heterotopic) and in 10 normal volunteers. Compared with normal hearts, the transplanted denervated and the recipient innervated hearts in the heterotopic group showed higher average HRs over the whole 24 hours, the waking and sleeping periods. The rates of the denervated and the recipient hearts did not differ significantly. The maximal HR was similar in all 3 groups, but the minimal HR was lower in the normal hearts than in denervated and recipient hearts. The 24-hour RR interval variability was greatly reduced in the denervated hearts (60 ± 22 ms) compared with the recipient (89 ± 26 ms) and normal (151 ± 38 ms) hearts. During arousal from sleep, the magnitude, time and rate of the HR change were significantly reduced in the denervated hearts compared with the innervated hearts and in the recipient compared with the normal hearts. These findings demonstrate that denervated hearts can show significant variations in HR during the 24-hour period, but to a lesser extent than normal hearts. The widest deviation from normal occurs during sleep, when the denervated heart shows minimal slowing probably due to lack of parasympathetic innervation. In heterotopic transplant recipients, the patients' own HR responses also are significantly blunted.

(Am J Cardiol 1988;61:880–884)

Although a transplanted heart originates from a young person with a healthy heart, it differs from the normal heart in being anatomically and functionally denervated.[1–3] The response of the denervated heart to dynamic and static exercise has been described previously.[4,5] The 24-hour variations in the heart rate (HR) of the transplanted human heart and its changes during usual daily activities have not been adequately studied. The present study defines the variation in HR over 24 hours after orthotopic and heterotopic cardiac transplantation and compares it with the recipient's own heart—in the case of the heterotopic transplantation—and with normal healthy volunteers.

Methods

Study population: Nineteen transplant recipients who survived >6 months were studied. Twelve men (mean age 45 ± 9 years) had orthotopic cardiac transplantation 20 ± 10 months earlier and 7 patients (6 men, 1 woman, mean age 39 ± 8 years) had heterotopic cardiac transplantation 11 ± 3 months earlier, with the donor heart inserted in parallel to the recipient's heart. Surgical techniques were described elsewhere.[6,7] Most patients were receiving a mixture of azathioprine, cyclosporine, prednisolone, aspirin, dipyridamole and diuretic. All patients were asymptomatic and performed their usual physical activities. Signs of mild rejection were present in the most recent cardiac biopsy in only 2 of the patients whereas the remaining patients had no evidence of rejection. Ten normal volunteers, 5 men and 5 women (mean age 38 ± 10 years), served as a control group. All were asymptomatic with normal physical examination and resting electrocardiogram.

Electrocardiogram recordings: Twenty-four-hour Holter monitoring was performed using a 2-channel recorder (Oxford Medilog II or MR14). The leads (modified V_1 and V_4) were recorded. In heterotopic transplants a modified V_{4R} lead was used, instead of V_1, to allow the optimal separation of QRS between donor and recipient hearts. The patients were provided with a diary to record all their symptoms and activities, and were not restricted in any way.

Heart rate analysis: Dual channel analysis was performed using a computerized, nontriggered, tem-

plate system able to classify the beats into many families. The system consisted of a Z80A preprocessor and a DEC LSI-11 master. The tapes from patients with heterotopic transplantation were analyzed twice in order to quantify separately the variations in HR in the donor and the recipient hearts. An example of a recorded electrocardiogram is presented in Figure 1.

The data were analyzed to obtain: (1) the 24-hour HR trend, with each point representing the mean HR over 1 minute. Maximal and minimal HR (minute averages) were measured; (2) a histogram (with mean value and standard deviation) of all the RR intervals observed over 24 hours; (3) the mean HR every hour; (4) the RR intervals—printed on a Medelec fiberoptic recorder (FOR-4.2) for 20 minutes before and after the time of waking. The HR change was measured using the RR change from the onset of arousal to the persistently lowest RR in the next 5 minutes. The change in HR over time was expressed as the rate of HR change.

All values are expressed as mean ± 1 standard deviation. Statistical analysis was performed using Student *t* test (paired or unpaired, as needed).

Results

The interval between operation and study was longer in the orthotopic than the heterotopic transplantation group ($p < 0.025$). Sleeping and waking times were similar in the 3 groups. Because a comparison of all studied parameters between the donor hearts in the 2 groups of orthotopic and heterotopic transplantation revealed no differences, they were analyzed as a single group.

Twenty-four-hour heart rate changes: The overall HR variation is shown in Figure 2. The mean HR for corresponding hours was higher in donor and in recipient hearts than in normal hearts, but not significantly different between donor and recipient hearts. When the 24 hours were considered as a whole, a higher HR was found in donor compared with recipient hearts ($p < 0.001$). The mean 24-hour, daytime and sleep HRs were higher in donor and recipient hearts compared with normal ones (Table I). The differences between donor and recipient hearts were not significant. There was a significantly wider separation between donor versus normal and recipient heart rates during sleep compared with daytime ($p < 0.001$ for both, Figure 2).

Maximal and minimal heart rate: The maximal HR was similar in the 3 groups (Table I). The minimal HR was higher in donor and in recipient compared with normal hearts. The difference between donor and recipient hearts was not significant.

Heart rate variability: The HR variability, as indicated by the standard deviation of the 24-hour mean RR interval, was reduced in donor hearts (60 ± 22 ms) compared with both recipient (89 ± 26) and normal (151 ± 38) hearts ($p < 0.02$ and $p < 0.001$). In recipient hearts, the HR variability was less than normal ($p < 0.005$). Examples of the RR interval histograms are presented in Figure 3.

Heart rate changes during waking: The HR increases in donor and in recipient were lower than normal during this period (Table II). Although donor hearts showed less change when compared with recipient hearts, there was no statistically significant difference. However, within the heterotopic transplantation group alone, HR changes were lower in the donor than the recipient heart (12 ± 4 vs 20 ± 6 beats/min, $p < 0.05$). These HR changes took longer to complete in

D vs R	NS	0.01	0.02

NS = not significant. Other abbreviations as in Table I.

donor than in recipient and normal hearts, and in recipient compared with normal hearts (Table II). Examples of these changes are given in Figures 4 and 5. All the studied parameters were independent of the age of the donor and recipient heart or the interval between the operation and the study.

Discussion

The transplanted heart offers a unique model for studying the hormonal and intrinsic control of the heart.[8] Heterotopic transplantation, with the existence of 2 hearts—denervated and innervated—is ideal for studying the behavior and reactions of the same organ to different stimuli with and without neural control.

Although Holter monitoring has been performed previously after orthotopic cardiac transplantation for detection of arrhythmias,[9,10] there is no previous detailed report concerning the 24-hour HR behavior of the transplanted heart. To our knowledge, continuous HR monitoring has not been described at all in patients following heterotopic heart transplantation. The responses to different stimuli of the remnant atria after orthotopic transplantation have been reported previously,[11,12] but the small amplitude of the recipient atrial P wave does not allow its Holter analysis. With the system we used (based on QRS-pattern recognition), we analyzed separately the ventricular electrical activity of the 2 hearts in the heterotopic transplants even when the 2 QRS complexes were of similar amplitude, which would defeat a QRS-triggered system.

The resting HR of the denervated heart is known to be elevated.[13,14] Our findings of higher mean 24-hour, waking and sleep HRs in the denervated hearts sup-

port this. The innervated recipient's own heart was significantly faster than the normal heart. Part of the increase in HR of the recipient's own heart may be due to elevated circulating catecholamines. Parasympathetic dysfunction[15] of the recipient heart may have also contributed to its higher than normal rate.

The maximal recorded HR during the 24-hour period was similar in the denervated and the innervated hearts and is consistent with previous studies[16] of HR responses of transplanted hearts to dynamic exercise. Following heterotopic transplantation the peak HR achieved during maximal dynamic exercise is almost identical in the donor and the recipient hearts.[7] The minimal HR was higher in the denervated hearts, mainly due to the absence of vagal innervation. The higher minimal HR in the recipient hearts may have been due to parasympathetic dysfunction of the diseased hearts or elevated circulating catecholamines.[17]

The 24-hour variability was reduced in the denervated hearts, largely due to the inability to achieve low HRs. A reduced variation in the resting cycle length of the denervated hearts has been reported previously.[18] By contrast, recipient hearts and normal control hearts demonstrated more HR fluctuation. The gradual changes seen during waking up were similar to the slower increase in HR of the denervated hearts during the early exercise stages.[16] An autonomic dysfunction of the diseased recipient hearts may explain the differences with normal subjects.[19,20] In contrast to our results, Guilleminault et al[21] have reported 7 orthotopic transplants with time courses and magnitudes of HR variation similar to those of normal subjects.

The underlying mechanisms that account for the blunted HR responses of the denervated and, to a lesser extent, the recipient innervated hearts, are certainly quite complex and not fully understood. Supersensitivity of the denervated heart to circulating catecholamines[22] or abnormalities related to damage originated during the donor's death, removal, preservation and implantation procedure, rejection episodes[23] and accelerated atherosclerosis[24] may be involved.

All patients were receiving drugs that might have influenced our results,[25] although the observed differences between the donor and the recipient hearts cannot be explained in this way because the medication was similar in all patients. In the long term, the behavior of the transplanted hearts may change due to adaptation, conditioning and possibly reinnervation.

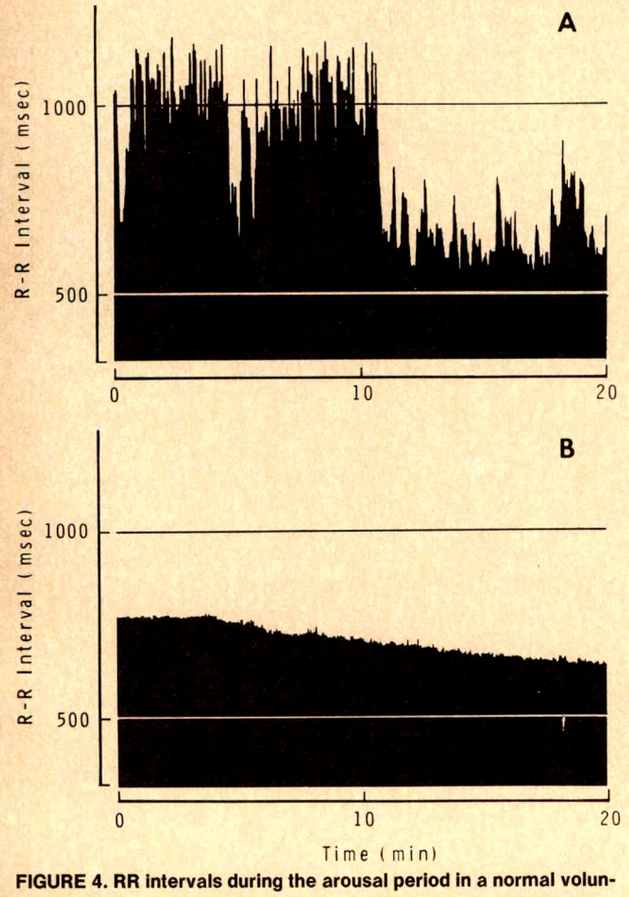

FIGURE 4. RR intervals during the arousal period in a normal volunteer (*A*), and an orthotopic transplantation patient (*B*). Note the smooth appearance in *B*, in contrast to the spiky appearance in *A*, reflecting the lack of beat-by-beat variability in the denervated heart.

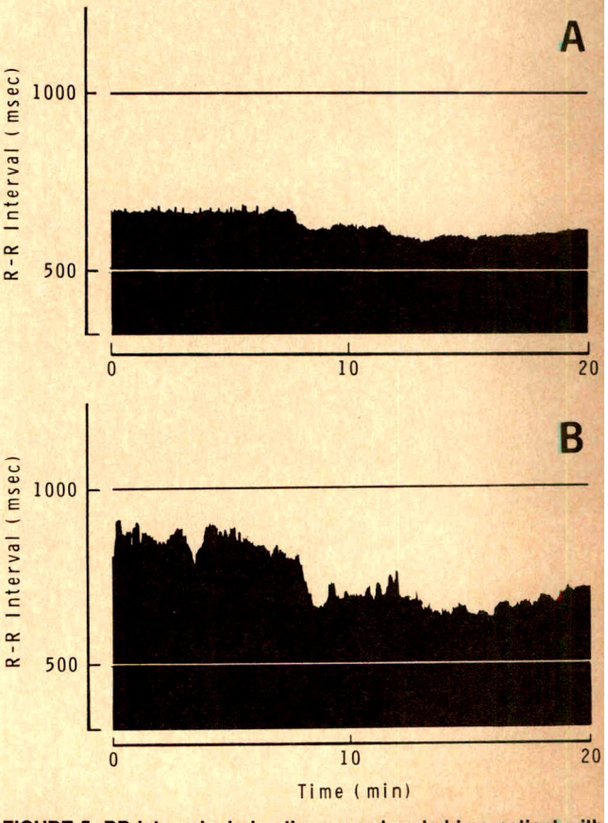

FIGURE 5. RR intervals during the arousal period in a patient with heterotopic transplantation. *A* = donor heart; *B* = recipient heart.

Optimal Lead Subsets for Reconstruction of QRS and ST-T in 35-Lead Precordial Maps

CHRISTOPHER D. McMANUS, MA, ALAN S. BERSON, PhD, JORGE C. RIOS, MD, EMIGDIO A. LOPEZ, MD, and HUBERT V. PIPBERGER, MD

Precordial maps have been used for some 15 years to estimate the extent of myocardial injury in patients with acute anterior or lateral wall infarction. Estimates have been based on various QRS- and ST-T-derived parameters, including amplitude sum of ST elevations. Application of the electrodes, commonly 35, is cumbersome and time-consuming with the critically ill. A subset of 5 or 7 selected leads can be applied instead, and the remaining leads calculated from that subset with minimal loss of QRS and ST-T information. Maps were recorded from 100 patients within 72 hours of onset of anterior or lateral infarct. Optimal lead subsets for QRS and ST-T feature extraction were found by the sequential selection method of Lux. Subsets numbering between 2 and 15 leads were derived, with their lead-transform coefficients. Measures to estimate goodness of fit for reconstructed leads included correlations, error-to-signal ratios and root-mean-square errors. These measures were calculated separately over the QRS and ST-T complexes. Reconstructions from a 7-lead subset had a mean 0.92 correlation with ST-T in the original leads and root-mean-square error of only 0.04 mV. Sum of ST elevation differed by only 2% between original leads and reconstructions based on 5 or more leads. To confirm repeatability, lead-transform coefficients were also calculated from a training population of 50 patients and applied to the maps of the other 50.

(Am J Cardiol 1988;61:885–890)

A new electrocardiographic technique to estimate the size of anterior wall myocardial infarcts was introduced in 1971 by Maroko,[1] Reid[2] and their co-workers. Arrays of electrodes are applied to the precordial area. The degree of ST-segment elevation in these leads is interpreted as an indicator for the extent of myocardial injury. In patients with acute myocardial infarction, serial precordial maps have also often been used to estimate increases or decreases of the injured myocardial area.

Problems with the underlying assumptions have been reviewed in detail by Holland and Brooks.[3] Nevertheless, the simplicity of the method and its noninvasive nature have led to its acceptance as a tool to estimate infarct size and to evaluate therapeutic interventions. In recent years, the number of leads was standardized to 35, based on the suggestion of Maroko et al.[4]

Application of large arrays of electrodes over the precordium is cumbersome and time-consuming. Past studies suggest that the information in precordial maps is contained in subsets of many fewer leads, since neighboring leads contain much redundant information. Akiyama et al[5] compared ST findings in precordial maps with those seen in Frank orthogonal 3-lead recordings. A correlation of 0.818 was found between maps and the Frank leads and the latter were considered adequate for ST-segment studies. In dog experiments, Foerster et al[6] found an even higher correlation between ST changes in precordial maps and orthogo-

From the Veterans Administration Medical Center, Washington, DC, and The George Washington University School of Medicine, Washington, DC. nal leads (r = 0.921). These high correlations confirm more basic studies on the "dipolar" behavior of ST and T potentials.[7,8]

In contrast to ST-T complexes, QRS potential distributions have not followed simple dipolar patterns in studies based on total body surface maps. Several precordial mapping studies[9,10] have used QRS-derived parameters to estimate infarct size; thus, any study on lead reduction must also consider the QRS complex.

We obtained complete precordial maps from patients with acute anterior and lateral infarcts, and applied data reduction techniques in order to identify a small subset of leads that would allow reconstruction of the QRS and ST-T complexes of the original 35 leads. Once such a subset has been identified from a sufficiently large base, only a small number of electrodes need to be applied to future patients with acute infarcts to derive full precordial maps.

Methods

Patients with acute anterior or anterolateral infarcts were selected by staff physicians in the coronary care units of George Washington University Hospital, Washington, DC, and Brigham and Women's Hospital, Boston, Massachusetts. Patients in this study from the latter hospital were selected from subjects in the Multicenter Investigation of the Limitation of Infarct Size study.[11] Only patients with anterior or anterolateral infarcts were included because precordial mapping is thought to provide a measure of myocardial ischemia and injury of the myocardium underlying the anterior and lateral chest wall. Diagnosis was based on clinical history, enzyme elevations and acute ST elevations in anterior and lateral precordial leads of the standard 12-lead electrocardiogram. Informed consent was obtained from patients and their attending physicians. Patients with other conditions that lead to ST elevations were excluded. The first record was taken as soon as possible after admission to the coronary care units, because ST abnormalities subside in some patients relatively soon after the acute event. Patients who did not exhibit ST abnormalities on admission were excluded from further study.

The recording procedure was reduced to less than 15 minutes by use of a flexible plastic sheet with 35 holes set in 5 rows for the electrodes. Distances between electrodes were set to the specifications of Maroko et al.[4] The area covered by the precordial map extends from the left midaxillary line to a vertical line to the right of the sternum corresponding to the position of the conventional lead V_1. In some patients the electrodes consisted of small disks of lithium chloride-impregnated balsa wood cemented to the silver/silver-chloride surface of Becton Dickinson-type electrodes. The contact of the balsa wood with the skin eliminates the need for electrode paste, which usually prolongs and complicates the recording procedure.[12]

Maps were recorded using model 2001 mobile carts (Instruments for Cardiac Research). Cart features include: 500 sample/s recording and storage of 12 simultaneous potentials on magnetic tape cassette; input impedance from each patient lead to ground and between any 2 leads >50 megohms; right leg lead used as driven ground; leakage currents <10 μV through use of an isolated battery-powered front end. All other safety and performance characteristics met or exceeded American Heart Association specifications.[13] The 35 electrodes were connected to a switchbox that allowed simultaneous transmission of 12 leads. One standard limb lead (II) was recorded continuously as a time reference. Standard-lead and Frank orthogonal-lead electrocardiograms were also recorded on all patients at the time of their mapping.

Precordial maps were recorded on 124 patients. Data analysis was performed at the Veterans Administration Medical Center in Washington, DC. System noise was first measured on each lead of each map. Mean system noise over all leads was 19 μV. Patients with noise on any lead exceeding 70 μV were excluded. Finally patients whose tracings had no signal ("dropout") in any lead were excluded. There remained 100 tracings for study: 86 from Brigham and Women's Hospital and 14 from George Washington University Hospital.

The maps were reduced to 1 time-aligned heart cycle per patient, using the wave-recognition algorithms of the Pipberger vectorcardiographic analysis program.[14] The algorithms were applied to 3 leads from each lead set, in order to obtain a representative cycle ("best beat") on that lead set. Beats found by this method have been shown to be especially free of respiratory influence and have high reproducibility.[15] QRS onsets in leads of different lead sets were aligned by cross-correlations between the reference lead QRS complexes in successive lead sets.

For selection of reduced lead sets, we used a method developed by Lux et al.[16] Their statistical approach involves no assumptions about the nature of the heart as an electric generator. The method first derives a set of equations for the best coefficients to apply to any chosen lead subset to approximate the potentials of the remaining leads. The surface potentials at each instant are treated as an n-dimensional random vector, P.

The vector P can be reordered and partitioned into an m-dimensional vector P_1 and an (n-m)-dimensional vector P_2. This process also partitions the covariance matrix K associated with P into:

$$K = \begin{bmatrix} K_{11} & K_{21} \\ K_{12} & K_{22} \end{bmatrix}. \quad (1)$$

If T represents the transformation that optimally estimates P_2 from P_1, then the mean-squared error J between the original and estimated lead values is minimized if $T = K'_{12}K_{11}^{-1}$. (2)

The method of Lux secondly develops a recursive algorithm for selecting the m lead locations to derive the remaining leads with least error, for any number m. From equation 2, the mean-squared estimation error J due to the transformation T is:

$$J = \mathrm{tr}(K) - \mathrm{tr}(K_{11}) - \mathrm{tr}(K'_{12}K_{11}^{-1}K_{12})$$
$$= \mathrm{tr}(K) - \mathrm{tr}(K_{11}^{-1}L_{11}), \quad (3)$$

where tr is the matrix trace operator and

$$L_{11} = K_{11}K_{11} + K_{12}K'_{12}. \quad (4)$$

TABLE I Mean Values of Goodness of Fit Measures to Assess Performance of Different Numbers of Optimal Leads for Reconstructing 35-Lead Maps (Optimal Leads Were Selected Separately for QRS and ST-T Complexes)

	Leads								
	2	3	5	7	9	12	15	Frank 3	Standard 12
QRS reconstruction									
Correlation coefficient	0.81	0.89	0.94	0.95	0.96	0.97	0.97	0.80	0.85
Root-mean-square error (mV)	0.23	0.16	0.12	0.10	0.10	0.08	0.08	0.23	0.19
Error-to-signal ratio	0.22	0.11	0.06	0.04	0.03	0.02	0.02	0.37	0.19
ST-T reconstruction									
Correlation coefficient	0.83	0.88	0.90	0.92	0.92	0.94	0.94	0.80	0.82
Root-mean-square error (mV)	0.06	0.05	0.04	0.04	0.03	0.03	0.03	0.07	0.06
Error-to-signal ratio	0.18	0.12	0.07	0.06	0.05	0.03	0.03	0.35	0.20

Since tr(K) cannot be changed, J is minimized when we maximize the "information index" $I = tr(K_{11}^{-1}L_{11})$. If the lead set P_1 is a single site j, then

$$K_{11}^{-1} = 1/s_j^2,\ L_{11} = \Sigma_i s_i^2 s_j^2 r_{ij}^2,$$

$$\text{and } I_j = tr(K_{11}^{-1}L_{11}) = \Sigma_i s_i^2 r_{ij}^2,$$

where s_i and r_{ij} are the standard deviation at site i and the correlation coefficient between sites i and j, respectively.

This single-lead selection method is incorporated into a simple sequential selection algorithm, as follows. Having selected a best lead j, consider the remaining (n-1) lead sites as a vector P, and find the lead k with maximal information index I_k for that vector. Recursively, after each lead selection, consider the remaining leads as a vector P, and find the site l with maximal index I_l for that vector. This procedure provides at each step both a specific lead set and a measure of the information content of the selected leads, so that a limit on acceptable estimation error can be preset and used to terminate the procedure. The algorithm is optimal in the sense that no other set of m leads has smaller error, although the set is not necessarily unique; i.e., other lead sets might have equal error.

The coefficients necessary to estimate or "reconstruct" the remaining leads from a chosen set are simply the entries of the transformation operator T from equation 2. Following Lux, the estimation error was expressed in 3 parameters: mean correlation coefficient, which characterizes similarity in lead patterns but not in amplitudes; ratio of error strength to signal strength, which characterizes both lead configuration and amplitude; and root-mean-square error. Their equations are, respectively:

$$r = X'Y/|X||Y|; \quad (5)$$

$$\text{ratio} = |X - Y|^2 / |X|^2; \quad (6)$$

$$\text{and } E = |X - Y| / n^{1/2}, \quad (7)$$

where X and Y are the original and reconstructed time sequences of a lead site, and n is the sequence length. For each reconstruction, these 3 measures were calculated for each estimated lead, to get the average value of each measure over all estimated leads.

Because QRS has been included in some estimates of infarct size,[9,10] the data reduction project was divided in 2 parts, one for QRS and one for ST-T. As expected, 2 sets of optimal leads resulted from this division of the study, with comparable accuracy from a smaller subset for ST-T studies and a slightly larger one for QRS. For practical reasons, a common set was also determined for both QRS and ST-T.

TABLE II Measures of Agreement Between Sum of R-Wave Amplitude (ΣR) in Original Precordial Maps and Maps Reconstructed from Different Numbers of Optimal Leads

	5-Lead Basis	7-Lead Basis	9-Lead Basis
Mean difference between ΣR of original and reconstructed maps (mV)	−0.15	−0.06	0.17
Difference as percent of original ΣR amplitude	−1%	0%	1%
Correlation coefficient between original and reconstructed ΣR	0.97	0.97	0.98

Mean ΣR in the original maps was 13.54 ± 1.11 mV (standard deviation).

Results

Final study data were lead values from a single, computer-determined QRS-T complex, over 35 leads, for each of 100 acute infarct patients. Lead subsets numbering between 2 and 15 leads were selected for their power in reconstructing the original 35-lead maps. In addition, the standard 12 leads and 3 orthogonal Frank leads were also tested for their power in reconstructing the total map. Using the aforementioned transformation method, the smaller lead sets served as bases for reconstruction of the original QRS and ST-T complexes.

Typical results, separated for QRS and ST-T, are listed in Table I. Reconstructing the QRS complex from only 2 leads resulted in a mean correlation coefficient of 0.81 between the original and reconstructed leads. With an increasing number of leads, this correlation coefficient rose to 0.97 when 12 leads were used for the reconstruction. Mean correlation coefficients for Frank leads were close to those obtained from 2 optimized leads. For the standard 12 leads, correlations were found to be in between 2 and 3 optimized leads. The mean root-mean-square error decreased from 0.23 mV for reconstructions from 2 leads to 0.08 mV for 12 leads. Corresponding mean root-mean-

TABLE III Measures of Agreement Between Sum of ST-T Elevations (ΣST) in Original Precordial Maps and Maps Reconstructed from Different Numbers of Optimal Leads

	3-Lead Basis	5-Lead Basis	7-Lead Basis	9-Lead Basis	12-Lead Basis
Mean difference between ΣST of original and reconstructed maps (mV)	−0.34	−0.07	−0.10	−0.09	−0.06
Difference as percentage of original ΣST amplitude	−6%	−1%	−2%	−1%	−1%
Mean difference between number of leads with ST elevation >0.1 mV (± SD)	−0.6 ±4.4	0.1 ±2.2	−0.3 ±1.7	−0.2 ±1.4	−0.5 ±1.3
Correlation coefficient between original and reconstructed ΣST	0.95	0.97	0.98	0.99	0.99

Mean ΣST in the original map was 5.51 ± 3.77 mV (standard deviation [SD]) at 40 ms after the J point.

TABLE IV Mean Values of Goodness of Fit Measures to Assess Performance of Different Numbers of Optimal Leads for Reconstructing 35-Lead Maps (Optimal Leads Were Selected Separately for QRS and ST-T Reconstruction, Based on a 50-Patient Training Set; Reconstructions from the Optimal Lead Sets Were Then Applied to the other 50 Patients as a Test Set)

	5 Lead		7 Lead		9 Lead	
	Train Set	Test Set	Train Set	Test Set	Train Set	Test Set

TABLE V Mean Values of Goodness of Fit Measures That Assess Performance of Different Lead Subsets for ST-T Reconstruction. Results in Columns Marked a Refer to Lead Bases Chosen from ST-T-Derived Statistics; Results in Columns b Refer to Lead Bases Chosen from QRS-Derived Statistics (Optimal Lead Bases Chosen from Either QRS or ST-T Data Allow Reconstruction of ST-T Features Nearly Equally)

	3 Lead		7 Lead		9 Lead		12 Lead		15 Lead	
ST-T Reconstruction	a	b	a	b	a	b	a	b	a	b
Correlation coefficient	0.88	0.88	0.92	0.90	0.92	0.92	0.94	0.93	0.94	0.93
Root-mean-square error (mV)	0.05	0.05	0.04	0.04	0.03	0.04	0.03	0.03	0.03	0.03
Error-to-signal ratio	0.12	0.12	0.06	0.07	0.05	0.05	0.03	0.04	0.03	0.03

square errors for the Frank and standard 12 leads were 0.23 and 0.19, respectively. Mean error-to-signal ratio was 0.22 for 2 leads and decreased to 0.02 for reconstructions from 12 optimized leads. For the Frank leads and the standard 12 leads, corresponding error-to-signal ratios were 0.37 and 0.19.

Reconstruction of the ST-T complex was slightly more efficient. The mean correlation coefficient increased from 0.83 to 0.94 when the number of leads was increased from 2 to 12. Mean root-mean-square error decreased from 0.06 mV with 2 leads to 0.03 mV when 9 leads were used. Mean error-to-signal ratio decreased from 0.18 for 2 leads to 0.03 with 12 leads. Reconstruction of the ST-T complex from Frank leads or standard 12 leads gave results similar to those found in the QRS complex. Results were even slightly worse than reconstructions based on 2 optimal leads selected from the original 35 lead set.

Comparisons between amplitude sums of original maps and reconstructed maps are listed in Tables II and III. For maps reconstructed from 5 or more optimal leads, the mean differences between R-wave voltage sums in original and reconstructed maps amounted to an insignificant 1% of the original R-wave amplitude sums. Correlation coefficients between original and reconstructed R-wave sums varied from 0.97 to 0.98. The sums of ST amplitudes were compared at 40 ms after the end of QRS. For maps reconstructed from

5 leads or more, the mean differences between sums of ST amplitudes in original and reconstructed maps were only 1 to 2% of the original ST-amplitude sums. Correlation coefficients between original and reconstructed ST-segments sums were high, increasing from 0.95 to 0.99 when the number of leads was increased from 3 to 9.

To test repeatability of results, the original 100 maps were divided into a training set of 50 maps and a test set of 50. Results from the training and test sets are listed for both QRS and ST-T in Table IV. A comparison of training and test sets shows results that are extremely stable with only very small differences.

Optimal lead locations determined for QRS and ST-T reconstruction are clearly not unique. Due to the short distances between electrodes and consequent high degree of redundancy between neighboring electrodes, a shift from 1 location to an adjacent one may lead only to minute changes in reconstruction. This lead redundancy makes practical a common set of reduced leads for both QRS and ST-T reconstruction. To confirm this redundancy, the original optimized lead sets for QRS were replaced by those of ST-T. This was also done in reverse order. Results are listed in Table V. As can be seen, reconstruction of QRS and ST-T complexes results in almost identical records when optimized lead sets for QRS are replaced by optimized sets for ST-T. Only minute differences in the second decimal position could be found. This indicates that optimal lead sets for QRS can be safely replaced by those obtained for ST-T.

Recommended lead locations for reduced lead sets are shown in Figure 1. Locations are valid for both QRS and ST-T reconstruction. Locations are widely spread with a slightly higher concentration of leads close to the sternum and a smaller number over the left precordium. Lead locations of the full precordial map are shown for comparison.

Discussion

The performance of optimal lead sets of various sizes is shown in Table I. As shown, mean correlation coefficients, root-mean-square errors and error-to-signal ratios are all unchanged when the number of electrodes in the optimal lead subset is increased above 12. In fact, improvement is only minimal when the subset is increased above 5 or 7 leads. For practical purposes, these smaller sets appear adequate for reconstructions.

Lux et al[16] used, as error limits for recomputing total body surface maps of 192 leads from a reduced set of 30 leads, an average root-mean-square error of 32 μV, average correlation coefficient of 0.983 and an error-to-signal ratio of 3.5% in the presence of 20 μV-system noise. Our error limits for QRS and ST-T reconstruction (Tables I, IV and V) significantly exceed their limits. Comparisons are misleading, however, because their reconstruction involved total body surface maps while our study is restricted to chest leads, which are nearest the center of cardiac electrical changes. Also, their study measured reconstruction errors over the entire cardiac cycle, while our study measured error only in the QRS and ST-T complexes, where amplitude changes are greatest.

In practical applications, the proper locations for the electrode subset can be easily determined. For the 7-lead optimal subset, for example, the first electrode is placed in the fourth intercostal space, on the right side of the sternum. On the left sternal border, 1 electrode is placed in the third intercostal space and 1 in the sixth. To determine the remaining locations, one must measure the horizontal distance between the left anterior axillary line and a vertical line following the left sternal border. One electrode each is placed at one-fourth of this measured distance, at the horizontal level of the second and of the fourth intercostal spaces. The next electrode is placed at three-fourths of the measured distance in the sixth intercostal space. The last electrode is placed in the left anterior axillary line, in the third intercostal space. When applying only 5 optimal leads, the same locations are used, but the 2 electrodes on the left sternal border are omitted.

The present recording procedure, involving 35 electrode sites, is cumbersome and time-consuming. When interpreted by human observers, repeat variability is large. Our study has shown that QRS-T information in the 35 electrode array can be reconstructed from a smaller set of 5 to 7 leads. Coefficients to transform these lead subsets to signal values in the remain-

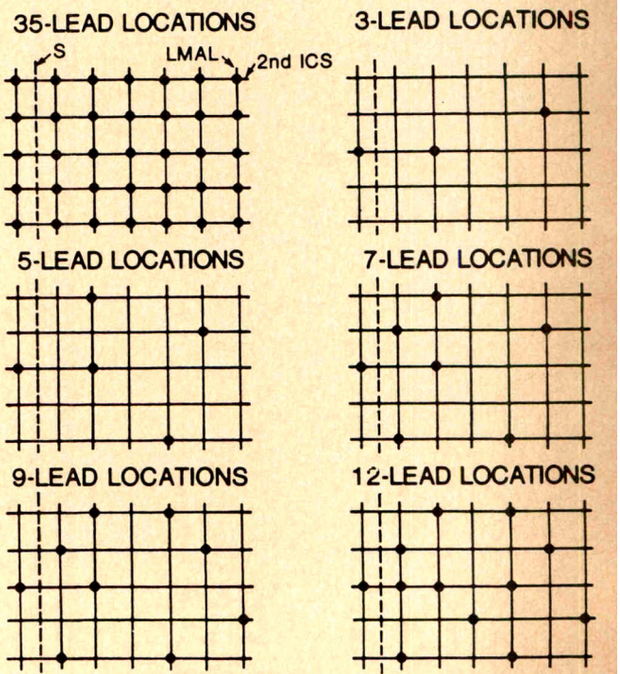

FIGURE 1. Optimal lead locations for reconstruction of the QRS-T component of precordial maps. *Top left*, the original 35 lead locations, with the sternum (S), left mid-axillary line (LMAL) and second intercostal space (2nd ICS) marked. The *bottom row* of this map is the sixth intercostal space. The other 5 figures show the optimal lead locations for reconstructing the precordial map from 3, 5, 7, 9 and 12 leads, respectively. Lead locations were chosen by a sequential algorithm. Thus, larger lead sets include the smaller sets.

ing leads are available by writing the authors. It is hoped that this data reduction will result in a more practical clinical method for studies of myocardial infarct evolution and the effect of therapeutic interventions.

Acknowledgment: We are deeply grateful for the assistance of Dr. Eugene Braunwald of Harvard University Medical School and Brigham and Women's Hospital for providing the case material from the Multicenter Investigation of Limitation of Infarct Size study, which made our study possible. We thank also Drs. John Rutherford and Zoltan G. Turi, and Jeremy Poole, Harvard School of Public Health, who reviewed and selected study cases, and formatted and copied magnetic tape records for our analysis. The computer programs for optimal lead selection, calculation of transform coefficients and estimation of error measures were made available to us by the program designer, Dr. Robert L. Lux, and used with minor system adaptations. We are most grateful to him for his assistance, which saved us considerable time and facilitated comparisons of results.

Limits of Reproducibility of Mitral Pulsed Doppler Spectra

JULES FAST, MD, INA VAN DAM, MD, ANCO HERINGA, MSc, THEO DE BOO, MSc, JOS ALSTERS, JEROEN HOPMAN, MSc, OTTO DANIELS, MD, and LAMBERT VAN DEN MERKHOF, MSc

The total intrinsic variability of pulsed Doppler spectra of mitral blood flow was evaluated in this study. Doppler examinations were performed in 10 normal volunteers (7 men, 3 women), ages 29 to 57 years (mean 41) with an interval period of 3 months. The recordings were made in the apical 4-chamber view, using a 2.25-MHz transducer. The sample was placed approximately 1 cm proximal (left atrium) and 1 cm distal (left ventricle) from the middle of the anulus of the mitral valve at the onset of diastole. Processing of the raw Doppler spectra was done in a way that avoided subjective manipulation by the investigators. Mitral peak velocities, accelerations and spectral widths were measured in early diastole and late diastole. From the parameters under investigation, maximal velocities showed the best reproducibility with a range of coefficients of variation of 9 to 13%. Peak acceleration in early diastole and spectral widths showed rather large coefficients of variation, ranging from 19 to 30 and 14 to 24%, respectively. Mitral pulsed Doppler spectra in the left atrium were more reproducible than in the left ventricle.

(Am J Cardiol 1988;61:891–894)

Introduction of the single gated pulsed Doppler technique in echocardiography has significantly contributed to the assessment of mitral valve pathology[1] and Doppler evaluation of left ventricular diastolic filling.[2–4] Because it is noninvasive, Doppler 2-dimensional echocardiography is ideally suited for repetitive use to establish changes in mitral pulsed Doppler spectra (MPDS) as a consequence of either the natural evolution of a disease or a treatment. This application, however, is hampered by the uncertainty as to whether these changes observed in patients during serial studies carried out by the same or a different observer are real or artificial, caused by technical, physiological and interpretative sources of variability. Some inaccuracy relates to the way parameters are acquired from Doppler spectra, including X-Y tablets[5] and visual evaluation.[6,7] The present study was designed to determine the extent of variability in MPDS when a standardized way of measurement is used in a group of normal volunteers. Processing of the raw Doppler data was completely computerized in order to increase the reproducibility of our measurements.[8]

Methods

The ultrasonic examination was performed in 10 normal volunteers (7 men, 3 women), ages 27 to 58 years (mean 42). They were diagnosed as healthy by their checkup examinations, which included interviews, blood pressure measurement, cardiac auscultation, an electrocardiogram and 2-dimensional echocardiogram. The clinical condition did not change during the follow-up period of 3 months. The serial studies were carried out during normal respiration, at identical diurnal time points, after an interval of 2 to 3 hours following a light breakfast. The subjects were examined in the left lateral position after a short period of supine rest. The echo-Doppler examination was performed with a Honeywell Ultra-Imager using a frequency of 2.25 MHz. The recordings were made in the apical 4-chamber view. The sample volume with a length of approximately 5 mm was placed about 1 cm proximal (left atrium) and 1 cm distal (left ventricle) from the middle of the anulus of the mitral valve at the onset of diastole. The Doppler beam was angled in such a way that it was parallel to the assumed mitral

valve flow. The direction of flow was assumed to be perpendicular to the plane of the mitral anulus. After 2-dimensional image positioning, the site of the sample volume was adjusted slightly in the third dimension based on the Doppler signal and echocardiographic verification. The device produced an amplitude spectrum with 100 points every 5 ms. The number of samples taken per second was 7,800 with a distance between transducer and sample of 6 to 10 cm and 4,875 with a distance of 10 to 16 cm. Depending on depth, time periods of spectral information were 100/7,800 s = 12.8 ms and 100/4,875 s = 20.5 ms, respectively. Hence, subsequent spectra were essentially not independent. The real-time amplitude spectra, together with adjustment data for the instrument (PRF, sample volume length and depth), were taken in digital form from the scanner with a Wicat computer offering a resolution of 12 bits. The spectrogram over 5 seconds (1,000 spectra) was stored. For further data processing, the data were transferred to a DEC PDP 11/44 minicomputer.

By squaring, the stored amplitude spectra were converted into power spectra, after correction for background noise, wall filter influence and transit time effects. The power over 3 successive spectra was averaged.

The lower quartile, median and upper quartile curves were computed from these smoothed spectra, considering each power spectrum as a velocity distribution.[8] For the characterization of the mitral blood flow, 4 parameters were calculated from the obtained curves: (1) the maximal median velocity in early diastole and in late diastole; (2) the ratio of peak E-wave velocity and peak A-wave velocity (E/A ratio); (3) the maximal acceleration during early diastole; (4) the dispersion of the velocity distribution around the maximal velocity in early and late diastole (width). The width was defined as the difference between the upper and lower quartile velocities.

For the analysis of each parameter, the median value of 3 successive heart beats was used. The recordings were made with an interval of 1 hour (numbers 1 and 2) and after 3 months (numbers 3 and 4). The recordings number 1, 2 and 3 were made by one and the same investigator and number 4 by another one. The time interval between the last 2 recordings was approximately half an hour. For each patient, the variability of the parameters was evaluated by the coefficients of variation, defined as the ratio of the standard deviation and the mean of 2 successive measurements, expressed in percentages. The coefficient of variation was averaged over all 10 patients.

The Wilcoxon signed rank test was used for evaluation of the presence of a systematic difference between 2 paired recordings. The level of significance was $p < 0.05$ in all tests.

Results

The parameters of MPDS for both left ventricle and left atrium are listed in Table I. All serial recordings with the sample volume located in the left atrium resulted in mean measurements significantly lower than those obtained at the level of the left ventricle inflow region for both peak velocities and accelarations in early diastole. The same was found for the E/A ratio in the recordings number 1 and 4. The coefficients of variation for each parameter are listed in Table II.

In general terms, the parameters in the left atrial outflow tract are more reproducible than those in the left ventricle's inflow region. Based on the analysis of the various parameters, the velocities showed the best reproducibility with a range of mean coefficients of variation from 5 to 14%. Peak acceleration and spectral width showed rather large coefficients of variation, ranging from 8 to 30 and from 8 to 28%, respectively. Reproducibility decreased as the time interval between the studies was prolonged from 1 hour (studies 1 and 2) to 3 months (studies 1 and 3). The sources of variability included the investigator as well. The coefficients of variation from studies 3 and 4 were larger than those from studies 1 and 2. The mean and standard deviation of the absolute differences between

* Significant difference between paired measurements ($p < 0.05$).

paired recordings are listed in Table III. In general, no significant difference was found between paired measurements. In studies 1 and 4, the sign of the mean of the differences was equal on both sides of the mitral valve, indicating a consistent difference. A significant change was found only for both spectral width in the left atrium and peak velocity in the left ventricle in early diastole. The absolute differences, however, were rather small.

Discussion

The sequential reproducibility of Doppler parameters is determined by the interplay of many different factors. Crucial at the time of recording is the orientation of the ultrasound beam relative to the mitral blood flow, which should be as identical as possible in repetitive studies. Interception angles measured at the mitral orifice have been reported to be close to 0°, show minimal variability and be highly reproducible.[5] MPDS depend on the spatial position of the sample in the heart[7] and its corresponding volume, the motion of the heart[9] and the instantaneous velocity profiles in the left atrium and left ventricle.[10] In our study the sample was placed on both sides of the mitral valve, a position that should be as identical as possible in repeated studies. The heart, being a 3-dimensional structure, is nevertheless only visualized in a 2-dimensional image. Variability in sample position during serial studies may occur because the third dimension is not known. In a pilot study of 5 healthy subjects we found the anulus of the mitral valve to move 0.6 to 1.1 cm away from the apex at the end of expiration during diastole. With normal respiration, an additional shift of 0.7 to 1.3 cm to the right was seen during inspiration. As opposed to the anulus, the sample remains in a fixed position with reference to the transducer during diastole. The distance between the sample in the left ventricular inflow region and the anulus of the mitral valve may increase and the distance between the sample in the left atrial outflow region and the anulus may decrease during diastole. The consequences of such a displacement of the sample for MPDS greatly depend on the velocity profiles near the mitral valve orifice.

At the level of the left ventricular inflow region the profile is nonaxisymmetric, with much more rapid velocities occurring anteriorly than posteriorly.[10] With the assumption of a flat blood velocity profile in the mitral orifice,[10] the better reproducibility of Doppler measurements in the left atrium may be explained by the movement of the mitral anulus toward the sample in the left atrium during diastole. If paired sample volumes are not placed identically in serial studies, the extent of MPDS variability may be reduced in the presence of a velocity profile, which tends to flatten as blood converges from the left atrium to the mitral anulus. In the pilot study, 1 respiratory cycle included 5 to 7 cardiac cycles, depending on the heart rate. The use of a single arbitrary cycle, or even the average of a sequence of 3 cardiac cycles as in our study, while respiratory changes are disregarded, may increase the variability of MPDS in serial studies. However, in a previous study of 215 healthy subjects, ages 1 to 65 years, no influence of respiration on the ratio of peak E-wave velocity and peak A-wave velocity was found.[3]

With the Honeywell equipment (a mechanical echo-Doppler scanner), simultaneous 2-dimensional echo imaging and Doppler evaluation were not possible, creating some uncertainty as to whether the displacement of the sample itself during the Doppler study might have contributed to the variability of MPDS.

In clinical practice, the variability of MPDS may be even greater than in our study. A Doppler echocardiograph has a number of adjustment possibilities. Some of these affect the signals as stored by the computer, whereas other settings control the display only. Because the choice of a specific setting is subjective, the

strength of the present study is the completely computerized processing of the raw Doppler data.

In conclusion, our equipment made possible Doppler measurements of MPDS with acceptable interobserver and day-to-day variability for mitral peak velocities and the ratio of peak E- and A-wave velocities only. Except for the ratio, there is a need for standardization of respiratory phases in the assessment of MPDS.

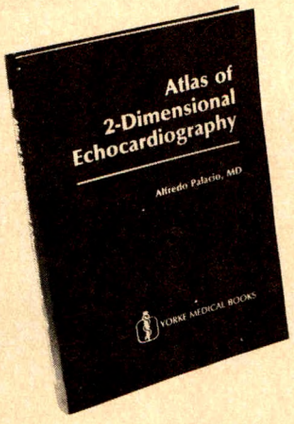
The First Practical Atlas of 2-D Echocardiography Ever Published



Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School; Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

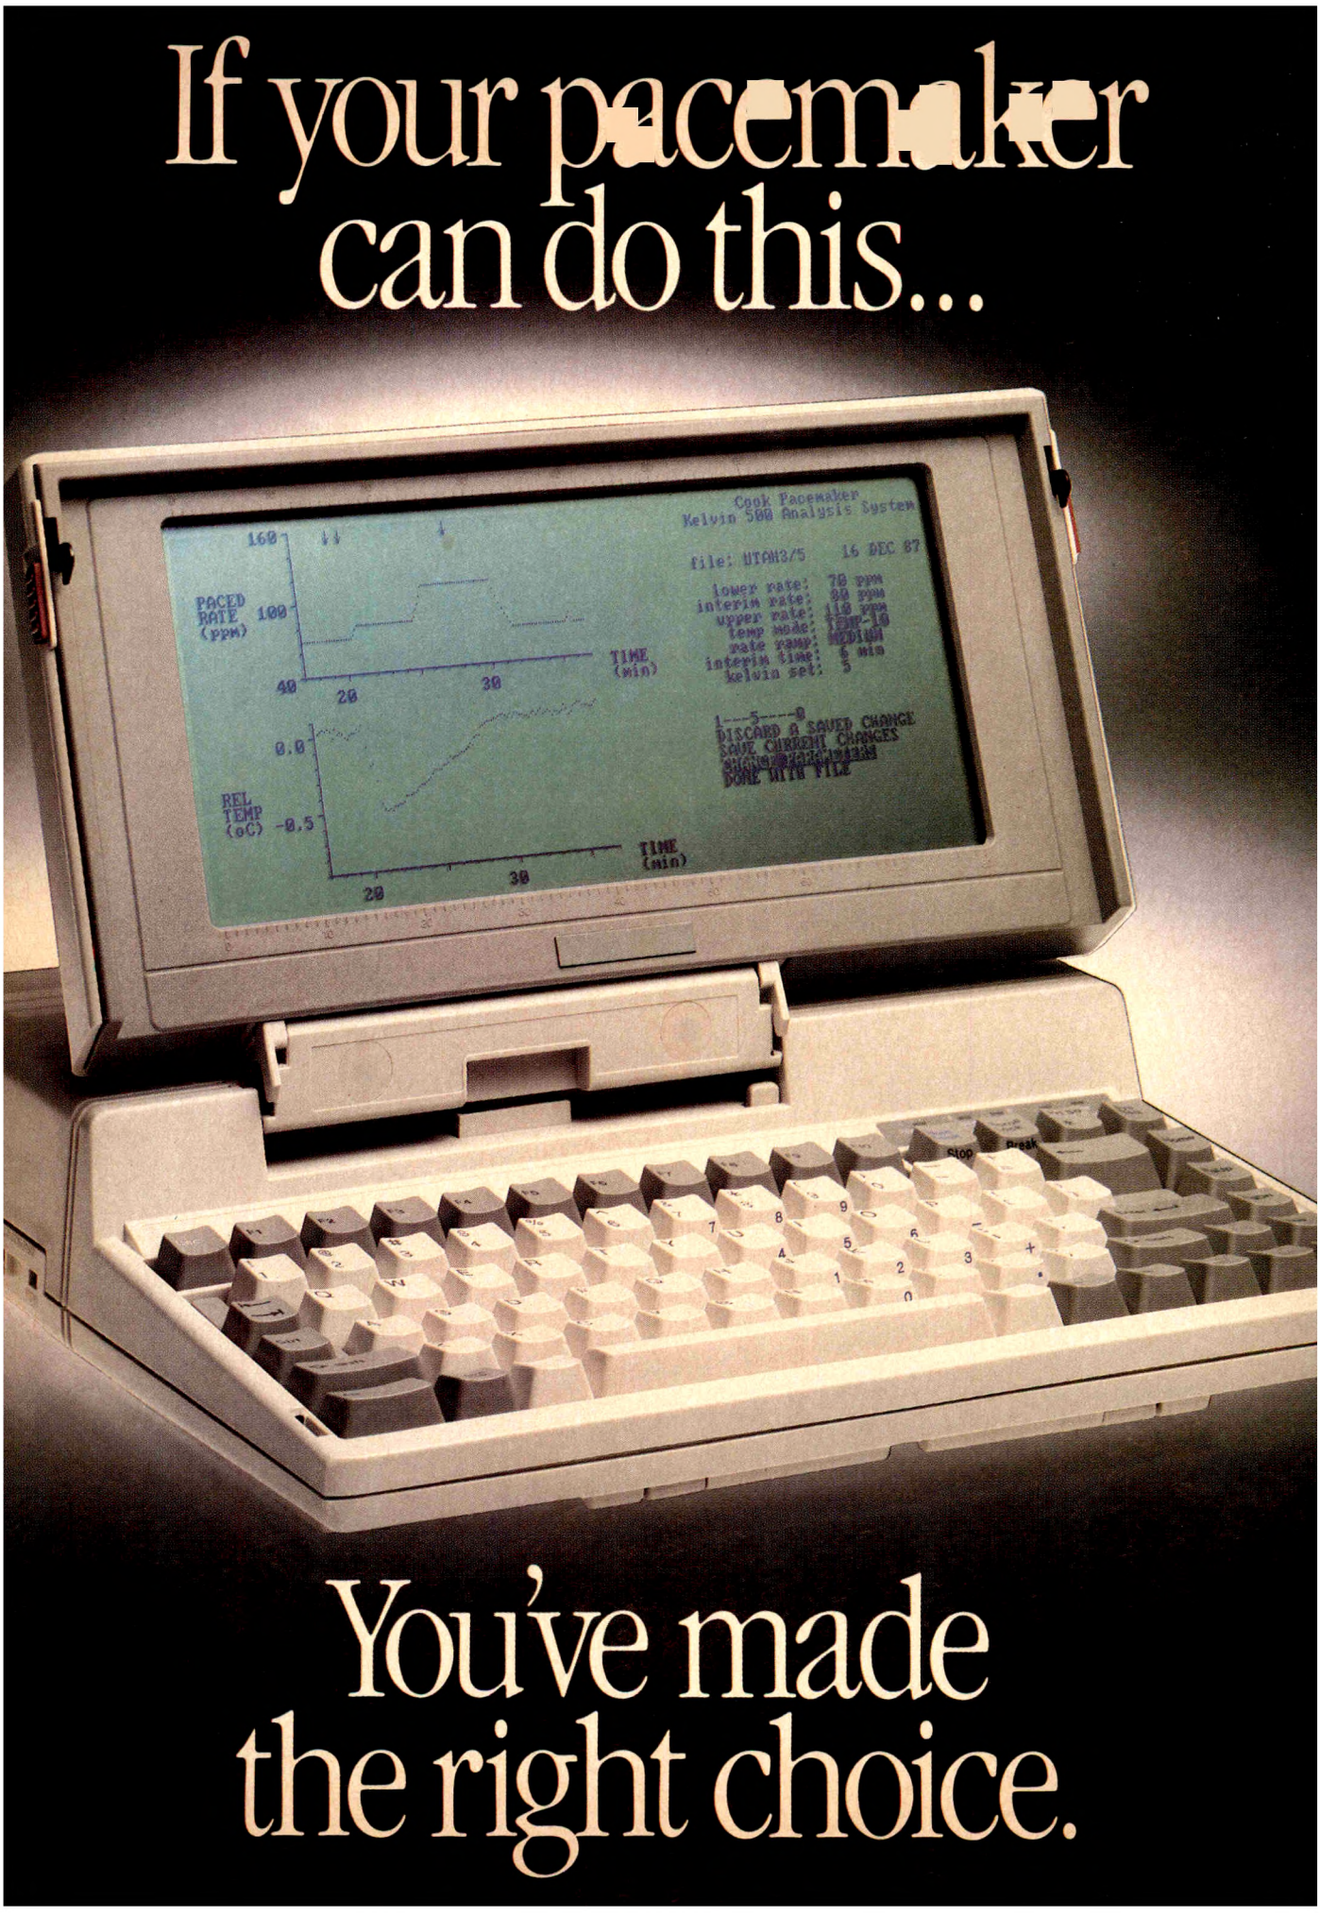
If your pacemaker can do this...



You've made the right choice.

A KELVIN 500®* --the world's first temperature sensing, rate-responsive pacemaker-- and a PC are what you need to end trial and error programming.

A unique analysis system.

Quickly and easily program your patient's KELVIN 500® pulse generator—and simulate how it will perform—in response to any KELVIN 500® temperature profile!

Compare. No other company offers the same advanced package of programming power:

- data collection
- data storage
- data processing
- data display
- data simulation
- data printing

We make programming as simple as 1-2-3.

Here's all you have to do:

1. Collect a temperature profile via telemetry from your KELVIN 500® implant.
2. Store the temperature profile in a PC.
3. Simulate pacemaker response to the temperature profile with the PC to determine the optimal program settings for your patient's pulse generator.

Without additional exercise tests.

One temperature profile is all you need to program your KELVIN 500® pacemaker! In fact, the telemetry profile may be obtained from something as simple as a brief walk around your office!

KELVIN 500™

Easy to use.

Our easy-to-use software asks questions and assists you at every step along the way. Most every function can be performed with the "cursor" and "enter" keys alone.

ONCE-A-DAY

Calan® SR

(verapamil HCl) 240mg

SUSTAINED-RELEASE **CAPLETS**

CALAN® SR (verapamil HCl) SUSTAINED-RELEASE CAPLETS 240 mg

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with significant ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan SR is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.

Adverse Reactions—oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, cerebrovascular accident, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation. 1/12/87 • 7W 107V

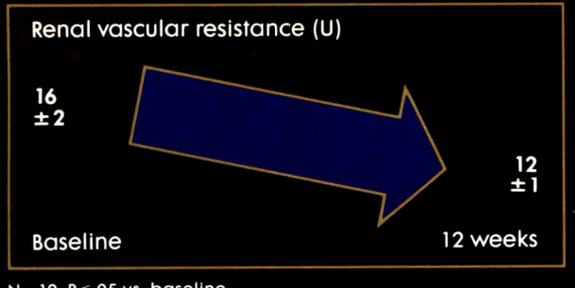
PRESERVES RENAL PERFUSION

CALAN SR maintains renal blood flow, glomerular filtration rate, filtration fraction, as well as other renal functions, while electrolyte balances are rarely disturbed. CALAN SR also significantly reduces renal vascular resistance.

HELPS PROTECT CARDIOVASCULAR FUNCTION

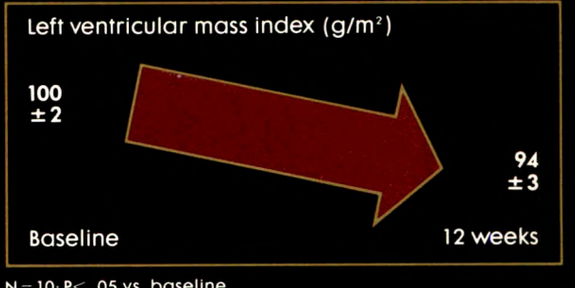
CALAN SR promotes coronary blood flow; furthermore, CALAN SR has been shown to significantly reduce left ventricular hypertrophy,[1] thus decreasing the associated risks.

SIGNIFICANTLY REDUCED RENAL VASCULAR RESISTANCE[1]



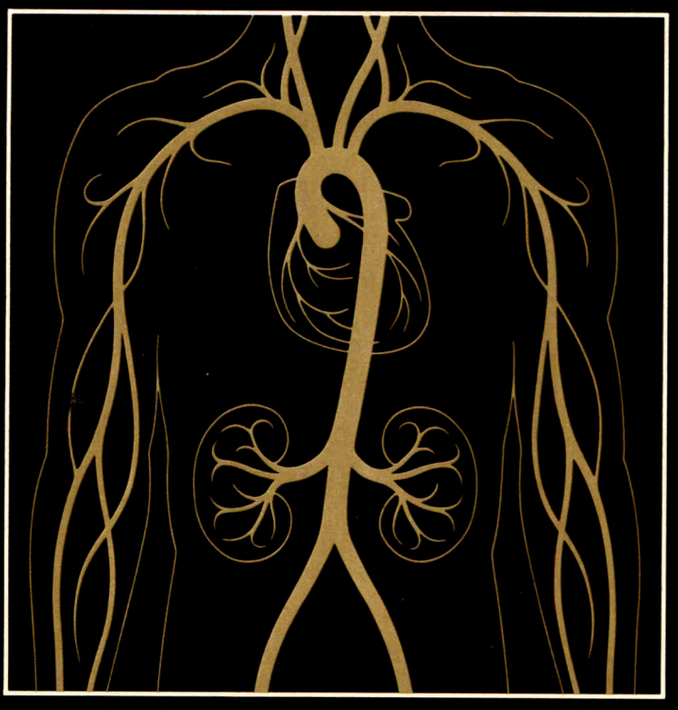
N = 10; P<.05 vs. baseline
Dosage: 240-480 mg/day

SIGNIFICANT REDUCTION OF LEFT VENTRICULAR HYPERTROPHY[1]



N = 10; P< .05 vs. baseline
Dosage: 240-480 mg/day

ONCE-A-DAY
Calan® SR
(verapamil HCl) 240mg
SUSTAINED-RELEASE CAPLETS



Taking antihypertensive therapy into the future

- A unique physiologic mechanism of action for immediate and long-term benefits
- Effective and safe monotherapy for most hypertensives
- Maintains blood flow to vital organs, including the kidneys and heart
- Helps preserve renal and cardiac performance
- Significantly reduces left ventricular hypertrophy and its associated risks
- Promotes patient compliance with well-tolerated, once-a-day therapy*

* Some patients may require *b.i.d.* dosing.

Please see the first page of this advertisement for references and a brief summary of the complete prescribing information.

From Irritable Heart to Mitral Valve Prolapse: World War I—The U.S. Experience and the Prevalence of Apical Systolic Murmurs and Mitral Regurgitation in Drafted Men Compared with Present Day Mitral Valve Prolapse Studies

CHARLES F. WOOLEY, MD, and HARISIOS BOUDOULAS, MD

The prevalence and recognition of disease have changed with time. During the present century in this country, rheumatic heart disease and coronary artery disease are examples of changing prevalence, whereas mitral valve prolapse (MVP) exemplifies changing recognition.

Whether the prevalence of MVP, presently recognized as a common form of valvular heart disease, has changed during this century is not known. In an attempt to address this question we reviewed U.S. military World War I physical examination data, specifically, the incidence of mitral regurgitation (MR) and apical systolic murmurs in 2.5 million young men examined for military service. We compared these data with the prevalence of MVP in U.S. men documented during the past decade.

World War I Examinations

Following the U.S. declaration of war in April 1917, the Selective Service Act, approved in May 1917, provided for registration of all men 21 to 30 years of age inclusive, setting the stage for the physical examination of almost 4 million men. The 1910 U.S. Army publication *Rules for Examination of Recruits* was revised and replaced with *Physical Examination Standards No. 1* in July 1917. Further clarification and simplification of diagnostic terminology and physical examination techniques and standards prompted 6 revisions, intended for the use of medical officers at recruiting stations, camps and cantonments, working with local or district boards or participating on medical advisory boards.

> The physical examinations were made by about 4,648 local boards, with more than that number of examining physicians. Many of the men were examined also by medical advisory boards, with a total number of 9,577 examining physicians. In addition, they were examined by thousands of medical officers at the numerous Army cantonments, camps, and posts.[1]

After the war, in 1920, the U.S. War Department published the 1,663-page document *Defects Found in Drafted Men*[1] (Figure 1), which contained statistical information compiled from the World War I draft records. Rarely referred to, the study included data on physical defects and diseases found in a half million men rejected by medical examiners of local boards and 2 million men examined at mobilization camps during the draft in 1917 and 1918, ages 18 to 30 inclusive. Data from the examination of 2,510,591 men were presented in the report.

The Cardiac Examination Criteria for Medical Officers

The criteria for cardiovascular examination were quite specific:

> Normal heart. A heart shall be considered normal when the apex impulse is within the left nipple line

From the Division of Cardiology, College of Medicine, The Ohio State University, Columbus, Ohio. This study was supported by the Overstreet Cardiovascular Teaching and Research Laboratory, Division of Cardiology, College of Medicine, The Ohio State University, and The Columbus Foundation, Columbus, Ohio. Manuscript received September 2, 1987; revised manuscript received and accepted December 10, 1987.

Address for reprints: Charles F. Wooley, MD, University Hospitals, Room 647, Means Hall, 1654 Upham Drive, Columbus, Ohio 43210.

and not below the fifth interspace, not heaving in character, with normal sounds, free from murmurs, absence of pulsation or dullness above the base of the heart, regular pulse of normal rate, no unusual thickening of the arteries or evidence of high blood pressure, and a normal response to the exercise test. . .The following defects shall be unconditionally rejected for all military service: a) Circulatory failure evidenced by definite symptoms such as a combination of breathlessness, marked cyanosis or edema, b) Hypertrophy and dilation of the heart evidenced by displacement of the apex impulse to the left of the nipple line or below the sixth rib, and of a heaving or diffuse character, c) Valvular disease, as evidenced by characteristic murmurs, enlargement of the heart, and a lack of the normal response to exercise. When Local Boards are in doubt concerning the physical fitness of registrants who suffer from defects due to conditions of the heart or blood vessels, they shall refer them to the Medical Advisory Boards.

Specific principles for interpretation of symptoms and signs referable to the heart were presented:

. . .given a heart of normal size and responding normally to effort, any murmur that is heard should be considered accidental and insignificant unless it can be positively demonstrated that it is a mitral or aortic diastolic murmur. . .Systolic murmurs unassociated with enlargement of the heart, alteration of the first sound, accentuation of the pulmonic second sound, or abnormal response to exercise may also be considered as without significance. Loud systolic murmurs, audible at the apex and in the left back, if associated with any enlargement of the heart, with snapping first sound, or accentuation of the pulmonic second sound, constitute a disqualifying defect.

FIGURE 1. Front page from the 1920 report released by the War Department.[1]

Results

Defects were found in approximately one-half of the men (Table I). Valvular heart disease was found in 85,143 (3.39% of the total 2,510,591 men examined). The incidence in each category of valvular disease is summarized in Table II. For reasons not stated, 44,143 of these men were not further classified, but, of the 40,330 men who were, 29,610 (73.4%) had MR. Assuming that the incidence of valvular disease was the same in the entire population, the *estimated percent incidence* of each valvular heart disease can be calculated (Table III).

Cardiovascular Examination of Recruits at the Camps During World War I

Special cardiovascular examinations were performed in many areas. The incidence of apical systolic murmurs in 3 different regions of the country comes from the following sources.

Texas: The cardiovascular board at Camp Travis, Fort Sam Houston, Texas, examined 55,000 men from Texas and Oklahoma 21 to 31 years of age.[2] Fifty men had aortic insufficiency (0.09%) and a lower incidence of mitral stenosis (0.02%), idiopathic hypertrophy (0.01%) and systemic hypertension (0.02%). "Accidental" systolic murmurs at the apex were found in 3.2%; because these were considered of no significance unless accompanied by signs of hypertrophy, only 39 men were diagnosed as having isolated MR (0.07%).

Washington: Special cardiovascular examinations were performed on every recruit at Camp Lewis, Washington, by a board that included 3 permanent cardiovascular examiners.[3] Although MR was diagnosed in 1,176 of the total 30,697 men examined (5.6%), only 418 were rejected. The large number of men with MR had the characteristic murmurs, but because there was no cardiac hypertrophy and no history of acute rheumatic fever or chorea, they were accepted for full duty.

New York: Marcus Rothschild, 1 of the 6 U.S. Army medical officers assigned earlier to the British "Heart Hospital," participated in the preparation of the U.S. medical officers' *Report on Neurocirculatory Asthenia*[4] and later discussed the diagnosis of MR based upon his experience at the Syracuse Recruit Camp.[5]

Systolic murmurs were recorded in 870 men (8.7%) in a group of 10,000 men accepted for limited service. When the criteria of cardiac hypertrophy, apical sys-

tolic murmur and history of articular rheumatism were used as the basis for the diagnosis of MR rather than the murmur alone, the diagnosis was limited to 33 cases (0.33%) of the total examined. Rothschild explained the dilemma:

> It must be admitted that, given a soldier with no hypertrophy, no definite history of acute articular rheumatism and no symptoms, but with a *loud, musical, systolic murmur at the apex transmitted to the axilla* and angle of the scapula, because of one's previous training and habit of thought, *it is extremely difficult to disregard this murmur absolutely*. (Emphasis added.) The plea is made, however, not to lay too much emphasis on this murmur. . .
>
> The differential diagnosis of mitral valvulitis (regurgitation) must be made from the following conditions: 1) functional cardiovascular disorder, disordered action of the heart, 'irritable heart of soldiers', neurocirculatory asthenia; 2) accidental systolic, apical murmurs. . .The ruling of Lewis (Thomas Lewis) on apical systolic murmurs is, to my mind, sound. *The systolic murmur per se is disregarded.* The soldier is disqualified because of a poor exercise response, not because of a systolic murmur; or his service is limited because of a definite attack of rheumatic fever, and not because of a systolic murmur.

The 1918 Perspective

The data from the massive report *Defects Found in Drafted Men* and the reports from the individual camps presented a repetitive theme. The majority of young men with the diagnosis of valvular heart disease were classified as isolated MR. That some of these young men with apical systolic murmurs were the precursors of the patients with MVP, as defined later in the twentieth century, seems reasonable in retrospect.

A. E. Cohn, then a major in the U.S. Army and senior consultant in general medicine in the American Expeditionary Force, discussed the basic questions. What was the significance of apical systolic murmurs, especially their relation to MR? This had been a subject of debate for at least a half a century. In addition, should these men be accepted for military service? Cohn expressed concern that reliable guides for decision-making were wanting.[6] He shared Rothschild's concerns and realized that new criteria were necessary to decide which types of systolic murmur were important and which were not. Most of the revised diagnostic criteria were other than auscultatory, i.e., heart size, history of rheumatism, intensity of the second heart sound and pulse rate response to exertion.

The 1918 experience involved the physical examination of approximately 4 million young men. Physicians developed, modified or standardized diagnostic and classification criteria where few had previously existed. Clinical judgments were based on conventional wisdom, however, for the matter of fitness for military service took precedence.

The impressive summary document *Defects Found in Drafted Men* reflected the massive effort that produced clinical epidemiologic classifications and tabulations of diseases and defects, based upon the examination of 4 million young men across the entire nation. This may have been the first published "medical census" in modern medicine.

TABLE I Common Defects in Drafted Men

Defect	%
Mechanical (bones, joints, hands, feet)	39
Sense organs (vision, hearing)	12
Tuberculosis and venereal diseases	11
Cardiovascular diseases	10
Development—metabolic diseases	10
Nervous—mental diseases	6

TABLE II Valvular Disease in Drafted Men (Classification of 40,330 Men)

	Pts (n)	%
Mitral regurgitation	29,610	73.4
Mitral stenosis	7,469	18.5
Aortic regurgitation	3,658	9.0
Aortic stenosis	1,263	3.1
Aortic and mitral lesions	1,184	2.9

TABLE III Valvular Disease in Drafted Men (Estimated Frequency in 2,510,559 Men)

Valvular Disease	%
Total valvular disease	3.39
Mitral regurgitation	2.48
Mitral stenosis	0.63
Aortic regurgitation	0.31
Aortic stenosis	0.11
Aortic and mitral lesions	0.10

Mitral Valve Prolapse and the 1980 Perspective

The prevalence of MVP is uncertain. Published figures reflect differences in selection, investigative techniques, diagnostic criteria and populations. Data comparing the incidence of MVP in different ethnic groups are limited, current diagnostic techniques have intrinsic limitations and there may be significant day-to-day variations in cardiac auscultatory findings in certain individuals. Phonocardiographic confirmation of the auscultatory findings, a valuable adjunct to auscultation, was not obtained in several of the epidemiologic studies. Evolving echocardiographic MVP criteria have been revised with the development of newer imaging techniques, and auscultatory—echocardiographic correlations are limited. Necropsy studies contribute to MVP natural history studies but involve older populations which do not necessarily reflect the incidence of MVP in the younger population. However, comparison of 1917–1918 MR data with current MVP epidemiologic studies may be relevant to the irritable heart-MVP story.

TABLE IV Prevalence of Mitral Valve Prolapse

Author	Year of Publication	Population	Pts (n)	Method	MVP (%) in Males
Bloch et al[7]	1977	U.S. Boston volunteers	73	Echo	4.1
Valdez et al[8]	1979	U.S. Stanford employees	105	Echo	4.7
Lucas et al[10]	1982	U.S.	750	Necropsy	8.3
Savage et al[13]	1981	U.S. Framingham	4976	Echo	2–4*
Greenwood[11]	1984	U.S. children	3100	Auscultatory	4.97
Greenwood[12]	1986	U.S. children	6168	Auscultatory	5.37
Khandheria et al[9]	1987	U.S.	2264	2-dimensional echo	11.6

* See also Figure 2.
MVP = mitral valve prolapse.

Results

The prevalence of MVP in men reported in the U.S. from different investigators using echocardiographic studies varied from 4.1 to 11.6%.[7–9] The incidence of floppy valves in 1 necropsy study was 8.3%,[10] whereas the incidence of MVP in auscultatory studies ranged from 4.97 to 5.37%[11,12] (Table IV).

Echocardiographic MVP was detected in 5% of the total 4,967 subjects in the Framingham study. The prevalence of MVP in the male population was reasonably consistent at 2 to 4% from those between ages 20 and 30 through those who were 80 to 90 years old[13] (Figure 2).

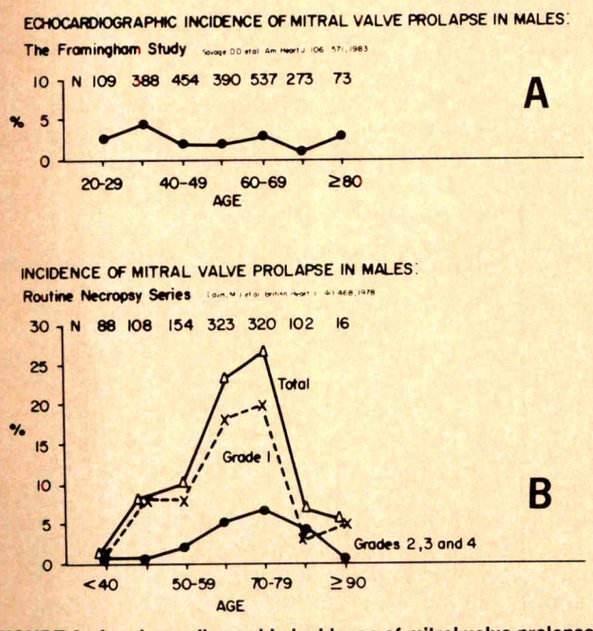

FIGURE 2. *A*, echocardiographic incidence of mitral valve prolapse (MVP) in males from the Framingham Study (modified from Savage DD et al[13]). *B*, incidence of MVP in males from a prospective necropsy study. Grade 1 = mild, grade 2 = moderate, grade 3 = moderately severe and grade 4 = severe floppiness of mitral valve (MVP). The total represents all patients with grades 1, 2, 3 and 4 (data from Davies MJ et al[14]). From Boudoulas H, Wooley CF.[19]

Davies et al[14] reported that the overall prevalence of MVP (floppy mitral valves) was 4% in men in 1,111 routine necropsies performed in men in 4 London general hospitals. The severity of prolapse was graded as 0 (none), grade 1 (minimal involvement), grade 2 (extensive prolapse of 1 or both cusps), grade 3 (chordal rupture) and grade 4 (chordal fusion to ventricular wall). MR was attributed only to grade 2 to grade 4 valves, which were called "floppy mitral valves" (Figure 2).[14]

The incidence of apical systolic murmurs in patients with MVP varies from study to study; in the younger population, systolic murmurs have been reported in <50% of patients with echocardiographic MVP. Thus, it appears that the reported contemporary incidence of apical systolic murmurs in males 20 to 40 years of age may approximate 2 to 3%.

Summing up: During the U.S. experience in World War I, approximately 4 million young men were examined. The incidence of cardiovascular defects was appreciable. MR was the most frequent valve lesion and far exceeded all other valve lesions, individual or combined. The repetitive theme, that MR is a common phenomenon, extends from World War I to the 1980s and has gained new clinical importance as we learn more about the natural history of MVP,[15] MR[16] and cardiovascular disorders of connective tissue origin.[17]

We conclude that the prevalence of apical systolic murmurs and the diagnosis of MR in young Americans during World War I parallels the prevalence of apical systolic murmurs and MVP among young men in the 1980s.

Lewis A. Conner, MD (1867–1950), and Lessons Learned from Examining Four Million Young Men in World War I

CHARLES F. WOOLEY, MD

The physical examination process of the U.S. Army during World War I involved almost 4 million young men. It required the U.S. Army to update the 1910 version of its *Rules for Examination of Recruits* and to revise and clarify cardiovascular physical examination standards and terminology.[1]

The definition, differential diagnosis and disposition of young men with irritable heart, soldier's heart and mitral regurgitation had been an early and major military medical problem in England during World War I. The consequences in terms of fitness for duty, military time loss and cost of disability, rehabilitation and pensions were enormous and unexpected.[2] The same concern, confusion and debate over cardiovascular diagnosis occurring in England[3–5] ultimately affected the U.S. Large numbers of asymptomatic young men with apical systolic murmurs without cardiomegaly posed diagnostic and disposition problems for examining physicians. Another large group of young men with a constellation of disabling cardiovascular symptoms, with or without apical systolic murmurs, required decisions about fitness for military service.

Lewis A. Conner took " . . . stock of what has been accomplished by all this elaborate effort" in the U.S. when he presented "Cardiac Diagnosis in the Light of Experiences with Army Physical Examinations" at the Association of American Physicians' meeting in Atlantic City in June 1919.[6] The present article reviews Conner's observations on cardiac diagnosis during the wartime physical examination process instituted in the U.S. Army. A brief sketch of his medical and cardiological experience in the U.S. is presented as a background to this link from irritable heart to mitral valve prolapse.

Lessons Learned

During the 19 months between the U.S. entrance into the war and the Armistice, approximately 4 million young men were "subjected to a special physical examination of their circulatory apparatus by officers chosen for their supposed special fitness for this work." Conner presented the lessons learned under several distinct categories:

The lessons learned about cardiac diagnosis: Simply put, standardized methods of examination and criteria for diagnosis of large numbers of normal young men had never been implemented before in the U.S.

"No similar examinations upon any such gigantic scale have ever before been attempted. . .a real advance has been made in certain phases of cardiac diagnosis. . .chiefly through the opportunity afforded to examine an immense number of young men, almost all of whom were normal subjects, and to learn the frequency and the extent of normal variations of the physical signs of the heart."

Just how to define and classify apical systolic murmurs concerned Conner. "Accidental murmurs. . . even under the most rigid interpretation of the term the occurrence of such systolic accidental or functional murmurs is surprisingly frequent. . .such apical accidental murmurs are very common. It is not possible to give accurate statistics, but I am convinced, in the light of my own experience, that it would be conservative to say that at least nine-tenths of all *apical systolic murmurs in young adults belong to the class of accidental or functional murmurs.* (Emphasis added.)

These apical systolic accidental murmurs have several features. . .their inconstancy. They may be absent during rest and be pronounced after exercise or during excitement. The first sound may be quite clear and normal in the erect posture and have all the character-

istics of a murmur in the recumbent position. . .they usually show no tendency to be transmitted to the left of the apex; then, too, the murmur is obviously only the modified and changed first sound; it is not something clearly distinct from and additional to the heart sound as is so commonly the case with the murmur of mitral insufficiency. Lastly, such accidental murmurs seem rarely if ever to have the peculiar high-pitched, whizzing or blowing quality usually possessed by those due to mitral insufficiency."[6]

The lessons learned about functional disorders of the heart: "The irritable heart of soldiers (The Effort Syndrome, Neurocirculatory Asthenia). . .was far away the commonest disorder encountered and transcended in interest and importance all the other heart affections combined." Conner reviewed the conventional wisdom about "Soldier's Heart" almost verbatim from a report on neurocirculatory asthenia and its management[7] written by the U.S. medical officers detailed to the British Heart Hospital in England, which in turn incorporated the "Soldier's Heart" experience[8] with only the name changed. He emphasized the difficulties in separating " . . . 'soldier's heart' and 'effort syndrome' from valvular heart disease, particularly mitral insufficiency. . .the great danger, even with experienced examiners, of mistaking this neurosis for some organic disease of the heart. . .It was indeed often difficult to believe that a soldier who, on even moderate exertion, showed an array of striking symptoms (dyspnea, exhaustion, precordial pain, tremulousness, cyanosis, extreme tachycardia) could be suffering merely from a neurosis. Moreover, certain of the physical signs sometimes bore a close resemblance to those of mitral insufficiency. . .The pronounced and widespread cardiac impulse often suggested cardiac enlargement; the first sound at the apex was usually extremely short and sharp and the second pulmonic sound often very loud; a systolic accidental murmur was sometimes present and the suggestion of a thrill was often given to the palpating hand in the apical region. . .Thus with such a combination of pronounced symptoms and suggestive physical signs it is not surprising that a good deal of time was needed to educate the great body of medical officers to the true nature of these cases."[6]

The lessons learned about mitral regurgitation: Conner addressed the differential diagnosis of mitral regurgitation as follows. "The Effort Syndrome was the condition most frequently mistaken for mitral insufficiency. . .The rapid and violent heart action and pronounced cardiac impulse frequently gave the impression of cardiac hypertrophy; if, in addition, there was to be heard an apical accidental murmur the resemblance to mitral insufficiency might be close and, to the uninitiated, the diagnosis would seem to be confirmed by the pronounced subjective symptoms of precordial pain, dyspnea, palpitation, etc. With increasing experience in the recognition of the effort syndrome its confusion with mitral insufficiency became less and less frequent, for the two conditions bear little real resemblance to each other. The tachycardia, which is so constant and marked a feature of the 'soldiers' heart' is no part of the clinical picture of mitral leakage, and, as has been said, the pronounced subjective symptoms were characteristic of the neurosis and were altogether lacking in the valvular cases.

The question has been much discussed of late as to whether one is ever justified in making a positive diagnosis of mitral insufficiency on the existence of an apical murmur alone, and in the absence of signs of hypertrophy and of a history of definite attacks of rheumatic fever, even though the murmur have those special characteristics of transmission and quality which are supposed to belong to that disease. My own attitude toward this question has been modified a good deal by my army experiences and without venturing to be dogmatic upon the subject I am inclined to believe that *one will make fewest mistakes in the diagnosis of mitral regurgitation by adhering to the rule of never venturing a diagnosis on the presence of a murmur alone, no matter how characteristic it may seem to be.* (Emphasis added.) It is certain that if this rule were generally followed, uncomplicated mitral insufficiency would take its place among the less frequent forms of valvular disease, as I believe it deserves to do."[6]

Conner illustrated this point with Rothschild's[9] analysis of the records of 10,000 recruits accepted for

FIGURE 1. Lewis A. Conner (1867–1950). Courtesy of the National Library of Medicine, National Institutes of Health.

limited service. Although 870 had apical systolic murmurs, when the criteria for the diagnosis of mitral regurgitation were modified from murmur alone to the combination of murmur, cardiac hypertrophy and a definite history of rheumatic fever, then only 33(3.8%) fulfilled these criteria for the diagnosis of mitral regurgitation.

The lessons learned about common types of heart disease seen by hospital physicians in civil life: Conner found that degenerative conditions common to middle and old age, severe forms and advanced stages of rheumatic valvular disease and syphilitic disease of the aorta and heart "were conspicuous by their rarity."

Lewis A. Conner (1867–1950)

Conner was one of the founders and the first president (1924–1925) of the American Heart Association; a major memorial lecture at the annual meeting bears his name. He was also the first editor-in-chief of *The American Heart Journal*, the original periodical of this association, from 1925 until 1937.

He wrote sparingly and left only a modest tangible legacy. His bequest took a different form. David Barr[10] recalled that his "preeminence as a teacher can be attested by all graduates of Cornell who came into . . .contact with his remarkable example and method. His learning, his clinical judgment, and above all his integrity, made him the idol of the students and particularly of those chosen young men who were permitted to work with him as interns or residents in the wards of the New York Hospital."

Conner was born in Indiana, attended Yale University and the College of Physicians and Surgeons of Columbia University. He received his MD degree in 1890 and was appointed as house officer at New York Hospital in January 1892.[10] Later, he served as a private in the Spanish-American War. A member of the original faculty of Cornell University Medical College in 1898, he was appointed professor of clinical medicine at the age of 34 and eventually succeeded W. Gilman Thompson as professor of medicine in 1916. All of his professional lifetime was devoted to the New York Hospital and Cornell University Medical College. During World War I he was a colonel in the U.S. Army Medical Corps.

Dickson W. Richards, in the 1953 Conner Memorial Lecture, commented ". . .he was throughout his long life primarily a clinician and a teacher of medicine. . .a master in the art and science of physical diagnosis . . .held firm to the belief that new advances should support and add to our simpler forms of knowledge, rather than replace them; that in the analysis and treatment of disease, laboratory findings, whatever their nature should be our servants and not our masters."[11]

J. James Smith[12] touched the legend and tells us about the man. "Educated at a time when the unaided senses still represented the only resource in the clinical study and recognition of many diseases, Dr. Conner's mastery of physical diagnosis must have frequently astonished the uninitiated house officer."

One such young physician, while presenting a case of lung abscess following pneumococcal pneumonia at Grand Rounds, reported incredulously that the correct diagnosis had been made at the Burke Convalescent Home by a very aged physician who didn't even have a stethoscope. This man had never seen Dr. Conner palpate for the cardiac apex with his gnarled fingers, after which he announced a "high degree of mitral stenosis." This was before he listened, which of course was with sounding towel and naked ear, for his hearing loss largely defeated the use of the stethoscope."

Smith also recounted the lumbar puncture vignette: "One of the few details about his career that Dr. Conner ever told me personally was said hesitatingly, almost sheepishly. He said he thought he had performed the first lumbar puncture on a living man on this Continent. . .

It seems that during a tour of Europe in the 1890s, which in those days was an important finishing-off process in medical education, he had visited the clinic in Kiel of Heinrich Quincke, who was then developing the technique of lumbar puncture. Quincke describes this in 2 papers published in *Berlin Klinische Wochenschrift*, 28, 929, 1891 and 32, 889, 1895. In the latter paper he reports that the needles were fabricated for him by 'instrumentenmacher Assman.' With rare foresight, apparently well aware of the importance of the technique, Lewis Conner brought a supply of these needles back with him. . .

It was in the House of Relief, probably in the reception ward, where Lewis Conner performed the lumbar puncture with his German-made needle. His introduction of this technique could not have been more timely [as]. . .epidemic meningitis was an important disease at the turn of the century."[12]

Perspective

While there are limitations in looking back and analyzing time-distorted experience, there are lessons to be learned.

The U.S. "Grand Experiment" during World War I, when 4,000,000 young men were examined in an organized, systematic manner was a new medical experience in this country. Physical defects were found in approximately one-half of the men examined.[13] Cardiovascular defects were discovered in approximately 5% of the men examined, the majority of which were classified as valvular heart disease. Of those within the group with valvular heart disease that were further classified by defect, 65% were classified as mitral insufficiency.[1,13] Another large group was classified under the title of functional heart disease, cardiac arrhythmias or persistent tachycardia.

Reviewing the Conner article[6] and the massive document *Defects Found in Drafted Men*[1] helps us to understand how the examiners interpreted the physical diagnostic criteria in the military setting and the difficulties they had in the differential diagnosis of irritable heart, effort syndrome, neurocirculatory asthenia and mild mitral regurgitation. Even the veteran clinicians were dealing with phenomena new to their experience.

The textbooks of the day described patients with well-established or far advanced valvular heart dis-

ease and the descriptions of patients with mitral regurgitations reflected this bias. The cardiovascular phenomena in young men that the physical examination process uncovered during World War I required a modification of the conventional wisdom.

Conner's conclusion that nine-tenths of all apical systolic murmurs were accidental or functional echoed the precepts of the early French auscultors[14] and the then current British dogma articulated by Mackenzie[3] and Lewis[5] from the "soldier's heart" and "Heart Hospital" experiences. Although Clifford Allbutt[4] presented a dissenting voice to those concepts in England as also did earlier American clinicians such as Griffith, Hall and Prince, these minority opinions were buried by the more authoritative views.[14]

When physicians serve masters other than their patients, the results are frequently difficult to understand in medical terms. The British insurance-government-military complex of those years supported the British "Heart Hospital" research but had the needs of the military service and the cost of prolonged hospital stays, rehabilitation and pensions as primary concerns.[2] A war that left 9 million dead and 22 million wounded required, while it raged, endless numbers of bodies for sacrifice and was not an ideal environment in which to attempt to resolve these cardiac diagnostic dilemmas.

Although the physical examination process instituted during World War I had a positive impact on the development of cardiovascular physical diagnostic criteria and standardization of terminology in the U.S., the authoritative, summary dismissal of apical systolic murmurs as diagnostic criteria for mitral insufficiency served to impede curiosity, retard original thought and limit natural history studies for another 4 decades.

Low Dose Aspirin After Early Thrombolysis in Anterior Wall Acute Myocardial Infarction

FREEK W.A. VERHEUGT, MD
ALBERT J. FUNKE KÜPPER, MD
TJEBBE W. GALEMA, MD
JAN P. ROOS, MD

Early thrombolysis has become the standard treatment of patients who have transmural acute myocardial infarction (AMI) and has proven to be the most effective in anterior AMI in terms of survival and left ventricular function.[1-3] Reinfarction as a result of coronary reocclusion remains the major drawback of early thrombolysis and occurs mainly in the first 3 months after AMI.[2] Strategies to prevent reinfarction include coronary artery bypass surgery, coronary angioplasty and drug treatment. Randomized trials of surgery after thrombolysis are lacking and those involving coronary angioplasty have had negative results.[4,5] We present the results of a prospective, randomized, double-blind placebo-controlled trial of low dose aspirin after early thrombolysis in patients with first anterior wall AMI.

Patients were eligible for entry in the study if they had (1) early (<4 hours) symptoms and electrocardiographic signs of first anterior wall AMI (ST-segment elevation of >2 mm in the precordial leads in the absence of precordial Q waves), (2) no contraindication to thrombolytic therapy (age older than 70 years, bleeding tendency, recent cerebrovascular accident, menstruation, antithrombotic treatment or cardiac massage) and (3) no contraindication to aspirin (recent gastrointestinal ulcer). After treatment with 1,500,000 U streptokinase intravenously, the patients provided informed consent. Subsequently, they were randomized to receive 1 capsule a day containing 100 mg acetylsalicylic acid or placebo. The first capsule was given immediately after informed consent. Further antithrombotic treatment consisted of heparin 5,000 U subcutaneously twice a day until full mobilization occurred. Standard coronary care was given to all patients.[2] If not contraindicated, atenolol 100 mg daily was administered routinely. Calcium antagonists and nitrates were added only when needed. Special attention was given to the recurrence of ischemic events. Unstable angina pectoris was defined as the occurrence of anginal pain at rest or minimal physical activity with accompanying ST changes on electrocardiography and normal plasma levels of creatine kinase-MB 6 hours later. Reinfarction was diagnosed when anginal pain recurred together with ST changes or new Q waves or both, followed by a significant increase in creatine kinase-MB, creatine phosphokinase, serum glutamine oxalate transferase and lactic dehydrogenase (more than twice the upper normal level or the last level before the pain attack). Sequential 2-dimensional echocardiopgraphy was performed during the coronary care unit stay and left ventricular wall motion abnormalities were scored as described earlier.[6] Heart catheterization was intended for all patients within 6 weeks after admission and consisted of left ventricular angiography and coronary angiography. Left ventriculograms were taken in the right anterior oblique position and left ventricular end-diastolic volume and ejection fraction were calculated.[3] On coronary angiography the left anterior descending artery was regarded as occluded when the vessel was not visualized at all, showed retrograde filling by collateral vessels or anterograde filling, but not complete within 3 heart cycles (functionally occluded). The angiograms were interpreted by 2 experienced cardiologists. In case of equivocal results the view of a third cardiologist was decisive. After discharge the patients were followed up in the out-patient clinic. The study medication was withdrawn after 3 months.

Twenty-four patients received aspirin and 26 placebo. Relevant baseline characteristics are listed in Table I. No significant differences were observed. Three-month follow-up was complete in all patients and the occurrence of recurrent ischemic events, death and revascularization are listed in Table II. Reinfarction in the aspirin group was noted on day 3 and days 2, 3, 7, 11, 14 and 27 in the placebo group. Angiography was performed in 25 patients (50%) within 6 weeks after randomization. In the other pa-

tients angiography was not performed because of death (2 in the aspirin group, 2 in placebo group), severe peripheral vascular disease (3 aspirin), brain embolism (1 aspirin) and refusal (9 aspirin, 8 placebo). The characteristics of patients who did and did not undergo angiography are listed in Table III. Except for age, there were no significant differences in clinical and hemodynamic parameters. Table IV shows the angiographic results. Bleeding complications as defined earlier[7] were not encountered in any patient, either in the acute phase of the AMI or during follow-up or heart catheterization.

Low dose aspirin (≤325 mg daily) has been shown to be effective in patients with unstable angina[8] and after coronary bypass surgery.[9] We report the effectiveness of the same regimen in the prevention of coronary reocclusin after early thrombolysis resulting in a lesser incidence of reinfarction and in better preservation of left ventricular function. This is in contrast with the negative outcome of earlier much larger studies on the effect of aspirin after AMI from the era before early thrombolytic therapy. These negative results might be due to the relatively low incidence of spontaneous early (<4 hours) coronary reperfusion, the dose of aspirin and the late patient inclusion in the earlier studies. However, our results correlate well with those of the recently published International Studies on Infarct Survival-2 on the efficacy of streptokinase, aspirin, heparin and placebo in AMI.[10] Although the design of the latter study lacks angiography and is much more complex and different, the clinical outcome in our patients treated with streptokinase and aspirin is similar in terms of reinfarction.

Unlike in inferior wall AMI, in anterior wall AMI the infarct-related coronary artery can be identified beyond doubt, which makes the angiographic design of our study reliable and simple. On the other hand, many of the angiographic data are lacking due to death or refusal. Therefore, our angiographic results should be interpreted with care. Special attention must be paid to the relatively high rate of occlusion of the left anterior descending coronary artery in the placebo-treated group. It is unlikely that this finding is due to patient selection, because both treatment groups undergoing angiography were highly comparable. After streptokinase infusion the patients received only subcutaneous heparin in a relatively low dose. This is a

generally accepted prophylactic regimen against deep venous thrombosis, but might be insufficient for the prevention of coronary reocclusion. In other trials of intravenous thrombolysis, patients have been treated with oral anticoagulants and found to have higher patency rates of the infarct-related coronary artery[11] than our patients in the placebo group. However, our angiographic results with aspirin are even better, which correlates well with the general results of our study. Further, aspirin treatment is safer, more convenient and less laborious than oral anticoagulation.

We have shown a low 3-month mortality rate in patients with anterior wall AMI, which might be due to the early thrombolytic treatment. This stresses the need for preservation of the excellent results of early thrombolysis in anterior wall AMI also reported by others.[1,2] Unlike coronary angioplasty,[4,5] platelet inhibition by low dose aspirin might offer this preservation, although angiographic studies with larger numbers of patients are necessary to confirm these results.

ANGEL CEQUIER, MD
JACQUES CRÉPEAU, MD
GILLES COTÉ, MD
PIERRE DE GUISE, MD
DAVID D. WATERS, MD

Among 2,000 patients who underwent PTCA at the Montreal Heart Institute between July 1980 and December 1986, 343 developed restenosis and had a second PTCA; 36 of these patients developed restenosis a second time and underwent a third PTCA. Indications for the third PTCA were reappearance of angina with a positive symptom-limited treadmill exercise test or unstable angina in association with angiographic documentation of restenosis. An additional 50 patients developed recurrent restenosis and were treated medically or with coronary bypass surgery, rather than a third PTCA. Choice of treatment appeared to be influenced more by the opinion of the treating cardiologist and the wishes of the patient than by clinical or angiographic factors; therefore, the patients who had a third PTCA are generally representative.

All PTCA procedures were performed by a percutaneous femoral approach, as previously described.[6] Based on our early experience,[7] since April 1983 we have used higher inflation pressures (8 to 12 atmospheres) and balloons that when inflated are slightly larger in diameter than the adjacent normal coronary segment. As a consequence, balloon/artery ratio in the study patients was higher ($p < 0.01$) for the third PTCA (1.14 ± 0.01) compared with either the second (1.07 ± 0.2) or the first (1.04 ± 0.1). Residual stenosis was less after the second PTCA (29 ± 12%, $p < 0.01$) compared with the first (33 ± 11%) and less after the third PTCA (27 ± 17%, $p < 0.01$) compared with the second.

Primary success was defined as a reduction in diameter stenosis to <50% in the absence of myocardial infarction, death or bypass surgery. All patients took aspirin during follow-up. Coronary arteriography was

The most important limitation of percutaneous transluminal coronary angioplasty (PTCA) continues to be restenosis, which occurs at a rate of 30 to 40%.[1–3] Most patients with restenosis undergo a second PTCA; the primary success rate is high, the complication rate is low and sustained improvement of the redilated lesion has been demonstrated.[4,5] Patients who have recurrent restenosis comprise a much smaller group and reported information describing their management and outcome is scant. This article reports our experience on the safety and efficacy of a third PTCA for recurrent restenosis.

repeated a mean of 12.2 ± 9 months after the third PTCA in 30 of the 33 patients with successful PTCA. Restenosis was defined as a diameter stenosis >50% at a site with primary success. All measurements were made by an experienced cardiovascular radiologist, as previously described.[8] Statistical comparisons were made using analysis of variance, t tests or chi square tests, where appropriate.

A third PTCA was performed in 32 men and 4 women. Their clinical features are listed in Table I and compared with a control group with a successful first PTCA without restenosis. Control subjects were matched to study patients for age, gender and date of PTCA. The duration of angina was shorter, previous myocardial infarction was less common and hypercholesterolemia was more common in the group with recurrent restenosis.

The clinical evolution of the study patients is summarized in Figure 1. The interval between the first and second PTCA was 3.8 ± 2.3 months and between the second and third it was 4.0 ± 2.0 months. The site of dilatation was the left anterior descending coronary artery in 26 patients, the right coronary artery in 8 and the circumflex in 2. The mean stenosis reduction was from 85 ± 10 to 33 ± 11% with the first PTCA, from 79 ± 12 to 29 ± 12% with the second and from 76 ± 13 to 27 ± 17% with the third PTCA. Primary success was obtained in 33 of 36 patients (92%). The lesion could not be crossed in 1 patient whose angina was subsequently controlled with medical therapy. Two patients suffered complications: 1 developed left anterior descending coronary artery dissection necessitating emergency bypass surgery and another had a non-Q-wave infarction after PTCA of a right coronary artery.

Coronary arteriography was done a mean of 12.2 ± 9 months after PTCA in 30 of the 33 patients (91%) with primary success. The 3 patients who refused angiographic restudy had no angina and no evidence of myocardial ischemia on their thallium exercise tests. Restenosis was found in 11 of the 30 restudied patients (37%). Four of these 11 were asymptomatic and had negative thallium exercise test results. In the other 7, angina had recurred a mean of 4.2 ± 2 months after PTCA. One of these patients underwent bypass surgery and the remaining 6 successfully underwent a fourth PTCA. Angina has not recurred in 4 of the 6; however, in 3 of these 4, follow-up is less than 6 months. One patient died suddenly 2 months after the fourth PTCA and the other developed angina with restenosis at 3 months. He had a fifth angioplasty, again had restenosis and finally underwent bypass surgery. Overall, 26 of 36 patients (72%) are asymptomatic at long-term follow-up after a successful third PTCA, excluding the effect of subsequent treatment. Including the results of bypass surgery and fourth PTCA, 32 of 36 patients (89%) are asymptomatic.

In our experience a third PTCA for recurrent restenosis is both safe and effective. The primary success rate (92%), complication rate (6%) and restenosis rate (37%) did not differ from the rates usually reported for first angioplasties.[1-3] At latest follow-up, most of our patients were free from angina.

TABLE I Characteristics of Patients with a Third Angioplasty Compared with a Control Group with Successful Angioplasty Without Restenosis

	Study Group (n = 36)	Control Group* (n = 36)
Mean age (yrs)	52 ± 9	52 ± 7
Systemic hypertension (%)	12 (33)	15 (42)
Diabetes mellitus (%)	6 (17)	3 (8)

2 (%)	10 (28)	11 (31)
3 (%)	2 (6)	3 (8)

* Matched to study patients for age, gender and date of angioplasty.
† $p < 0.05$.

Previous studies have reported on the efficacy of a second PTCA for restenosis. Williams,[4] Meier[5] and their co-workers concluded that the incidences of restenosis are similar after a first or second PTCA. Their angiographic follow-up rates, however, were only 48 and 61%. Our experience supports the contention that repeat PTCA can be performed with the usual restenosis rate; the high angiographic follow-up rate (91%) increases the precision of our results.

Abi-Mansour et al[9] reported good clinical results after a third PTCA in 17 patients; the restenosis rate was only 24%, but most patients did not undergo repeat arteriography. Teirstein et al[10] reported a primary success rate of a third PTCA of 93% (69/74), similar to our study. Complications included urgent surgery in 3 patients and 2 deaths. The per patient restenosis rate was 42%, and after a fourth PTCA, 53% (8/15). They concluded that restenosis rates are higher following third and fourth angioplasties. Our results do not support their conclusion. Additional information not in-

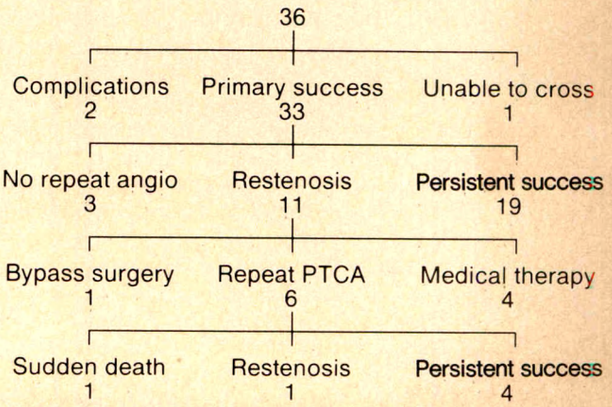

FIGURE 1. Clinical evolution of the 36 patients who underwent a third PTCA for recurrent restenosis.

cluded in their report might resolve this discrepancy. Restenosis rates vary according to the definition used, and per patient rates are higher after multivessel compared with single-vessel PTCA.

Restenosis has been correlated with procedural variables, such as the severity of residual stenosis and the absence of intimal dissection, and clinical variables, such as recent onset or unstable angina, diabetes and smoking.[11] Hypercholesterolemia, absence of previous infarction and shorter duration of angina were the clinical characteristics that differed in our study patients compared with a control group with no restenosis. Clinical factors such as these may reflect an underlying pathophysiologic tendency favoring restenosis. Procedural variables may be easier to manipulate; larger balloons and higher inflation pressures were used for the third PTCA in this study. The slightly milder residual stenoses that resulted may have favorably influenced subsequent restenosis rates.

In summary, a third PTCA is safe and effective treatment for recurrent restenosis. Although some patients may later require bypass surgery or another PTCA, most will eventually be asymptomatic.

Effect of Nifedipine on Out-of-Hospital Silent Myocardial Ischemia in Asymptomatic Men with Coronary Artery Disease

PETER F. COHN, MD
WILLIAM E. LAWSON, MD
With the technical assistance of
VIRGINIA GENNARO
DOROTHY BRADY

Most investigations using ambulatory electrocardiography to document episodes of myocardial ischemia during daily life have studied patients with angina.[1-7] This is also true of therapeutic trials with antiischemic agents.[5-7] Recently, however, 3 studies[8-10] have reported the frequency and duration of ischemic episodes in coronary artery disease patients who do not have angina, i.e., patients asymptomatic after myocardial infarctions or those who have never had symptoms. Information on drug therapy for these patients with silent myocardial ischemia is confined to 1 study with the β blocker metoprolol.[11] The purpose of the present pilot study was to test the effect on silent myocardial ischemia of the calcium antagonist nifedipine as used in standard therapeutic doses.

From the Cardiology Division, Department of Medicine, State University of New York Health Sciences Center (T-17-020) Stony Brook, New York. This study was supported in part by a grant from Pfizer Laboratories, Inc. Manuscript received October 28, 1987; revised manuscript received and accepted December 10, 1987.

Our original patient group consisted of 15 male patients studied in our unit because of (1) no history of angina or anginal equivalents, (2) a positive but asymptomatic exercise test result and (3) coronary artery disease documented by coronary arteriography. None of the patients was taking cardiac medications during the exercise tests or the subsequent ambulatory monitoring period. Twelve of the 15 patients demonstrated >1 episode of ischemia on ambulatory electrocardiographic (Holter) monitoring during the initial 48 hours of monitoring and formed the final study group.

Ambulatory electrocardiographic monitoring was performed (usually using leads V_1 and V_5) with a Del Mar Avionics 445B 2-channel recorder, which has a frequency response of 0.50 to 100 Hz and meets the American Heart Association's specifications for heart rate and ST changes. In our laboratory this system has been tested for reliability by comparing conventional 12-lead electrocardiographic recordings during exercise tests to simultaneous Holter recordings. Before a study, each patient underwent positional changes and hyperventilation to assess lability of the ST segment; no baseline ST abnormalities were present, nor did any develop during these maneuvers. Recordings were scanned on an Avionics 9100 scanner; electrocardiographic strips showing horizontal or downsloping ST-segment depression of at least 1 mm, lasting at least 1 minute and separated by 1 or more minutes from successive episodes were printed out and reviewed in a blinded fashion. Patient diaries were also kept with patients instructed to record their daily activities on an hourly basis, except, of course, when

A = anterior; CA = coronary artery; I = inferior; LAD = left anterior descending coronary artery; LC = left circumflex coronary artery; MI = myocardial infarction.

asleep. After giving informed consent, each patient was monitored for 48 hours consecutively and then given nifedipine therapy, either 10 or 20 mg orally 3 times a day. (Two patients received the larger dose because they had previously required it for blood pressure control). Two to 3 days later, patients underwent repeat 48-hour Holter monitoring.

Coronary arteriography was performed in a standard manner. A significant lesion was one that occluded a major coronary artery or one of its large branches by at least 70%.

All 12 patients were men aged 42 to 67 years. Three patients had prior Q-wave myocardial infarction (1 was unrecognized), and 1 patient had a prior non-Q-wave infarction. The site of the infarctions and vessel stenoses on coronary arteriography is listed in Table I. Six of the 12 patients had 3-vessel disease.

During the initial 796 hours of monitoring there were 80 episodes of silent ischemia. The number ranged from 3 to 17 (Table I). Total duration was 1,487 minutes with a range of 14 to 699 minutes. Heart rate at onset of ST depression ranged from 60 to 150 beats/min with a mean of 88 ± 8. As recorded in the diaries, activity during these episodes was usually not related to heavy exertion. A circadian variation was found: 32 of the 80 episodes (40%) occurred in the 6 A.M. to 12 noon time period.

The total number of ischemic episodes decreased to 37 ($p < 0.01$) and the duration of 625 minutes ($p < 0.05$) (Table II). As depicted in Table I, 7 of the 12 patients showed at least a 50% decrease in both the number and duration of episodes. Of the other 5, 2 (patients 2 and 12) had lesser reductions, and 3 (5, 9, 10) had no reduction in frequency but a reduction in duration. In 2 patients, ischemia was eliminated entirely and in 3 others, reduced to 1 episode. Heart rate at the onset of ischemic events was unchanged from that before therapy (Table II) and there was no change in frequency of episodes between 6 A.M. and 12 noon. There were no adverse side effects from the drug.

TABLE II Effect of Treatment on Holter Findings

	Pretreatment	During Nifedipine Administration	p Value
Ischemic episodes (n)	80	37	<0.01
Duration of ischemic episodes (min)	1,487	625	<0.05

NS = difference not significant.

To date, 3 studies of asymptomatic patients with coronary artery disease and silent myocardial ischemia out-of-hospital have been published.[8-10] Whether these patients should be treated and if so, with what agents, is unclear because pertinent prognostic data are limited. What studies are available show that prognosis in asymptomatic coronary populations with silent ischemia on exercise testing (with or without prior infarctions) appears to be related to the extent of vessel disease and the degree of left ventricular dysfunction. Certainly, if one were going to treat an asymptomatic population with antiischemic drugs, the subgroup of high-risk patients with 3-vessel disease and moderate left ventricular dysfunction would seem best suited for such trials (although coronary artery surgery is also an option in these patients). But what agents—or combinations of agents—should one choose? Choice of drugs can be empiric (based on antianginal experience) or can depend on the results of pilot studies with asymptomatic patients. In our pilot study, we used nifedipine, a calcium antagonist with well-documented coronary vasodilatory properties, because increased vasoconstrictor tone as a contributing mechanism to silent ischemia has been suggested by (1) the lower

than expected heart rates observed during many silent ischemic episodes and (2) the relative infrequency of episodes related to strenuous exertion. In the present study we used standard doses of the drugs and no attempt was made to titrate to higher levels.

One of the warnings in interpreting our study data is day-to-day variability of ischemic episodes. This is especially important since this was not a randomized placebo-controlled trial. Preliminary studies by Deanfield et al[12] suggest that for a trial of this size, one would need to show at least a 50% decrease in ischemic episodes before one could attribute the reduction to therapeutic agents. In our study, this level was achieved. Further, despite the use of just 1 drug at low doses, 9 of the 12 patients had marked improvement in both ischemic frequency and duration.

Our reduction in ischemic frequency and duration is comparable to that achieved by Imperi et al[11] using low dose metoprolol (50 mg 2 times daily) although the mechanisms of action of these 2 drugs are obviously different. Even after treatment, we found the percentage of ischemic activity was still highest from 6 A.M. to 12 noon. This was also true in the study by Imperi et al.

In summary, even in standard dosages, nifedipine was effective in reducing the frequency and duration of silent myocardial ischemia in our patient population. Based on this initial pilot study, it would appear reasonable to consider nifedipine for testing in large scale, randomized, placebo-controlled studies of asymptomatic patients with silent ischemia. (If higher doses are used, however, they probably should be combined with β blockers to reduce reflex tachycardia). These trials could be designed to explore not only the therapeutic benefits of antiischemic drugs, but also the prognostic implications of treating ischemic episodes—whether they are painful or not.

Relation of Left Ventricular Free Wall Rupture in Acute Myocardial Infarction to Forced Immobilization

CHRISTIAN TORP-PEDERSEN, MD
FRANK STEENSGAARD HANSEN, MD
ASGER PEDERSEN, MD

Left ventricular (LV) free wall rupture occurs in approximately 10% of fatal acute myocardial infarctions (AMI).[1] In 1 report[2] 73% of the deaths associated with myocardial infarcts among institutionalized psychotic patients were due to LV rupture. This raised the possibility of a relation between physical activity and LV rupture. In a later report[3] no difference was observed between psychotic and nonpsychotic patients at the same hospital. At present it is unclear whether physical activity is a risk factor for LV rupture in myocardial infarcts. We studied 7,009 consecutive cases of AMI for a possible relation between mobilization and LV rupture.

From the Department of Cardiology, Glostrup County Hospital, DK2600 Glostrup, Denmark.

Manuscript received May 14, 1987; revised manuscript received and accepted November 24, 1987.

Glostrup County Hospital serves a well-defined urban and suburban area in Copenhagen, Denmark, with a population between 250,000 and 350,000. The coronary care unit receives all cardiac emergencies in the region. AMI is rarely treated at home. We have analyzed all cases of AMI admitted during the period 1959 to 1983. From 1959 to 1977 the diagnosis of AMI was based strictly on the World Health Organization criteria.[4] After 1977 a transient increase in serum levels of the heart-specific creatine kinase isoenzyme in patients with a supposed onset of AMI within the preceding 36 hours was considered a prerequisite for the diagnosis. In a study from this department[5] positive and negative predictive values of the transient increases in creatine kinase isoenzyme were 0.98 and 1.00 compared with the World Health Organization criteria.

AMI was assumed to take place at the onset of severe chest pain. This time was well defined in all cases of LV rupture but 6. In all patients with LV rupture who survived more than a few hours after admittance, increased levels of creatine kinase isoenzyme or aspartate aminotransferase were demonstrated. In no case did autopsy indicate that the infarct was older than estimated by the onset of chest pain.

Postmortem examination was performed routinely in all patients who died from known or suspected AMI. Data were available in 91% of fatal cases. The

TABLE I Influence of Age and Sex on Relative Risk of Left Ventricular Rupture in Acute Myocardial Infarction (n = 7,009)

Age (yrs)	Men	Women	Both
<40	0	0	0
40–49	0.2 (0.1–0.5)	0.4 (0.2–2.6)	0.2 (0.1–0.5)
50–59	0.4 (0.2–0.6)	0.8 (0.4–1.7)	0.4 (0.3–0.6)
60–69	0.9 (0.7–1.3)	1.5 (0.9–2.3)	1.1 (0.8–1.5)
70–79	1.6 (1.1–2.3)	1.7 (1.1–2.5)	1.8 (1.3–2.4)
≥80	2.6 (1.6–4.3)	2.9 (1.8–4.6)	2.9 (2.1–4.2)
Total	0.6 (0.4–0.8)	1.8 (1.3–2.4)	

Data in parentheses are 95% confidence limits. The risk of left ventricular rupture increases steeply with age ($p < 0.0001$) and is higher for women ($p = 0.002$).

TABLE II Influence of Immobilization on Left Ventricular Rupture in Acute Myocardial Infarction

	1959 to 1969 Immobilization	1969 to 1983 Immobilization
	+	0
Infarctions (n)	907	6,102
Deaths (n)	269 (30%)	1,263 (21%)
Ruptures (n)	24 (2.7%)	165 (2.7%)
Place of LV rupture		
Bed	19 (79%)	132 (80%)
Out of bed	0	12 (7%)
Lavatory	0	10 (6%)
Unclear	5 (21%)	11 (7%)
Total	24 (100%)	165 (100%)

Before 1968 patients with acute myocardial infarction were immobilized for the first days after onset; after 1968 patients were allowed to move about freely.

LV = left ventricular; + = present; 0 = absent.

diagnosis of LV rupture was based on the findings of an infarction and a hemipericardium. In most cases a perforation was located within the infarct. In a minority of cases where the perforation was not obvious, a dissecting infiltration of blood into the myocardium was demonstrated. Infarct-related septal defects were not included in this investigation.

From 1959 to 1966 patients with suspected AMI were strictly immobilized during the first days and then gradually mobilized. From 1966 to 1968 patients were allowed to get out of bed from the first day on. After 1968 no immobilization was imposed, and all patients with AMI were allowed to move about freely in the department (monitored by telemetric equipment) from the first day on.

Statistical analysis of contingency tables was performed with the chi-square test, for 2 × 2 tables with Yates correction. Relative risks (fraction of LV ruptures in risk group divided by fraction of LV ruptures in group without risk) and their 95% confidence intervals were calculated as described by Katz et al[4] assuming near normal distribution for ln (relative risk). No corrections were made for the frequency of autopsy.

During the period 1959 to 1983, 7,009 patients were admitted to Glostrup County Hospital with a confirmed AMI. Of these 1,532 died during admission (mortality rate 23%). An LV rupture of the free wall of the heart was demonstrated at autopsy in 189 cases: 2.7% of all patients with AMI and 12% of fatal cases.

Table I lists the calculated relative risk of LV rupture in each age and sex group with AMI. The relative risk increases steeply with age ($p < 0.0001$), almost doubling with each decade.

Figure 1 shows the interval from onset of anginal pain to occurrence of LV rupture. One-third of all LV ruptures occurred within 24 hours of onset of AMI. The latest occurred 61 days after onset of AMI. Positive evidence of reinfarction preceding LV rupture was not demonstrated in any case, either clinically or by autopsy.

Data on the site of AMI were available in 3,253 cases. Of these 43% were anterior infarctions by standard electrocardiographic criteria, 39% were inferior infarctions and 17% were indefinite or had other location. Among the 189 LV ruptures 61% were anterior infarctions (autopsy), 32% inferior infarctions and 7% indefinite or had other location. Assuming that distribution of infarct site for the 3,223 cases is representative for the whole series, the relative risk of LV rupture is 2.1 (95% confidence interval 1.5 to 2.7) in anterior infarction and 0.7 (0.5 to 1.0) in inferior AMI ($p < 0.0001$).

LV rupture occurred during the first AMI in 164 cases (87%), during the second AMI in 21 cases (11%) and during the third AMI in 1 case. In 3 cases the number of previous AMIs could not be stated.

Twenty-eight patients had a history of systemic hypertension (15%), while 156 patients (83%) did not have hypertension. The average blood pressure at admission was 146/93 mm Hg; 44 patients had a systolic blood pressure >160 mm Hg and 16 a diastolic blood pressure >110 mm Hg. On the day of LV rupture average blood pressure was 126/85 mm Hg; 11 patients had a systolic blood pressure >160 mm Hg and 7 a diastolic blood pressure >110 mm Hg.

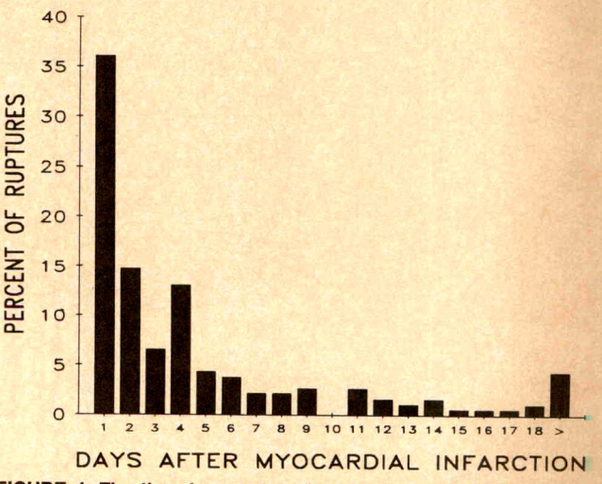

FIGURE 1. The time from onset of acute myocardial infarction to occurrence of left ventricular rupture is shown for 183 of 189 consecutive cases of left ventricular rupture of the free wall of the heart in patients with acute myocardial infarction. In the remaining 6 cases time of onset could not be determined. > = left ventricular ruptures occurring 19 days after acute myocardial infarction or later.

Table II lists the incidence of LV rupture in patients with AMI with and without forced immobilization.

Data were also analyzed for relation between site of AMI, age, activity at time of LV rupture and time of AMI. For pairwise analysis all p values were >0.14.

This is the only large series of patients with unselected AMI defined by modern criteria where a high frequency of autopsy allowed estimation of incidence and risk factors of LV rupture. The increased risk with high age and female sex that we found is as expected. Our finding that LV rupture is an early event—and the lack of relation with systemic hypertension—agrees with some investigations and disagrees with others.[1]

In our institution patients have been allowed to move about freely since 1968 and the frequency of LV rupture has not changed. Even among the nonimmobilized patients most LV ruptures occurred while the patient was in bed. Only 12 LV ruptures among 6,102 patients with AMI actually took place while the patient was sitting or walking. We conclude that there is no advantage to forced immobilization with respect to risk of LV rupture.

Assessment of Left Ventricular Volume Changes During Exercise Radionuclide Angiography in Coronary Artery Disease

PIERCE J. VATTEROTT, MD
RAYMOND J. GIBBONS, MD
DAVID C.K. HU, MD
MANUEL L. BROWN, MD
IAN P. CLEMENTS, MD

During exercise radionuclide angiography, the effect of exercise on left ventricular (LV) volumes has been inferred from changes in LV counts.[1,2] A single published study using in vivo labeling techniques found that the radiotracer concentration per milliliter of blood did not remain constant during exercise.[3] This finding implies that measurement of LV volume during exercise based on a single determination of blood radioactivity is not valid. We have evaluated the effect of exercise on hematocrit and blood radioactivity concentration after technetium-99m in vivo-in vitro labeling.

We studied 13 subjects (12 men, 1 woman; mean age 59 years) referred for exercise radionuclide angiography for assessment of coronary artery disease. Erythrocytes were labeled by the in vivo-in vitro labeling technique described by Callahan et al.[4] For this study, an additional central intravenous line catheter was inserted through the basilic vein. The catheter was positioned with its tip resting in a central vein within the thorax. A separate peripheral intravenous line was inserted. A 10-ml resting sample of venous blood was obtained through each line while the subject was at rest. The patients then underwent symptom-limited supine bicycle exercise; a set of 10-ml venous samples were obtained at peak exercise and at 6 minutes after exercise. Immediately after exercise, the tubes of blood were placed on the center of the collimator of the gamma camera, and blood radioactivity was measured for 2 minutes. The hematocrit of each sample was measured by centrifuge.

Changes in blood radioactivity and hematocrit were evaluated for statistical significance by the paired t test.

Age, sex, medications, exercise duration, maximal workload, reasons for stopping exercise and baseline and peak blood pressures and heart rates for each patient are shown in Table I. Blood radioactivity did not increase during exercise (Figure 1), but hematocrit value did (Figure 2). The mean central hematocrit value increased from a resting value of 40% to 42% at peak exercise (p = 0.001) and to 42% after exercise (p = 0.001). Twelve of the 13 patients had increases in hematocrit. The mean peripheral hematocrit value increased from 41% at rest to 42% at peak exercise (p = 0.308) and to 43% after exercise (p = 0.013). Eleven patients had increases.

Using the in vivo technique for erythrocyte labeling, Konstam et al[3] found that blood radioactivity increased with exercise. LV volume calculations based on a single resting blood activity measurement could therefore result in overestimation of exercise volumes by as much as 20%.[3] With the in vivo technique, multiple blood samples would be necessary to determine volume changes with exercise.

A major difference between this study and that of Konstam et al[3] is the labeling technique. Callahan et al[4] evaluated the in vivo labeling technique with stannous DTPA and found that labeling efficiency increased slowly from 62% at 30 seconds to an equilibrium value of 95% in 10 minutes. A significant amount of free pertechnetate is distributed throughout the

body. With the in vivo-in vitro labeling technique, approximately 90% of the technetium-99m pertechnetate is bound firmly to erythrocytes and less free pertechnetate is available.

There are 2 possible explanations for our findings: (1) introduction of an unlabeled population of erythrocytes into the intravascular space or (2) concomitant hemoconcentration and loss of the technetium-99m label from the erythrocytes. The in vivo technique used by Konstam et al[3] may allow free pertechnetate to label erythrocytes outside the intravascular pool. A sequestered but labeled erythrocyte population may have been released into the circulation during exercise in their study, as opposed to an unlabeled population in this study.

The source of this unlabeled population of erythrocytes is uncertain. In animal studies, Vatner et al[5] found that the mean hematocrit value in dogs in-

creased from 40% to 49% during running and that this effect was abolished by splenectomy. The state of the human spleen during exercise is poorly understood. However, Gates and Ames[6] recently demonstrated decreasing splenic radioactivity during the maximum exercise phase of gated stress testing in 24 patients. Thus, it is possible that the human spleen has a sequestered erythrocyte population that is released under the influence of catecholamines during exercise.

Hemoconcentration during long- and short-term ergometer exercise has been reported.[7-9] The former is secondary to dehydration, and the latter is due, at least in part, to a small loss of protein from the vascular system. A loss of radionuclide from cell membranes could exist concomitant with hemoconcentration. This would be reflected as an increase in hematocrit value but as a smaller increase, no change or overall decrease in radionuclide level in the blood sample.

This study showed an increase in hematocrit value but no change in blood radioactivity during exercise radionuclide angiography using in vivo-in vitro labeling. This finding validates volume estimations throughout exercise based on a single blood sample. This is a significant advantage over the more commonly used in vivo method.

Propafenone for Prevention of Recurrent Atrial Fibrillation

CHARLES R. KERR, MD
GEORGE J. KLEIN, MD
JAMES E. AXELSON, PhD
JOCELYN C. COOPER, RN

Propafenone, an investigational class 1C antiarrhythmic drug, is effective in the treatment of ventricular arrhythmias[1-5] and paroxysmal supraventricular tachycardia.[6] Relatively few studies have evaluated its effect on atrial flutter or fibrillation.[7] In this study we evaluated the efficacy of propafenone in the prevention of recurrent atrial fibrillation (AF).

Fifty-three patients (21 women, 32 men, mean age 53 ± 15 years) presenting with recurrent episodes of AF were studied. All patients had multiple episodes of AF, recorded at least once by electrocardiogram. All antiarrhythmic drugs except digoxin were discontinued a minimum of 5 half-lives before initiation of the study. Digoxin was continued in 14 patients with a rapid ventricular response to AF. Propafenone was started at an initial dose of 150 mg 3 to 4 times daily. Dosage adjustment was made at intervals of at least 72 hours. In patients with frequent episodes of AF, the dose was increased as necessary up to 300 mg 4 times daily and adjusted to the lowest level that prevented recurrence of AF. In patients with infrequent episodes, the dose was increased as tolerated up to 300 mg 3 times daily. Patients were advised to take the drug with food to enhance bioavailability.[8] Patients were asked to report any recurrence of arrhythmia. Patient compliance was monitored by visits every 6 to 12 weeks when pill counts were performed. The drug was withdrawn for either severe side effects not responding to dose reduction or inefficacy after reaching the maximum dose of 300 mg 3 to 4 times daily (total dose of 900 to 1,200 mg daily).

Of the 53 patients in the study, 48 had been previously treated with 1 or more antiarrhythmic drugs, whereas only 5 were treated with propafenone as their first drug. Of those patients previously treated, the mean number of drugs used was 3 ± 2 (standard deviation). Previous drug therapy could be divided into drugs that slowed the ventricular rate including digoxin (37 patients), β-blocking agents (30), verapamil (19), diltiazem (1) and those known to prevent AF, including quinidine (34), procainamide (15), disopyramide (15), sotalol (1) and amiodarone (1). Three patients had been receiving only drugs that principally slow ventricular rate, whereas 45 had been receiving only drugs to prevent AF, or a combination of the 2 groups. Drugs had been discontinued for side effects or inefficacy. In 1 patient amiodarone administration was stopped 3 months before the initiation of propafenone treatment. Recurrent AF had been present for

From the Division of Cardiology, Department of Medicine, and Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver V6T 2B5, and the Division of Cardiology, Department of Medicine, University of Western Ontario, Canada. This work was supported in part by grants from the British Columbia Heart Foundation, Vancouver, British Columbia, The Medical Research Council of Canada, Ottawa, Ontario, Canada, and Knoll Pharmaceutical Company of Canada. Dr. Kerr is a Scholar of the Medical Research Council of Canada. Manuscript received July 28, 1987; revised manuscript received and accepted November 23, 1987.

periods ranging from 2 months to 17 years (mean 5 ± 4 years). All patients had had more than 1 episode of AF, with 45 reporting over 5 episodes in the preceding 2 years and 36 over 5 episodes in the last year. Potentially contributory underlying heart disease was observed in 14 patients, mitral valve disease in 3, congestive heart failure in 6, previous myocardial infarction in 3, hypertrophic cardiomyopathy in 1 and previous atrial septal defect repair in 1. In the other 39 patients AF was considered primary.

Forty patients have had complete or partial success and continue receiving propafenone with a follow-up from 1 to 24 months (mean 9 ± 6). Thirteen have discontinued the drug after periods of 1 day to 7 months (mean 1 ± 2 months). Of the 40 patients with complete or partial success, 7 had significant heart disease whereas in 33 the AF was primary. The doses of propafenone in these 40 patients ranged from 300 to 1,200 mg daily (mean 700 ± 190 mg). The most common dosing regimens were 300 mg twice daily (14 patients) and 300 mg 3 times daily (13 patients).

Of those 40 who continued receiving propafenone, 34 have had complete or near-complete success, defined as complete absence of arrhythmia or rare episodes for which no additional therapy was indicated or requested by the patient. In these 34 patients, 26 had had over 5 episodes in the previous year. An additional 6 who previously had been receiving multiple drugs showed significant improvement. In all 6, propafenone was more effective than previous drugs and patients elected to continue receiving it. In 4 the episodes were less frequent with a slower ventricular rate whereas the other 2 remained in AF with a well-controlled ventricular rate. In 5 patients given propafenone as initial therapy, 4 had complete control and 1 stopped the drug due to side effects.

Of the 40 patients who continued receiving propafenone, 20 have had mild side effects (including 8 with headache or dizziness followed, in 7, by complete resolution). Eight complained of taste alteration, with subsequent resolution of this symptom in 4 and persistence of very mild and tolerable taste alteration in the other 4. Three patients complained of constipation, which was controlled by stool softeners. Three complained of fatigue, later resolved in 2. Thirty-three of these 40 patients either had no initial symptoms or had symptoms that have resolved. In 2 patients without preexistent evidence of conduction system disease, propafenone administration resulted in the suppression of sinus node function and the development of symptomatic bradycardias. Both had implantation of permanent pacemakers, continued receiving propafenone and evidenced complete arrhythmia control.

Propafenone was discontinued in 13 patients, 8 due to drug intolerance and 5 due to inefficacy. Three developed severe headache. Two developed dizziness and insisted on stopping the drug after 24 hours, without attempting dose manipulation. One had severe, persistent diarrhea. One asthmatic patient had an increase in bronchoconstriction. One had coincidental pacemaker failure (lead insulation failure with a resultant cardiac arrest) and elected to remain off the drug although the association of the drug to these events was unclear. Thus, the overall frequency of definite, persistent side effects was 14 in 53 patients (26%). Cessation of drug therapy due to possible side effects occurred in 15%, with the additional 11% having mild, persistent symptoms.

Of the 5 in whom the drug was tolerated but failed to control AF, 4 had underlying heart disease. One woman with a previous myocardial infarction had recurrent AF on a dose of 750 mg daily. She declined a dosage increase. A second patient with Wolff-Parkinson-White syndrome and AF was initially controlled with 1,200 mg daily of propafenone. However, he developed a severe alcoholic dilated cardiomyopathy and his AF now is diagnosed as chronic. A third patient with obstructive hypertrophic cardiomyopathy and atrial flutter had recurrent AF on 900 mg daily and is now receiving amiodarone to control it. A fourth patient with previous atrial septal defect repair and AF had electrical cardioversion performed while taking propafenone (900 mg daily). Sinus rhythm was restored for 48 hours before return to AF. Amiodarone also failed to maintain sinus rhythm and he remains in AF. A fifth patient, without heart disease, likely had chronic AF for 2 years. Electrical cardioversion during propafenone therapy (900 mg daily) restored sinus rhythm for 24 hours only and he now remains in AF. Corrected QT intervals before propafenone (QT_C = 0.42 ± 0.04 s) were not different than those during propafenone administration (QT_C = 0.41 ± 0.03 s, $p > 0.5$). No patient had more prolonged or more frequent episodes of AF.

Propafenone is an investigational antiarrhythmic drug extensively evaluated for treatment of ventricular arrhythmias. Its primary effect in ventricular and atrial myocardial cells and Purkinje fibers is the slowing of the rate of rise of phase 0 of the action potential (V_{max}).[9-11] The mechanism of AF is generally considered to be reentry within the atrial myocardium.[12-14] The mechanism of propafenone's action in preventing AF may be due to several factors. The depression in V_{max} may slow conduction and block 1 limb of the reentry circuit. The abolition of atrial premature beats may remove the trigger for the reentrant arrhythmia and the mild β-adrenergic antagonism may suppress sympathetic stimulation. In addition, propafenone, unlike type 1A antiarrhythmic drugs, may beneficially slow the ventricular response during AF.[15]

In the present study, we report the efficacy of propafenone in preventing recurrent AF in 53 patients. In 48 patients, other drugs had been either ineffective or led to intolerable side effects. Thus, the patient population was skewed to those with previous drug failures. In spite of this skewed population, propafenone was effective in controlling 34 of 53 patients with partial control in 6 more (overall 77%).

Ours was a nonrandomized, open-label study to assess drug efficacy. Thus, it is prone to errors and observer bias known to this type of study. Nonetheless, propafenone appeared to be effective in eliminating or reducing the frequency of episodic AF in a highly

symptomatic group of patients. Study design does not permit comparison to other drugs but it does suggest that propafenone is generally well tolerated and effective in controlling AF in many patients.

Ventriculoatrial Conduction and Atrial Activation During Ventricular Flutter and Fibrillation

GUIDO CAPELLA, MD
PEDRO BRUGADA, MD
HEIN J.J. WELLENS, MD

Electrophysiologic studies have evaluated retrograde conduction over the atrioventricular (AV) conduction system during ventricular pacing.[1–3] From these studies it has become clear that ventriculoatrial conduction during ventricular pacing is present in about 70% of patients with normal AV conduction. It has also been shown that ventriculoatrial conduction is often present during ventricular tachycardia.[4] Little is known about presence and patterns of ventriculoatrial conduction during ventricular flutter (VFl) and fibrillation (VF).[5]

From the Department of Cardiology, Academic Hospital of Maastricht, University of Limburg, P.O. Box 1918, 6201 Bx Maastricht, The Netherlands. Manuscript received August 18, 1987; revised manuscript received December 2, 1987, and accepted December 4.

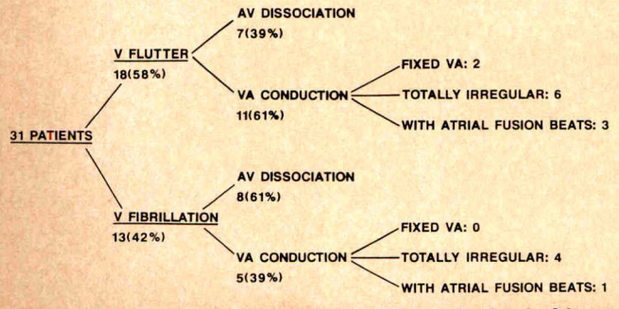

FIGURE 1. Patterns of ventriculoatrial (VA) conduction in 31 patients. A = atrium; V = ventricular.

We recently reviewed 31 patients in whom VFl or VF was induced during programmed stimulation of the heart and where at least 2 simultaneously recorded intracavitary atrial leads allowed the evaluation of mode and direction of atrial activation during VFl/VF. Patients in whom an accessory pathway was present and patients with abnormal AV conduction during atrial pacing were excluded. VFl was diagnosed when the ventricular rate was >260/min and a continuous sequence of sinusoidal waves was present on the surface electrocardiogram, making it impossible to distinguish the QRS complex from the ST segment and the T wave.

The analysis of the 31 patients revealed the following (Figure 1). In 15 patients (48%) there was no ventriculoatrial conduction during VFl/VF: atrial activation showed the same sequence as during sinus rhythm. In the remaining 16 patients (52%) ventriculoatrial conduction was present during VFl/VF. In these patients, 3 types of atrial activation were observed: (1) retrograde atrial activation with a completely irregular atrial response (Figure 2) was found in a total of 10 patients—6 patients during VFl and 4 patients during VF; (2) retrograde atrial activation with a fixed ventriculoatrial ratio and regular atrial response (ventriculoatrial ratio was 3:1 and 4:1) was observed in 2 patients, both with VFl (Figure 3); (3) anterograde atrial activation and retrograde atrial activation from ventriculoatrial conduction, with atrial fusion complexes, was found both during VFl (3 patients) and VF (1 patient). Periods of ventriculoatrial dissociation and retrograde atrial activation could be observed in the same patient (Figure 4). In these patients fusion P waves from anterograde and retrograde atrial activation were also observed.

During ventricular pacing at a rate of 100/min, 21 patients (64%) had 1:1 ventriculoatrial conduction. Five of them had complete ventriculoatrial dissocia-

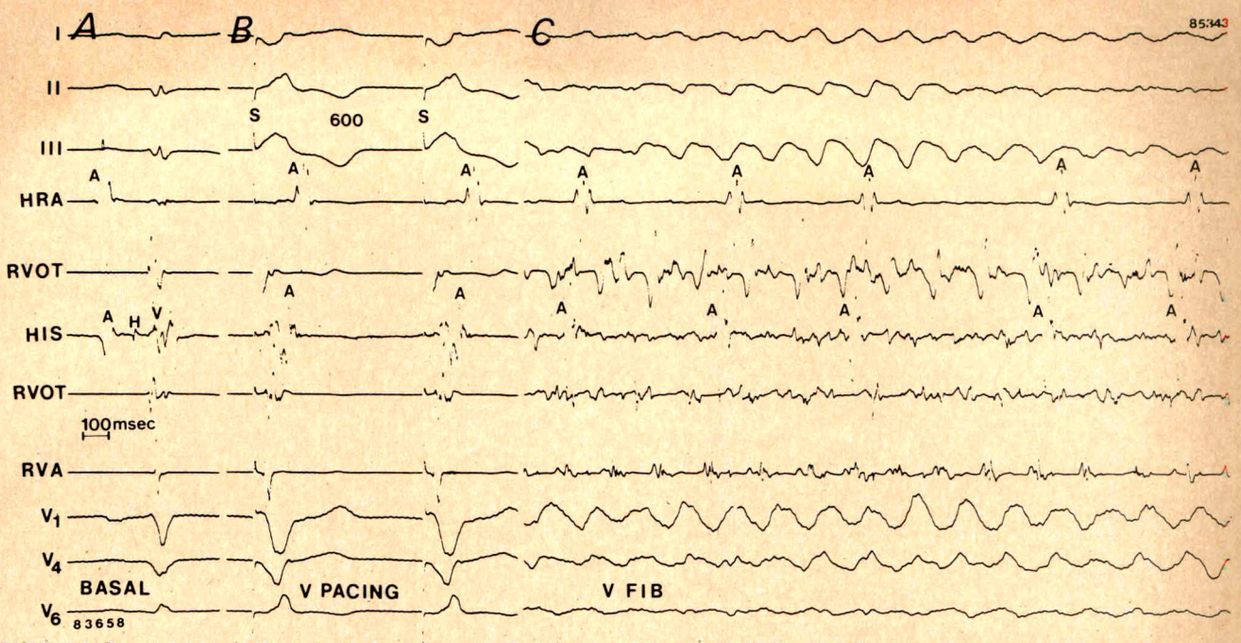

FIGURE 2. Completely irregular retrograde atrial activation during ventricular fibrillation (V FIB). *A*, anterograde atrial activation during sinus rhythm. *B*, retrograde atrial activation during ventricular pacing at 100/min. *C*, sequence of atrial activation during ventricular fibrillation. Note the complete irregularity of the AA intervals and the similarity to atrial activation in *B*. HRA = high right atrial recording; RVA = right ventricular apex; RVOT = right ventricular outflow tract.

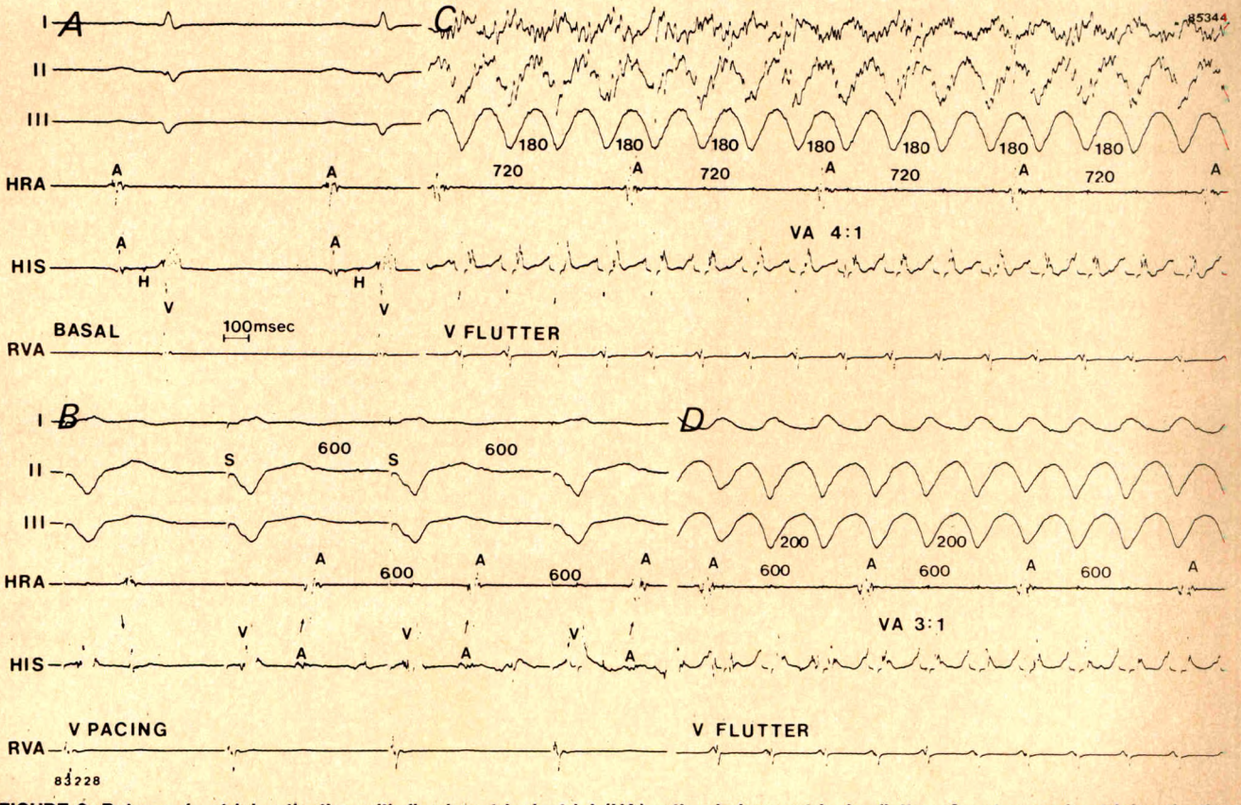

FIGURE 3. Retrograde atrial activation with fixed ventriculoatrial (VA) ratio, during ventricular flutter. *A*, anterograde atrial activation during sinus rhythm. *B*, retrograde atrial activation is present during ventricular pacing at 100/min after the second to fourth paced beat. *C*, 4:1 retrograde conduction during ventricular flutter at a rate of 330/min. *D*, 3:1 retrograde conduction during ventricular flutter at a rate of 300/min.

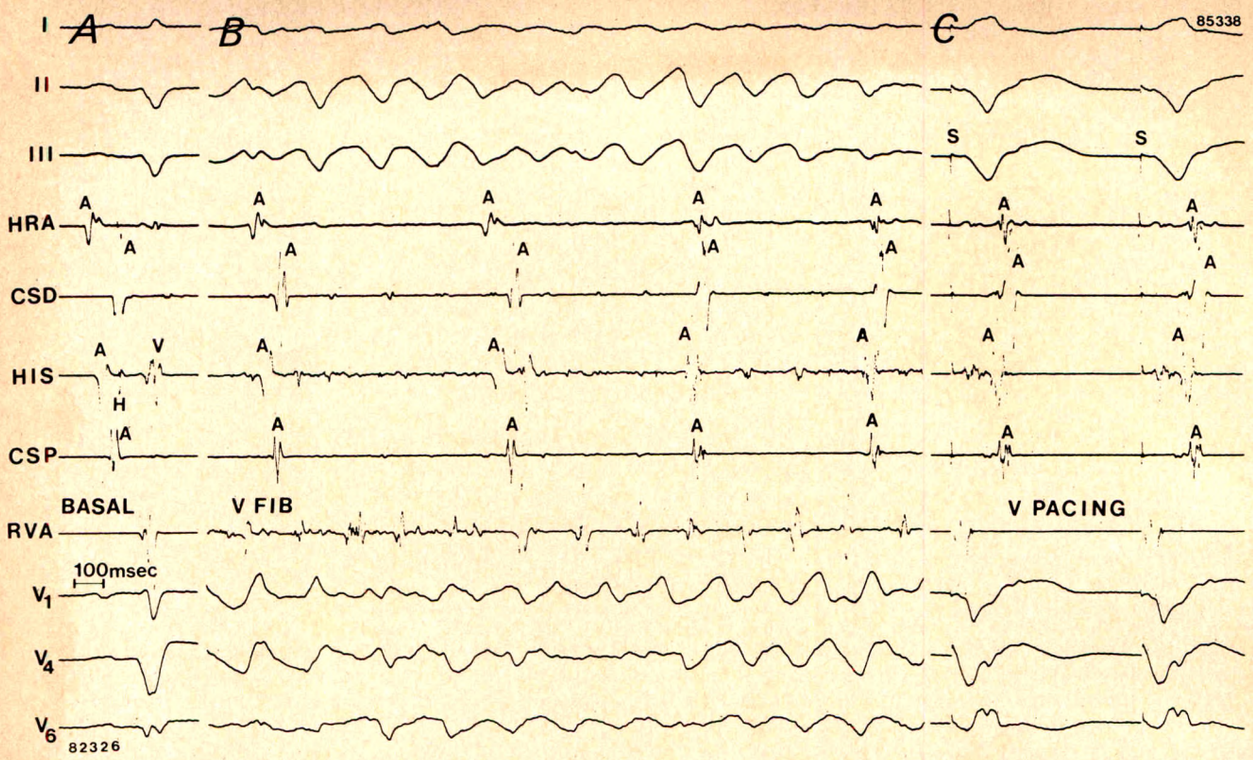

FIGURE 4. Anterograde and retrograde atrial activation in the same patient during ventricular fibrillation. On the *left* of *B*, the anterograde atrial activation is identical to the one during sinus rhythm, *A*. On the *right* of *B*, retrograde atrial activation occurs identical to that visible during ventricular pacing at 100/min, *C*.

tion during VFl/VF. No patient without ventriculoatrial conduction during ventricular pacing at a rate of 100/min subsequently showed ventriculoatrial conduction during VFl/VF. Looking at the ventriculoatrial ratio in patients with ventriculoatrial conduction during VFl/VF, we found a fixed ventriculoatrial ratio in only 2 patients, both with VFl. A 3:1 and 4:1 ratio occurred at ventricular rates of 300 and 330/min, respectively. When ventriculoatrial conduction occurred during VFl with higher rates and during all cases of VF, atrial activation showed a completely irregular pattern.

In 1976 Scher et al[6] reported on retrograde depolarization of AV junctional tissue during VF in the dog. Using histograms and autocorrelograms, they concluded that atrial depolarization intervals did not remain constant but varied widely. They postulated that during retrograde conduction the AV junctional tissues during VF behaved similarly to the anterograde direction during atrial fibrillation. Which cardiac structure is responsible for the irregular atrial rhythm during retrograde conduction in VFl and VF is uncertain. Unfortunately the lack of His bundle electrograms (hidden by VFl or VF waves) made it impossible to know the site of retrograde block: the His-Purkinje system, the AV node or both. This will require further investigation.

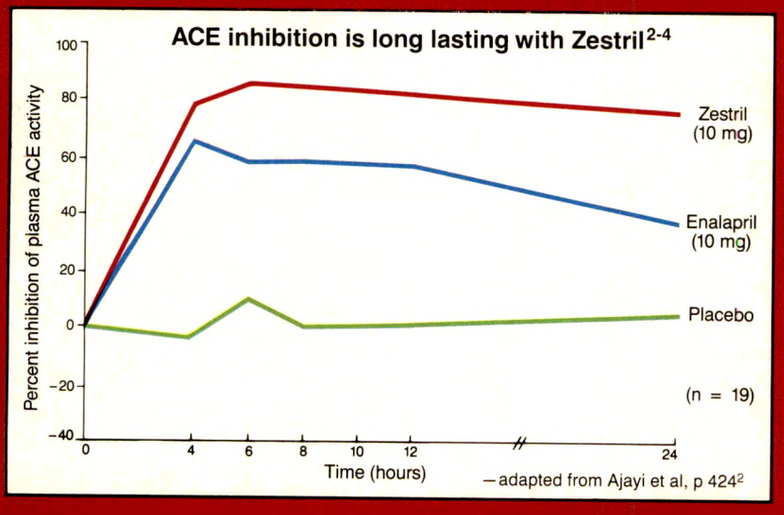
Wilmington, Delaware 19897

Zestril: The long-acting ACE inhibitor

Zestril achieves 24-hour blood pressure control with a half-life of 12 hours.[1] Angiotensin converting enzyme (ACE) inhibition** is long lasting with Zestril—sustained 24 hours after a single dose.[2-4] The clinical significance of pharmacodynamic differences in hypertensive patients has not been determined.



** In pharmacodynamic studies (utilizing 10 mg of enalapril and lisinopril), ACE inhibition was significantly correlated to plasma renin activity and fall in diastolic blood pressure in normal volunteers.

Zestril: Hypertensive patients start and stay at one tablet a day

A single tablet of Zestril controls blood pressure for a full 24 hours[1]—unlike other ACE inhibitors, which may have to be increased to b.i.d.[5] or t.i.d.[6] dosing in some patients. The predictable once-daily dosage of Zestril enhances patient compliance and cost-effectiveness.

Zestril: 24-hour blood pressure control without liver metabolism

Zestril provides 24-hour control. Zestril is not metabolized by the liver.[7] It does not require bioactivation[7]—as needed with prodrugs such as enalapril:**[5,7] Zestril is absorbed as an active drug.[1] Absorption is unaffected by food.[8]

Zestril: 24-hour blood pressure control that's well tolerated

Zestril achieves 24-hour control with a low incidence of side effects. Rash and/or taste disturbance are rarely seen with Zestril. In Zestril clinical trials, the most frequently reported side effects were as follows:

Side Effects	Zestril (n = 2,003‡)	—	Placebo (n = 207)
Dizziness	6.3%	—	1.9%
Headache	5.3%	—	1.9%
Fatigue	3.3%	—	1.0%
Diarrhea	3.2%	—	2.4%
Upper respiratory symptoms	3.0%	—	0.0%
Cough	2.9%	—	1.0%

‡Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

- Only 6% of patients discontinued therapy in controlled clinical trials.
- Symptomatic hypotension occurs infrequently (0.8%) in patients with normal renal function but is a possible consequence in salt/volume-depleted persons such as those treated vigorously with diuretics.
- Evaluation of the hypertensive patient should always include assessment of renal function. (See Dosage and Administration.)
- Angioedema has been reported with ACE inhibitors, including Zestril. (See Warnings.)

Zestril dosage in hypertension
Starting dose is 10 mg once a day. Usual dosage range for maintenance: 20 to 40 mg per day, administered in a single daily dose.

ZESTRIL®!
LISINOPRIL

**Clinical significance has not been determined in hypertensive patients.

*The antihypertensive effect may diminish at the end of the dosing interval.

Please see last page of this advertisement for brief summary of prescribing information.

INDICATIONS AND USAGE. Zestril is indicated for the treatment of hypertension. It may be used alone as initial therapy or concomitantly with other classes of antihypertensive agents. In using Zestril, consideration should be given to the fact that another angiotensin converting enzyme inhibitor, captopril, has caused agranulocytosis, particularly in patients with renal impairment or collagen vascular disease, and that available data are insufficient to show that Zestril does not have a similar risk. (See WARNINGS.) **CONTRAINDICATIONS.** Zestril is contraindicated in patients who are hypersensitive to this product. **WARNINGS. Angioedema:** Angioedema of the face, extremities, lips, tongue, glottis and/or larynx has been reported in patients treated with angiotensin converting enzyme inhibitors, including Zestril. In such cases, Zestril should be promptly discontinued, and the patient carefully observed until the swelling disappears. In instances where swelling has been confined to the face and lips the condition has generally resolved without treatment, although antihistamines have been useful in relieving symptoms. Angioedema associated with laryngeal edema may be fatal. **Where there is involvement of the tongue, glottis or larynx, likely to cause airway obstruction, appropriate therapy, eg, subcutaneous epinephrine solution 1:1000 (0.3 mL to 0.5 mL) should be promptly administered. (See ADVERSE REACTIONS.) Hypotension:** Excessive hypotension was rarely seen in uncomplicated hypertensive patients but is a possible consequence of use with Zestril in salt/volume-depleted persons, such as those treated vigorously with diuretics or patients on dialysis. (See PRECAUTIONS, Drug Interactions and ADVERSE REACTIONS.) In patients with severe congestive heart failure, with or without associated renal insufficiency, excessive hypotension has been observed and may be associated with oliguria and/or progressive azotemia, and rarely with acute renal failure and/or death. Because of the potential fall in blood pressure in these patients, therapy should be started under very close medical supervision. Such patients should be followed closely for the first two weeks of treatment and whenever the dose of Zestril and/or diuretic is increased. Similar considerations apply to patients with ischemic heart or cerebrovascular disease in whom an excessive fall in blood pressure could result in a myocardial infarction or cerebrovascular accident. If hypotension occurs, the patient should be placed in supine position and, if necessary, receive an intravenous infusion of normal saline. A transient hypotensive response is not a contraindication to further doses which usually can be given without difficulty once the blood pressure has increased after volume expansion. **Neutropenia/Agranulocytosis:** Another angiotensin converting enzyme inhibitor, captopril, has been shown to cause agranulocytosis and bone marrow depression, rarely in uncomplicated patients but more frequently in patients with renal impairment especially if they also have a collagen vascular disease. Available data from clinical trials of Zestril are insufficient to show that Zestril does not cause agranulocytosis at similar rates. Periodic monitoring of white blood cell counts in patients with collagen vascular disease and renal disease should be considered. **PRECAUTIONS. General. Impaired Renal Function:** As a consequence of inhibiting the renin-angiotensin-aldosterone system, changes in renal function may be anticipated in susceptible individuals. In patients with severe congestive heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with angiotensin converting enzyme inhibitors, including Zestril, may be associated with oliguria and/or progressive azotemia and rarely with acute renal failure and/or death. In hypertensive patients with unilateral or bilateral renal artery stenosis, increases in blood urea nitrogen and serum creatinine may occur. Experience with another angiotensin converting enzyme inhibitor suggests that these increases are usually reversible upon discontinuation of Zestril and/or diuretic therapy. In such patients, renal function should be monitored during the first few weeks of therapy. Some hypertensive patients with no apparent pre-existing renal vascular disease have developed increases in blood urea nitrogen and serum creatinine, usually minor and transient, especially when Zestril has been given concomitantly with a diuretic. This is more likely to occur in patients with pre-existing renal impairment. Dosage reduction of Zestril and/or discontinuation of the diuretic may be required. **Evaluation of the hypertensive patient should always include assessment of renal function. (See DOSAGE AND ADMINISTRATION.) Hyperkalemia:** In clinical trials hyperkalemia (serum potassium greater than 5.7 mEq/L) occurred in approximately 2.2% of hypertensive patients and 4.0% of patients with congestive heart failure. In most cases these were isolated values which resolved despite continued therapy. Hyperkalemia was a cause of discontinuation of therapy in approximately 0.1% of hypertensive patients. Risk factors for the development of hyperkalemia include renal insufficiency, diabetes mellitus, and the concomitant use of potassium-sparing diuretics, potassium supplements and/or potassium-containing salt substitutes, which should be used cautiously, if at all, with Zestril. (See Drug Interactions.) **Surgery/Anesthesia:** In patients undergoing major surgery or during anesthesia with agents that produce hypotension, Zestril may block angiotensin II formation secondary to compensatory renin release. If hypotension occurs and is considered to be due to this mechanism, it can be corrected by volume expansion. **Information for Patients. Angioedema:** Angioedema, including laryngeal edema, may occur especially following the first dose of Zestril. Patients should be so advised and told to report immediately any signs or symptoms suggesting angioedema (swelling of face, extremities, eyes, lips, tongue, difficulty in swallowing or breathing) and to take no more drug until they have consulted with the prescribing physician. **Symptomatic Hypotension:** Patients should be cautioned to report lightheadedness especially during the first few days of therapy. If actual syncope occurs, the patient should be told to discontinue the drug until they have consulted with the prescribing physician. All patients should be cautioned that excessive perspiration and dehydration may lead to an excessive fall in blood pressure because of reduction in fluid volume. Other causes of volume depletion such as vomiting or diarrhea may also lead to a fall in blood pressure; patients should be advised to consult with their physician. **Hyperkalemia:** Patients should be told not to use salt substitutes containing potassium without consulting their physician. **Neutropenia:** Patients should be told to report promptly any indication of infection (eg, sore throat, fever) which may be a sign of neutropenia. **NOTE:** As with many other drugs, certain advice to patients being treated with Zestril is warranted. This information is intended to aid in the safe and effective use of this medication. It is not a disclosure of all possible adverse or intended effects. **Drug Interactions. Hypotension – Patients on Diuretic Therapy:** Patients on diuretics and especially those in whom diuretic therapy was recently instituted, may occasionally experience an excessive reduction of blood pressure after initiation of therapy with Zestril. The possibility of hypotensive effects with Zestril can be minimized by either discontinuing the diuretic or increasing the salt intake prior to initiation of treatment with Zestril. If it is necessary to continue the diuretic, initiate therapy with Zestril at a dose of 5 mg daily, and provide medical supervision after the initial dose for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS, and DOSAGE AND ADMINISTRATION.) When a diuretic is added to the therapy of a patient receiving Zestril, an additional antihypertensive effect is usually observed. Studies with ACE inhibitors in combination with diuretics indicate that the dose of the ACE inhibitor can be reduced when it is given with a diuretic. (See DOSAGE AND ADMINISTRATION.) **Indomethacin:** In a study in 36 patients with mild to moderate hypertension where the antihypertensive effects of Zestril alone were compared to Zestril given concomitantly with indomethacin, the use of indomethacin was associated with a reduced effect, although the difference between the two regimens was not significant. **Other Agents:** Zestril has been used concomitantly with nitrates and/or digoxin without evidence of clinically significant adverse interactions. No clinically important pharmacokinetic interactions occurred when Zestril was used concomitantly with propranolol or hydrochlorothiazide. The presence of food in the stomach does not alter the bioavailability of Zestril. **Agents Increasing Serum Potassium:** Zestril attenuates potassium loss caused by thiazide-type diuretics. Use of Zestril with potassium-sparing diuretics (eg, spironolactone, triamterene or amiloride), potassium supplements, or potassium-containing salt substitutes may lead to significant increases in serum potassium. Therefore, if concomitant use of these agents is indicated because of demonstrated hypokalemia, they should be used with caution and with frequent monitoring of serum potassium. **Carcinogenesis, Mutagenesis, Impairment of Fertility.** There was no evidence of a tumorigenic effect when lisinopril was administered for 105 weeks to male and female rats at doses up to 90 mg/kg/day (about 56 times* the maximum recommended daily human dose) or when lisinopril was administered for 92 weeks to (male and female) mice at doses up to 135 mg/kg/day (about 84 times* the maximum recommended daily human dose). *Based on patient weight of 50 Kg. Lisinopril was not mutagenic in the Ames microbial mutagen test with or without metabolic activation. It was also negative in a forward mutation assay using Chinese hamster lung cells. Lisinopril did not produce single strand DNA breaks in an in vitro alkaline elution rat hepatocyte assay. In addition, lisinopril did not produce increases in chromosomal aberrations in an in vitro test in Chinese hamster ovary cells or in an in vivo study in mouse bone marrow. There were no adverse effects on reproductive performance in male and female rats treated with up to 300 mg/kg/day of lisinopril. **Pregnancy. Pregnancy Category C:** Lisinopril was not teratogenic in mice treated on days 6-15 of gestation with up to 1,000 mg/kg/day (625 times the maximum recommended human dose). There was an increase in fetal resorptions at doses down to 100 mg/kg; at doses of 1,000 mg/kg this was prevented by saline supplementation. There was no fetotoxicity or teratogenicity in rats treated with up to 300 mg/kg/day (188 times the maximum recommended dose) of lisinopril at days 6-17 of gestation. In rats receiving lisinopril from day 15 of gestation through day 21 postpartum, there was an increased incidence in pup deaths on days 2-7 postpartum and a lower average body weight of pups on day 21 postpartum. The increase in pup deaths and decrease in pup weight did not occur with maternal saline supplementation. Lisinopril, at doses up to 1 mg/kg/day, was not teratogenic when given throughout the organogenic period in saline supplemented rabbits. Saline supplementation (physiologic saline in place of tap water) was used to eliminate maternotoxic effects and enable evaluation of the teratogenic potential at the highest possible dosage level. The rabbit has been shown to be extremely sensitive to angiotensin converting enzyme inhibitors (captopril and enalapril) with maternal and fetotoxic effects apparent at or below the recommended therapeutic dosage levels in man. Fetotoxicity was demonstrated in rabbits by an increased incidence of fetal resorptions at a dose of lisinopril at 1 mg/kg/day and by an increased incidence of incomplete ossification at the lowest dose tested (0.1 mg/kg/day). By whole body autoradiography, radioactivity was found in the placenta following administration of labeled lisinopril to pregnant rats, but none was found in the fetuses. There are no adequate and well-controlled studies in pregnant women. Zestril should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Nursing Mothers:** Milk of lactating rats contains radioactivity following administration of ^{14}C lisinopril. It is not known whether this drug is excreted in human milk.

ZESTRIL® (lisinopril)

Because many drugs are excreted in human milk, caution should be exercised when Zestril is given to a nursing mother. **Pediatric Use:** Safety and effectiveness in children have not been established. **ADVERSE REACTIONS.** Zestril has been found to be generally well tolerated in controlled clinical trials involving 2003 patients and subjects. The most frequent clinical adverse experiences in controlled trials were dizziness (6.3%), headache (5.3%), fatigue (3.3%), diarrhea (3.2%), upper respiratory symptoms (3.0%), and cough (2.9%), all of which were more frequent than in placebo-treated patients. For the most part, adverse experiences were mild and transient in nature. Discontinuation of therapy was required in 6.0% of patients. In clinical trials, the overall frequency of adverse experiences could not be related to total daily dosage within the recommended therapeutic dosage range. For adverse experiences which occurred in more than 1% of patients and subjects treated with Zestril or Zestril plus hydrochlorothiazide in controlled clinical trials, comparative incidence data are listed in the table below.

Percent of Patients in Controlled Studies

	Zestril (n = 2003†) Incidence (discontinuation)	Zestril/Hydrochlorothiazide (n = 644) Incidence (discontinuation)	Placebo (n = 207) Incidence
Dizziness	6.3 (0.6)	9.0 (0.9)	1.9
Headache	5.3 (0.2)	4.3 (0.5)	1.9
Fatigue	3.3 (0.2)	3.9 (0.5)	1.0
Diarrhea	3.2 (0.3)	2.6 (0.3)	2.4
Upper Respiratory Symptoms	3.0 (0.0)	4.5 (0.0)	0.0
Cough	2.9 (0.4)	4.5 (0.8)	1.0
Nausea	2.3 (0.3)	2.5 (0.2)	2.4
Hypotension	1.8 (0.8)	1.6 (0.5)	0.5
Rash	1.5 (0.4)	1.6 (0.2)	0.5
Orthostatic Effects	1.4 (0.0)	3.4 (0.2)	1.0
Asthenia	1.3 (0.4)	2.0 (0.2)	1.0
Chest Pain	1.3 (0.1)	1.2 (0.2)	1.4

†Includes 420 patients treated for congestive heart failure who were receiving concomitant digitalis and/or diuretic therapy.

Clinical adverse experiences occurring in 0.3% to 1.0% of patients in the controlled trials and rarer, serious, possibly drug related events reported in uncontrolled studies or marketing experience included: BODY AS A WHOLE: Chest discomfort, fever, flushing. CARDIOVASCULAR: Angina pectoris, orthostatic hypotension, rhythm disturbances, tachycardia, peripheral edema, palpitation. DIGESTIVE: Abdominal pain, anorexia, constipation, flatulence. METABOLISM: Gout. MUSCULOSKELETAL: Joint pain, shoulder pain. NERVOUS SYSTEM/PSYCHIATRIC: Depression, somnolence, insomnia, stroke. RESPIRATORY SYSTEM: Bronchitis, sinusitis, pharyngeal pain. UROGENITAL: Oliguria, progressive azotemia, acute renal failure. OTHER: Blurred vision, pruritus, urinary tract infection, vasculitis of the legs. ANGIOEDEMA: Angioedema has been reported in patients receiving Zestril (0.1%). Angioedema associated with laryngeal edema may be fatal. If angioedema of the face, extremities, lips, tongue, glottis and/or larynx occurs, treatment with Zestril should be discontinued and appropriate therapy instituted immediately. (See WARNINGS.) HYPOTENSION: In hypertensive patients, hypotension occurred in 1.2% and syncope occurred in 0.1% of patients. Hypotension or syncope was a cause of discontinuation of therapy in 0.5% of hypertensive patients. (See WARNINGS.) In patients with congestive heart failure, hypotension occurred in 5.0% and syncope occurred in 1.0% of patients. These adverse experiences were causes for discontinuation of therapy in 1.3% of these patients. **Clinical Laboratory Test Findings. Serum Electrolytes:** Hyperkalemia (See PRECAUTIONS.) **Creatinine, Blood Urea Nitrogen:** Minor increases in blood urea nitrogen and serum creatinine, reversible upon discontinuation of therapy, were observed in about 2.0% of patients with essential hypertension treated with Zestril alone. Increases were more common in patients receiving concomitant diuretics and in patients with renal artery stenosis. (See PRECAUTIONS.) Reversible minor increases in blood urea nitrogen and serum creatinine were observed in approximately 9.1% of patients with congestive heart failure on concomitant diuretic therapy. Frequently, these abnormalities resolved when the dosage of the diuretic was decreased. **Hemoglobin and Hematocrit:** Small decreases in hemoglobin and hematocrit (mean decreases of approximately 0.4 g% and 1.3 vol%, respectively) occurred frequently in patients treated with Zestril but were rarely of clinical importance in patients without some other cause of anemia. In clinical trials, less than 0.1% of patients discontinued therapy due to anemia. **Other (Causal Relationship Unknown):** Rarely, elevations of liver enzymes and/or serum bilirubin have occurred. Overall, 2.0% of patients discontinued therapy due to laboratory adverse experiences, principally elevations in blood urea nitrogen (0.6%), serum creatinine (0.5%), and serum potassium (0.4%). **OVERDOSAGE.** The oral LD_{50} of lisinopril is greater than 20 g/kg in mice and rats. The most likely manifestation of overdosage would be hypotension, for which the usual treatment would be intravenous infusion of normal saline solution. **DOSAGE AND ADMINISTRATION. Initial Therapy:** In patients with uncomplicated essential hypertension not on diuretic therapy, the recommended initial dose is 10 mg once a day. Dosage should be adjusted according to blood pressure response. The usual dosage range is 20-40 mg per day administered in a single daily dose. The antihypertensive effect may diminish toward the end of the dosing interval regardless of the administered dose, but most commonly with a dose of 10 mg daily. This can be evaluated by measuring blood pressure just prior to dosing to determine whether satisfactory control is being maintained for 24 hours. If it is not, an increase in dose should be considered. Doses up to 80 mg have been used but do not appear to give greater effect. If blood pressure is not controlled with Zestril alone, a low dose of a diuretic may be added. Hydrochlorothiazide, 12.5 mg has been shown to provide an additive effect. After the addition of a diuretic, it may be possible to reduce the dose of Zestril. **Diuretic Treated Patients:** In hypertensive patients who are currently being treated with a diuretic, symptomatic hypotension may occur occasionally following the initial dose of Zestril. The diuretic should be discontinued, if possible, for two or three days before beginning therapy with Zestril to reduce the likelihood of hypotension. (See WARNINGS.) The dosage of Zestril should be adjusted according to blood pressure response. If the patient's blood pressure is not controlled with Zestril alone, diuretic therapy may be resumed as described above. If the diuretic cannot be discontinued, an initial dose of 5 mg should be used under medical supervision for at least two hours and until blood pressure has stabilized for at least an additional hour. (See WARNINGS and PRECAUTIONS, Drug Interactions.) Concomitant administration of Zestril with potassium supplements, potassium salt substitutes, or potassium-sparing diuretics may lead to increases of serum potassium. (See PRECAUTIONS.) **Use in Elderly:** In general, blood pressure response and adverse experiences were similar in younger and older patients given similar doses of Zestril. Pharmacokinetic studies, however, indicate that maximum blood levels and area under the plasma concentration time curve (AUC) are doubled in older patients so that dosage adjustments should be made with particular caution. **Dosage Adjustment in Renal Impairment:** The usual dose of Zestril (10 mg) is recommended for patients with creatinine clearance > 30 mL/min (serum creatinine of up to approximately 3 mg/dL). For patients with creatinine clearance > 10 mL/min ≤ 30 mL/min (serum creatinine ≥ 3 mg/dL), the first dose is 5 mg once daily. For patients with creatinine clearance < 10 mL/min (usually on hemodialysis) the recommended initial dose is 2.5 mg. The dosage may be titrated upward until blood pressure is controlled or to a maximum of 40 mg daily.

Renal Status	Creatinine-Clearance mL/min	Initial Dose mg/day
Normal Renal Function to Mild Impairment	>30	10
Moderate to Severe Impairment	≥10 ≤30	5
Dialysis Patients	<10	2.5‡

‡Dosage or dosing interval should be adjusted depending on the blood pressure response. Rev E 12/87

Fatal and Nonfatal Cardiac Arrest in Patients with an Implanted Antitachycardia Device for the Treatment of Supraventricular Tachycardia

CHU PAK LAU, MB, MRCP
ELIZABETH CORNU
A. JOHN CAMM, MD, FRCP

Paroxysmal supraventricular tachycardia (SVT) is a frequent and disabling condition, sometimes unresponsive to medical therapy.[1] Tachycardia termination pacing is a useful alternative treatment in patients with SVT. The use of antitachycardia pacing has been shown to have acceptable long-term efficacy.[2] However, in patients with ventricular tachycardia it is known to carry a risk of tachycardia acceleration[3] or induction of ventricular fibrillation.[4] Therefore, for the treatment of ventricular tachycardia it is recommended that such pacemakers be physician activated (a manual nonautomatic mode) or used in association with an automatic implantable defibrillator.[5] The potential danger of tachycardia termination pacing for SVT is less well defined. We report 4 cases of fatal and 1 case of nonfatal cardiac arrest in patients fitted with an antitachycardia pacemaker, the Programmable Automatic Scanning Arrhythmia Reversion (PASAR) pacemaker (model 4151).

The data were collected in the form of questionnaires filled out by implanting physicians and returned to the pacemaker manufacturer (Telectronics). On a worldwide basis, a total of 122 patients (139 devices) had been implanted for the control of SVT. The follow-up period was 4 to 65 months (mean 34). Most patients (55%) had accessory pathways and 36% had atrioventricular nodal reentrant tachycardia. Sixty-one percent of the patients were paced from the right ventricular apex. Four cases of sudden unexplained cardiac deaths and 1 case of near sudden death were identified.

The PASAR model 4151 was a prototype, implantable, bipolar pulse generator that was designed to sense the occurrence of a tachycardia by programmable high rate criteria. After 4 consecutive tachycardia beats, 1 or 2 timed premature stimuli were delivered in an attempt to revert the tachycardia to sinus rhythm. How this device functions in tachycardia termination is shown in Figure 1. If tachycardia termination failed, the initial coupling interval between the last tachycardia cycle and the first stimulus was automatically decreased by 6 ms. This process could be repeated up to a maximum of 14 times. The coupling delay (between the first and second stimulus) was programmable but remained fixed as the first stimulus scanned the diastolic interval. The intervals successful in terminating tachycardia were stored so that when tachycardia was next confirmed, initial stimulation occurred at these intervals.

The clinical characteristics of the 4 patients who died suddenly are listed in Table I. Patient 1 was a 9-year-old girl who had dilated cardiomyopathy and SVT resistant to drug therapy. Electrophysiologic study showed the tachycardia to be due to intranodal reentry, and preexcitation was due to a nodoventricular (Mahaim) fiber that did not form a part of the tachycardia substrate (bystander). She also had congestive heart failure. Despite very frequent tachycardias (>50 episodes daily), the PASAR was considered the only possible treatment. Initially, the device performed satisfactorily, with effective control of all her arrhythmias. However, on the night before she was due to be discharged, she died suddenly. Figure 2 shows recordings from a Holter monitor and the possible causes of the arrhythmia at the time of her cardiac arrest. The most likely initiating event of ventricular fibrillation is the degeneration of an atrial arrhythmia into rapid atrial fibrillation during a tachycardia termination attempt by the PASAR. This had presumably conducted rapidly down the Mahaim fiber and resulted in ventricular fibrillation. A preimplantation electrophysiologic study had not documented this potential. There was also the possibility of inadvertent direct ventricular pacing by the proximal pole of the atrial wire, which may have prolapsed through the tricuspid valve and was possibly in contact with the ventricular endocardium. This might have accelerated the ventricular response by ventricular pacing during spontaneous tachycardia.

Patients 2 and 3 had Wolff-Parkinson-White syndrome with relatively short accessory pathway anterograde refractory periods (≤270 ms) and were paced from the right ventricle. Both had documented atrial fibrillation induced during electrophysiologic study with the shortest preexcited RR interval being 310 and 225 ms, respectively. Patient 2 had an 8-year history of palpitations requiring almost daily hospital visits. She had been perfectly well for the 11 months after the implantation of the PASAR. She had begun working as a newspaper delivery girl but collapsed while on her first delivery round. She had very recently discontinued therapy with β blockade. Patient 3, whose arrhythmia was satisfactorily controlled by the PASAR for over a year, died suddenly while reading a book without prior complaint of palpitation. In neither case was a cause of death identified at autopsy.

Patient 4 had atrioventricular nodal reentrant tachycardia. He also had ischemic heart disease and episodes of epigastric discomfort during tachycardia. The tachycardia was fully controlled by the PASAR. A 12-lead electrocardiogram showed an old inferior wall myocardial infarction and right bundle branch block. Holter monitoring had documented ventricular

ectopic activity of >10 beats/hour. Atrial flutter was induced during electrophysiologic study with a ventricular response of 140 beats/min. Two weeks before sudden death, he had complained of an episode of dizziness but the electrocardiogram was unchanged. The electrode was implanted in the coronary sinus. He died suddenly while playing bowls without any complaint of chest pain or palpitation. No autopsy was performed.

A case of nonfatal cardiac arrest was documented in a 59-year-old woman with Wolff-Parkinson-White syndrome with a left-sided pathway. Electrophysiologic study showed atrioventricular reentrant tachycardia and atrial fibrillation, with a minimum preexcited RR interval of 155 ms. A temporary right ventricular wire was implanted in the right ventricular apex and over 80 successful attempts were made to terminate induced tachycardia by an external PASAR. A PASAR model 4151 was then implanted. In the first year she remained well. After 14 months she complained of more frequent palpitations and a Holter recording showed that appropriate pacemaker stimulation during a tachycardia termination attempt resulted in acceleration of tachycardia to a ventricular rate of more than 250 beats/min. This pacing system was immediately replaced by a PASAR model 4171 and an atrial electrode, and she has remained asymptomatic for the last 20 months.

Three of the 4 units from patients who died suddenly were recovered and returned to the manufacturer for testing. Two were operating close to the beginning of life and antitachycardia function was normal. The third unit was standard in all parameters but "auto-triggering" of the antitachycardia response by normal sinus rhythm was observed. This phenomenon has also been seen in some prototype units of the PASAR 4151 series, and implanting physicians had been appropriately informed. However, in this particular patient, several defibrillation attempts had been delivered during resuscitation and the auto-triggering might have been induced by this. Auto-triggering was not the cause of sudden death in patient 1 because the Holter recording near the time of death did demonstrate appropriate interventions by the pacemaker (Figure 2).

This report demonstrates a sudden death rate of 3% in this group of patients after a mean follow-up period of 34 months. Patients with SVT usually have a good prognosis, and sudden deaths are unusual but can oc-

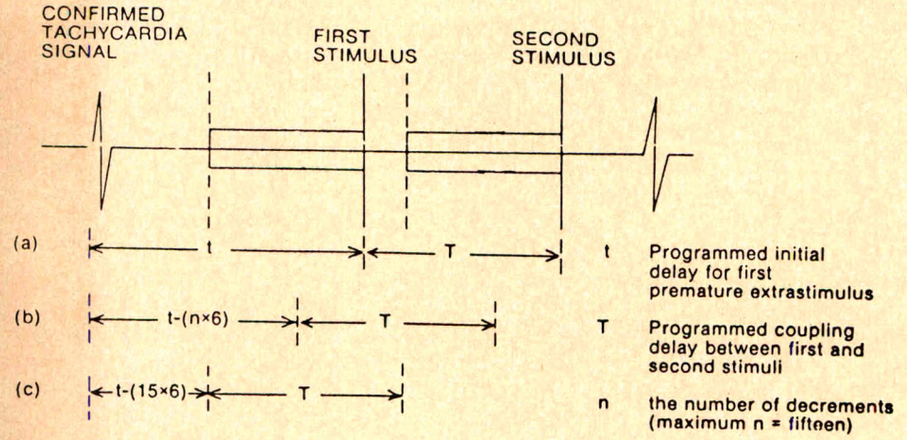

FIGURE 1. Tachycardia termination sequence of PASAR model 4151. The first and second stimuli were delivered at time *t* and *T*, respectively, after a sensed tachycardia. The coupling delay T remained fixed as the first stimulus is scanned through the diastole with 6-ms decrements. When a total of 15 attempts had occurred (*c*) the first stimulus returned to the initial delay (*t*) and the cycle was repeated.

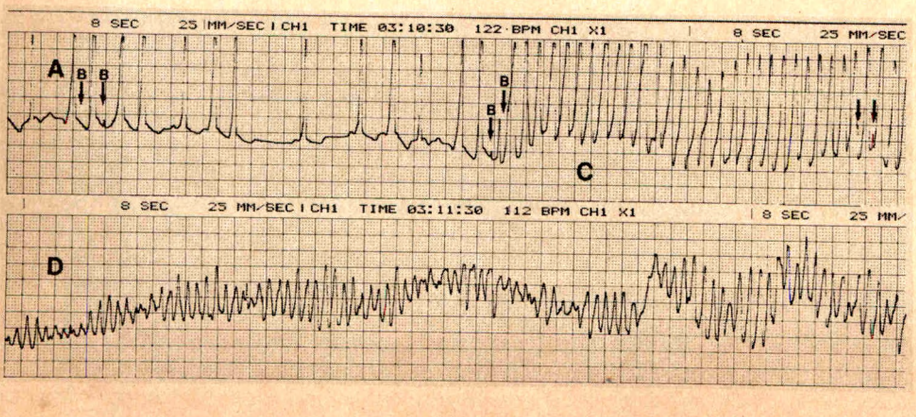

FIGURE 2. Holter recording of patient 1 at the time of sudden death. Possible explanations of the electrocardiographic recordings are listed as follows. *A* = spontaneous atrial tachyarrhythmia; *B* = PASAR stimulus artifacts emitted in response to spontaneous atrial arrhythmia resulting in atrial stimulation or ventricular stimulation; *C* = either atrial fibrillation with a rapid ventricular response due to PASAR-induced degeneration of atrial arrhythmia or spontaneous degeneration of atrial arrhythmia, or ventricular tachycardia due to inadvertant ventricular stimulation; *D* = ventricular fibrillation.

TABLE I Clinical Features of Four Patients Who Died Suddenly

Pt	Age (yrs), Sex	WPW	Anterograde Bypass ERP (ms)	SVT Type	SVT Rate	Pacing Site	Stimuli (n)	Heart Disease	Circumstances of Death	Follow-Up (mo)
1	9, F		Mahaim	AVRT	190	RA?	2	DC	Sudden (asleep)	1.5
2	13, F	A	270	AVRT	190	RV	2		Sudden (cycling)	11
3	52, F	A	260	AVRT	200	RV	2		Sudden (reading)	21
4	69, M		—	AVNRT	170	CS	2	CAD	Sudden (playing bowls)	13

AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reentrant tachycardia; CAD = ischemic heart disease; CS = coronary sinus; DC = dilated cardiomyopathy; ERP = effective refractory period; RA = right atrium; RV = right ventricle; SVT = supraventricular tachycardia.

cur in patients with the Wolff-Parkinson-White syndrome who develop atrial fibrillation. In a series reported by Gallagher et al,[6] 18 of a total of 163 patients with Wolff-Parkinson-White syndrome presented with ventricular fibrillation. However, most of these patients had an RR interval during preexcited atrial fibrillation of <205 ms, which was shorter than in those of our patients who died suddenly. Thus 4 cases of sudden death among 122 patients who received a PASAR is an unusually high mortality rate and raises the possibility of induction of lethal arrhythmias by the pacemaker.

Ventricular pacing has the danger of accelerating ventricular tachycardia.[3,4] Atrial fibrillation and nonsustained ventricular tachycardia have been documented during pacing attempts to terminate SVT.[7] The risk of inducing nonclinical arrhythmias is higher with multiple premature stimuli.[7] In the patient with nonfatal cardiac arrest ventricular tachycardia was induced when attempts were made to stop an SVT by ventricular pacing. The use of closely coupled double extrastimuli is thought to increase the risk of tachycardia acceleration. Patients 2 and 3 both had accessory pathways with short anterograde refractory periods (≤270 ms), and pacing stimuli were delivered in the right ventricle. Induction of ventricular tachycardia could be the responsible mechanism for sudden death. Alternatively, the extrastimuli might have provoked atrial fibrillation after conducting retrogradely to the atria.[7]

The Holter recording of patient 1 at the time of death illustrates degeneration of an atrial arrhythmia into ventricular fibrillation. Although the possibility of spontaneous degeneration cannot be excluded, inadvertent ventricular pacing could have been responsible. This might have resulted in ventricular tachycardia, especially if the pacing stimulus was delivered in the ventricular vulnerable period.

We have reported the potential danger of antitachycardia pacing for patients with SVT. Ventricular pacing, especially using closely coupled extrastimuli, should probably be avoided. Care should be taken in using this technique in patients with underlying heart disease. In patients with preexcitation syndromes with a short accessory pathway anterograde refractory period, pacing can result in atrial fibrillation with consequent rapid ventricular response. Tachycardia termination pacing should probably be avoided in this group of patients.

Analysis of Antiarrhythmic Drug Concentrations Determined During Electrophysiologic Drug Testing in Patients with Inducible Tachycardias

NADA S. BERRY, PharmD
JERRY L. BAUMAN, PharmD
JOSE L. GALLASTEGUI, MD
WAYNE BAUMA, PharmD
KAREN J. BECKMAN, MD
ROBERT J. HARIMAN, MD

The approved type IA antiarrhythmic drugs quinidine, procainamide and disopyramide are widely used in the treatment of cardiac rhythm disturbances and serum concentrations of these drugs are frequently obtained. These drug levels are routinely interpreted in the context of commonly cited "therapeutic ranges" and used to guide therapy decisions and manipulate dosages. The present study was undertaken to evaluate the value of isolated serum concentrations of antiarrhythmic drugs and to analyze the effect of concentration on concordance and discordance of response.

The criteria for patient inclusion into the present study were: (1) symptomatic tachycardia requiring drug treatment, (2) control (drug free) and repeat (after drug therapy) electrophysiologic studies performed as clinically indicated and (3) serum drug concentration(s) determined during electrophysiologic drug testing. Between October 1978 and January 1987, 123 patients met these inclusion criteria and are the subject of this report. Data were compiled by a review of these patients' records. Of the 123 patients, 58 had paroxysmal supraventricular tachycardia (SVT) either due to atrioventricular (AV) nodal reentry or AV reentry incorporating an accessory AV connection, and the remaining 65 patients had ventricular tachycardia (VT). All patients had inducible sustained or symptomatic nonsustained SVT or VT during control electrophysiologic studies performed in the fasting, nonsedated state after all antiarrhythmic drugs had been discontinued for at least 5 elimination half-lives. The details of the stimulation protocol used in our laboratory for the induction of both SVT and VT have been reported elsewhere.[1-4]

Selection of a particular antiarrhythmic drug to be tested was based on the patient's history of response as well as any previous intolerable side effects noted. Patients were tested with quinidine (81 patients), procainamide (119) or disopyramide (44) in the following manner: quinidine 200 to 400 mg orally every 6 hours until presumed steady state; procainamide 1.0 to 1.5 g intravenously at 50 mg/min 30 minutes before programmed stimulation; and disopyramide 150 to 400 mg orally every 6 hours until presumed steady state. Initial dosages were selected based on patient-specific variables; lower amounts were used if concurrent diseases were suspected (e.g., coexisting liver disease, heart failure or renal disease). Serum for determination of antiarrhythmic drug concentrations was drawn in the postabsorptive (oral quinidine and disopyramide) or postdistributive (intravenous procainamide) state, at the time of the stimulation protocol. Serum concentrations were determined using the Syva EMIT assay. For the purposes of this study, the arbitrarily defined "therapeutic ranges" for these drugs were: quinidine 2 to 6 μg/ml; procainamide 6 to 12 μg/ml; and disopyramide 2 to 5 μg/ml. By definition, the antiarrhythmic drugs were well tolerated at the time of electrophysiologic testing and concentration sampling.

Patients were stratified into responders and nonresponders based on the results of electrophysiologic drug testing. Drug response was defined as inability to induce the tachycardia or induction of only brief (<15 beats) self-terminating SVT or VT not associated with symptoms.[5] If nonsustained tachycardia was induced during the drug-free control study, then patients were classified as responders only when the tachycardia was not inducible during drug testing. Nonresponse was defined as inducible SVT or VT that was unchanged from that induced during the control study. Concordance between the antiarrhythmic drugs was defined as the same result of electrophysiologic drug testing for all drug trials. Positive concordance was response to all drugs tested and negative concordance was no response to all drugs tested. Discordance resulted if there was a response to at least 1 of the drugs but nonresponse to at least 1 of the other agents.

Statistical analysis was performed by the Student t test for independent samples. Significance was deter-

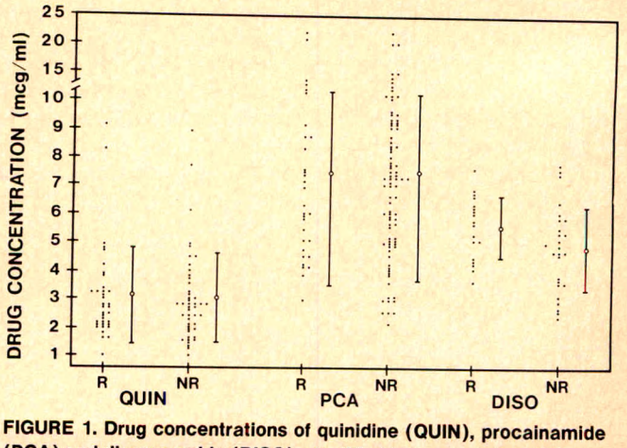

FIGURE 1. Drug concentrations of quinidine (QUIN), procainamide (PCA) and disopyramide (DISO), stratified into responders (R) and nonresponders (NR) in 123 patients. *Closed circles* represent individual drug concentrations. *Open circles* represent mean drug concentration and are illustrated to the *right* of each scatter plot; vertical bars represent standard deviation.

mined at $p < 0.05$. All data were expressed as mean ± standard deviation.

The serum concentrations of the 3 antiarrhythmic drugs, independent of the type of tachycardia, were analyzed (Figure 1). In the 33 patients responding to quinidine the serum concentrations ranged from 1.0 to 9.1 (3.1 ± 1.7) μg/ml compared with 1.0 to 8.9 (3.0 ± 1.6) μg/ml for the 48 nonresponders (difference not significant). In those receiving procainamide, the 30 responders had serum concentrations ranging from 2.9 to 22.2 (7.4 ± 4.0) compared with 2.1 to 22.2 (7.4 ± 3.8) μg/ml in the 89 nonresponders (difference not significant). The 18 responders to disopyramide had serum concentrations ranging from 3.6 to 7.5 (5.5 ± 1.1) compared with 2.3 to 7.7 (4.7 ± 1.5) μg/ml for the 26 nonresponders (difference not significant). Of the 123 patients, 58 responded to at least 1 of the 3 agents; 16 patients (28%) had drug concentrations below the therapeutic range. Drug concentrations were further analyzed by stratifying the patients into those with SVT and those with VT (Table I).

Of the 123 patients, 83 were tested with multiple drugs and the effect of drug concentration on concordance and discordance was examined. Of these 83 patients, 26 had discordant and 57 had concordant responses. In the former group of 26 patients, 12 (46%) had drug concentration patterns that could explain the discordant responses (Figure 2). These 12 patients consisted of 4 responding to an antiarrhythmic associated with isolated high drug concentrations (above the therapeutic range) and 8 who did not respond to 1 of the drugs associated with an isolated low concentration (below the therapeutic range). The remaining 14 patients in this group displayed no pattern relating

TABLE I Serum Drug Concentrations (μg/ml) in Patients with Paroxysmal SVT or VT for Responders and Nonresponders

	No.	Range	Mean ± SD	p Value
Supraventricular tachycardia

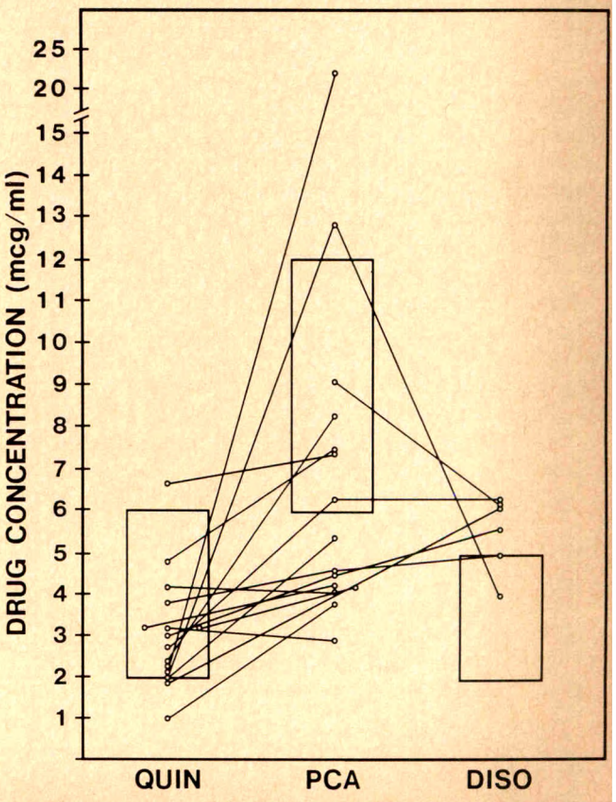

FIGURE 3. Drug concentrations of quinidine (QUIN), procainamide (PCA) and disopyramide (DISO) for 16 patients with positive concordance. Symbols as in Figure 2.

response to drug concentration; all serum levels were generally within the therapeutic range despite the observed discordant responses. In the group of 57 patients with concordance, 41 had negative concordant responses. The remaining 16 patients had positive concordance and 9 (56%) responded to an antiarrhythmic despite low concentrations of that agent (Figure 3).

These results indicate that the published therapeutic ranges of the type IA antiarrhythmic drugs should be used only as a rough guide to therapy and certainly not as any form of therapeutic endpoint. The mean effective concentrations in patients responding to therapy were virtually identical to the mean ineffective concentrations in patients not responding to these drugs. Also, the range of concentrations in which efficacy was demonstrated was extremely wide: procainamide 2.9 to 22.2 μg/ml and quinidine 1.0 to 8.9 μg/ml. When the data were analyzed separately for patients with SVT or VT, the results were similar. It is clear that one cannot differentiate responders from nonresponders solely on the basis of serum concentrations.

Because the type IA agents have similar electrophysiologic actions, some investigators have suggested a concordance of response for these drugs,[3,6] while others have found no concordance.[7,8] It is possible that differences in drug concentrations may account for some of the discrepancies in these findings. For this reason, we analyzed patients with discordant responses, searching for those with very high or low drug concentrations. Almost one-half of those patients with discordant responses had either isolated low drug concentrations (nonresponders) or isolated high drug concentrations (responders). Thus, it is possible that discordant responses are attributable to differences in drug concentrations in a significant number of patients. However, drug concentrations were also analyzed in a group displaying positive concordance. Similarly, about one-half of these patients had an isolated low concentration, yet were responders to that specific drug. This finding implies the opposite possibility, namely that response in some patients is relatively concentration insensitive. A likely explanation for these results is that a wide range of effective concentrations exists within a population of patients. This may be due to differences in the determinants and sensitivities of the reentrant circuit, differences in drug distribution to the site of the tachycardia or both. We believe there is a threshold concentration for effectiveness, but in a given patient, this threshold is highly variable and, at present, unpredictable.

Our electrophysiologic testing protocols have changed in the past decade to include the use of triple extrastimuli (but not left ventricular stimulation); it is possible that these procedural changes may have affected the results. Also, patients were not routinely retested if the serum concentration was low. Recently, Wyse et al[8] prospectively studied 32 patients with inducible VT after quinidine, procainamide and disopyramide therapy in both a low- and high-dose regimen. The high-dose regimen resulted in higher drug concentrations but did not appreciably improve response rate (particularly for quinidine and disopyramide). In reviewing our patients' records, 7 were retested at higher drug concentrations if nonresponse was observed at a low serum level. Of these 7 patients, only 1 responded at a higher concentration. It is therefore unlikely that the administration of several dosage regimens and retesting at various resultant serum concentrations would have caused the results to be dramatically different.

Although some patients display a concentration-dependent response to antiarrhythmic drug therapy, a significant number of patients seem to display a response that is relatively independent of drug concentration. Because of this and the observed high variability in effective concentrations, we offer the following guidelines when using serum concentrations of the antiarrhythmic drugs. When efficacy is demonstrated (by electrophysiologic testing or electrocardiographic monitoring), a serum concentration is determined at presumed steady state. Unless drug intolerance is encountered, this level then becomes the patient's therapeutic level and long-term oral administration is tailored to match the effective concentration. Commonly quoted therapeutic ranges are used only as rough guidelines and the effective concentration is specific for that patient's tachycardia.

LISINOPRIL

STUART

The first potassium this strong...

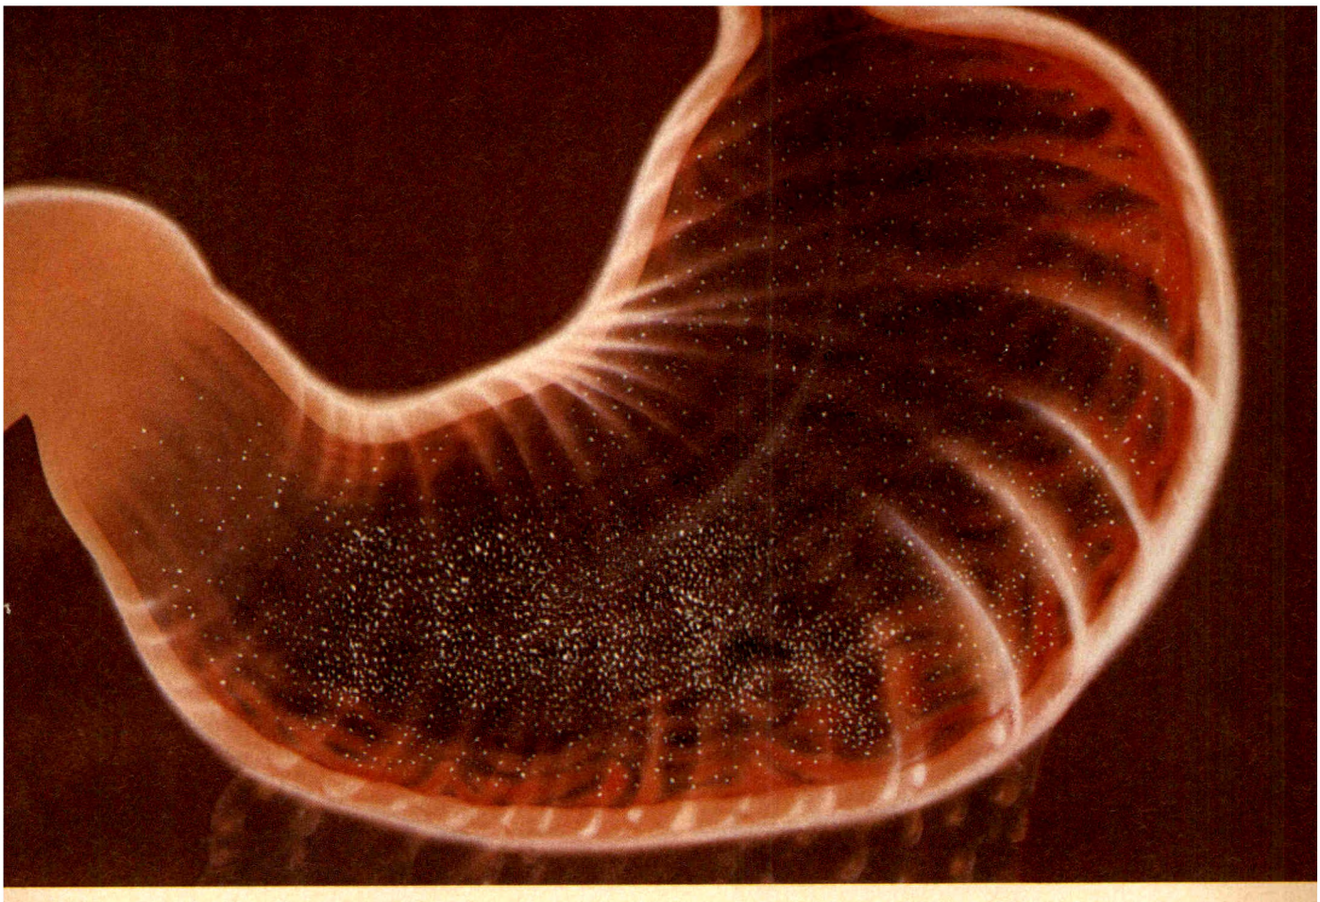
The first tablet to provide 20 mEq of potassium.

Greater strength (20 mEq) means fewer tablets, resulting in greater convenience, greater patient compliance.

Just one daily tablet for prevention of hypokalemia.

Only two to five tablets daily for treatment of hypokalemia. For greater dosing flexibility, the scored tablet can be halved or dispersed in half a glass of water by patients who can't swallow tablets.*

*See full prescribing information for Dosage and Administration.



Yet this safe.

Unique Microburst Release System shown safe in endoscopic study.[1]

		Number of Patients with Gastric Irritation	
	Total Daily Dose (80 mEq) Given	Gastric Erosion	Hyperemia and/or Edema
K-Dur 20 (n = 15)	b.i.d.	0	2
Kaon Elixir (n = 15)	b.i.d.	2	3
Slow-K (n = 15)	t.i.d.	2	1
SR KCl Capsule (n = 15)	t.i.d.	0	2
Placebo (n = 15)	b.i.d.	0	4

Like a liquid, K-Dur 20 Microburst Release System is designed to disperse immediately. Minute, sustained action particles are distributed over a wide surface area. The potassium chloride is then slowly released. Rapid, wide dispersion followed by slow release of the potassium minimizes contact between the gastric mucosa and concentrated quantities of potassium chloride.[1]

K-DUR™ 20 | Microburst Release System™

(potassium chloride) 20mEq

Solid strength, solid safety—
for patients who can't or won't tolerate liquid KCl.

Please see next page for summary of prescribing information.

K-DUR Release System™

(potassium chloride) Sustained Release Tablets

INDICATIONS AND USAGE: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage or perforation.

K-DUR tablets contain micro-crystalloids which disperse upon disintegration of the tablet. These micro-crystalloids are formulated to provide a controlled release of potassium chloride. The dispersibility of the micro-crystalloids and the controlled release of ions from them are intended to minimize the possibility of a high local concentration near the gastrointestinal mucosa and the ability of the KCl to cause stenosis or ulceration. Other means of accomplishing this (e.g., incorporation of potassium chloride into a wax matrix) have reduced the frequency of such lesions to less than one per 100,000 patient years (compared to 40–50 per 100,000 patient years with enteric-coated potassium chloride) but have not eliminated them. The frequency of GI lesions with K-DUR tablets is, at present, unknown. K-DUR tablets should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

PRECAUTIONS: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Laboratory Tests: Regular serum potassium determinations are recommended. In addition, during the treatment of potassium depletion, careful attention should be paid to acid-base balance, other serum electrolyte levels, the electrocardiogram, and the clinical status of the patient, particularly in the presence of cardiac disease, renal disease, or acidosis.

Drug Interactions: Potassium-sparing diuretics; see **WARNINGS.**

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies in animals have not been performed.

Pregnancy Category C: Animal reproduction studies have not been conducted with K-DUR. It is also not known whether K-DUR can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. K-DUR should be given to a pregnant woman only if clearly needed.

Nursing Mothers: The normal potassium ion content of human milk is about 13 mEq per liter. Since oral potassium becomes part of the body potassium pool, so long as body potassium is not excessive, the contribution of potassium chloride supplementation should have little or no effect on the level in human milk.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: One of the most severe adverse effects is hyperkalemia (see **CONTRAINDICATIONS, WARNINGS,** and **OVERDOSAGE).** There have also been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration, and perforation (see **CONTRAINDICATIONS** and **WARNINGS);** other factors known to be associated with such conditions were present in many of these patients.

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by taking the dose with meals or reducing the dose.

Skin rash has been reported rarely.

OVERDOSAGE: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see **CONTRAINDICATIONS** and **WARNINGS**). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-waves, depression of S-T segment, and prolongation of the QT-interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10–20 units of insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

The Heart and Hypertension

Franz H. Messerli, MD, Editor

"Like the kidney and the brain, the heart plays a three-fold role in essential hypertension: first, it is directly involved in the pathogenesis of arterial hypertension. ... Second, the heart suffers as a target organ of long-standing hypertension.... Third, cardiac function and structure are directly and indirectly affected by a variety of antihypertensive agents.

[This] book is written for physicians, cardiologists, or investigators who would like to deepen their understanding of cardiac involvement in hypertension, and of progression as well as regression of left ventricular hypertrophy, and the heart's structural and functional response to various blood pressure lowering agents."

—from the Editor's Preface

The Heart and Hypertension features contributions from 88 internationally recognized experts. *The Heart and Hypertension:* 482 pages—including a subject index—in 45 chapters.

Supraventricular tachyarrhythmia, in contrast to arrhythmias in adults, is the most common abnormal tachycardia in infants and children.[1] When the tachyarrhythmia is reentrant, conversion by physiologic, pharmacologic or electrical interruption of conduction within a limb of the circuit is highly probable. Manipulation of physiologic vagal tone, the obviously preferred mode, is not successful or feasible in a number of patients. Pharmacologic manipulation has been the most commonly used; however, digoxin and propranolol may require several hours for conversion. Intravenous administration of verapamil offers prompt termination[2,3]; however, in newborns it may be unsuccessful and carries the risk of hypotension, bradycardia, apnea and negative inotropy, especially in patients with coexisting congestive heart failure.[4] Electrical conversion by transvenous atrial pacing or by direct current cardioversion requires invasive entry for 1 technique and frequently general anesthesia for the other. Recent reports from our institution[5-7] as well as from others[8,9] have demonstrated the usefulness, simplicity and safety of transesophageal atrial burst pacing for conversion of reentrant tachyarrhythmias in infants and children. The technique, however, has not been included among the recent recommendations of several authorities.[10-12] Our purpose, therefore, is to report our experience with transesophageal pacing in infants and children so that the technique may be more widely known.

Between April 15, 1983, and December 31, 1986, 43 children (25 boys and 18 girls) seen at our institution experienced 73 episodes of supraventricular tachyarrhythmia. Three of these children were less than 1 week of age; 7 children were 1 to 4 weeks of age; 9 were 1 to 12 months of age; 13 were 1 to 10 years of age; and 11 were 10 years of age at the time of their initial episode. Among the 43 patients, 25 had no structural heart disease; 18 had associated postoperative heart disease (9 transposition of the great arteries, 3 univentricular heart and 1 each of 6 different lesions). The older children were symptomatic with palpitations and the infants were symptomatic with tachypnea; 1 infant had hydrops. Twenty-six children had supraventricular tachycardia (SVT) and 17 had atrial flutter. For the purposes of this study, SVT was defined as narrow QRS tachycardia (except in patients in whom preexisting bundle branch block was known), and by history or observation of abrupt initiation and termination and retrograde P waves with short RP intervals.

Atrial flutter was defined by typical sawtooth-pattern P waves and variable atrioventricular block (leads II, III, aVF, V_1) on the electrocardiogram. Following the Mustard or Fontan operation, because of slow intraatrial conduction, the typical pattern is frequently absent in such patients. Atrial flutter in this group of patients was considered present if variable atrioventricular block was observed during the tachycardia and history or observation of abrupt initiation and termination was present. Of the 26 children with SVT, only 2 had associated structural heart disease; in contrast, 14 of the 17 children with atrial flutter had structural heart disease. Among the 25 children with SVT, 10 had preexcitation. Four patients, including 2 infants, were converted from 6 different episodes as outpatients, avoiding hospitalization. In addition 4 patients were converted after surgery while still in the intensive care unit.

To begin transesophageal pacing the patient is first connected to a 3-lead standard electrogram. An intravenous line is not routinely placed. The choice of the electrode catheter depends on the patient's age and size. In infants and small children up to 2 to 3 years of

TABLE I Clinical and Electrophysiologic Data

	No.	Mean ± SD	Range
Age (yr)			
Initial episode	43	5 ± 6	1 day–19 yr
Weight (kg)	43	—	2–77
Height (cm)	43	—	46–170
Arrhythmia (episode)			
Cycle length (ms)			
Supraventricular tachycardia	43	236 ± 46	140–333
Atrial flutter	27	241 ± 51	160–350
Pacing cycle at converison length (ms)			
Supraventricular tachycardia (episodes)	44	188 ± 36	100–300
Atrial flutter (episodes)	26	170 ± 34	110–220
Pacing stimulus strength at threshold (capture)			
Supraventricular tachycardia			
Amplitude (mA)	43	14 ± 4	8–20
Pulse duration (ms)	43	5 ± 2	3–10
Atrial flutter			
Amplitude (mA)	26	16 ± 3	10–20
Pulse duration (ms)	26	6 ± 2	4–10

The descrepancy in numbers between the arrhythmia and the pacing cycle length is related to incomplete data in a few patients.

From the Division of Pediatric Cardiology, C.S. Mott Children's Hospital, and the Department of Pediatrics, University of Michigan, Ann Arbor, Michigan. Manuscript received October 15, 1987; revised manuscript received and accepted December 11, 1987.

age, a 4Fr bipolar (10 mm interelectrode distance) catheter is used (n = 49 episodes). For children 3 to 8 years of age, a 6Fr endocardial pacing catheter (interelectrode distance 2.9 cm) is used (n = 13). Children 8 years and older are asked to swallow an electrode "pill" (n = 11). The 2 electrodes of the bipolar catheter are then connected to a recording amplifier and strip chart recorder. The electrodes are positioned close to the atrium by identifying the maximal atrial electrogram, thus enhancing the atrial signal, which may be small or within the QRS complex on the electrocardiogram. The battery powered stimulator provides constant current pulses from 1 to 40 mA and 1 to 10 ms in impulse amplitude and duration, respectively (Arzco Inc.). However, because of the experience in adults of excessive esophageal discomfort at stimulus strengths of >20 mA current and >10 ms pulse duration, no attempt to pace patients at outputs in excess of those values is made. The threshold is measured at the minimal current and pulse duration required for constant atrial capture (Table I). Pacing is delivered in bursts of 3 to 10 seconds at 90% of the tachyarrhythmia cycle length, reducing the cycle length of each burst by 10 ms until either the arrhythmia is converted or refractoriness of the atria is reached. Details of the technique have been published previously.[5-7] Other than one 18-month-old infant, no children under 2 years of age received sedation. Children aged 2 to 12 years often expressed apprehension regarding passage of the electrode catheter. In the 10 patients with continuing apprehension, sedation was accomplished with 75 to 100 mg/kg of chloral hydrate by mouth, an intramuscular injection (1 patient) of meperidine (1 mg/kg), phenergan (0.5 mg/kg) and thorazine (0.5 mg/kg), or diazepam (1 to 5 mg) administered intravenously. Because swallowing the pill electrode requires an awake, cooperative state, the 11 children using the pill did not receive (or request) sedation.

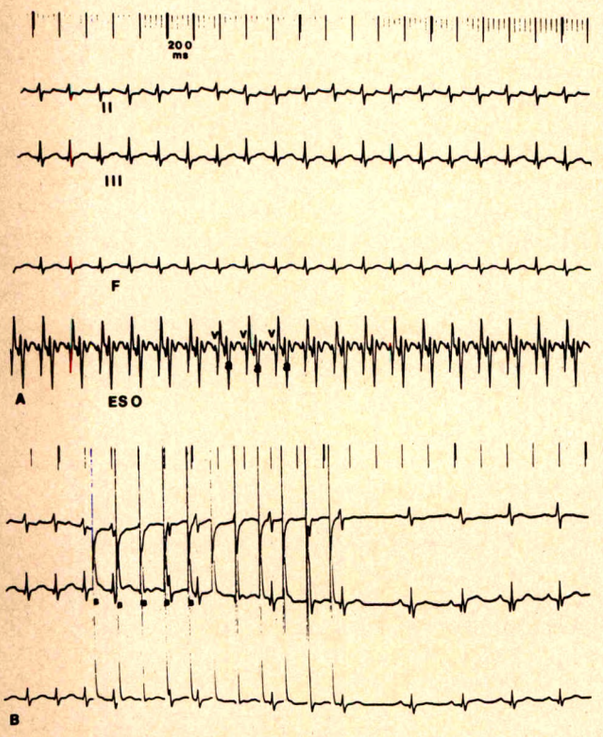

FIGURE 1. *A*, 3 surface electrocardiographic leads (II, III, F) and simultaneous esophageal lead (ESO) demonstrating tachycardia at a heart rate of 273 beats/min (cycle length 220 ms) in a 1-month-old infant. Note the narrow QRS and the large atrial (a) electrogram equal to the ventricular (v) electrogram. *B*, pacing stimuli (s) are delivered at a cyclic length of 170 ms (353 beats/min) for 1.7 seconds. Normal sinus rhythm appears after termination of pacing.

The threshold could be determined in each patient before conversion. Ninety-one percent (42/46) of episodes of supraventricular tachycardia were successfully converted using this technique (Figure 1). In contrast 74% (20/27) of episodes of atrial flutter were successfully converted to sinus rhythm ($p = 0.06$). Reasons for failure in the SVT group include failure to achieve capture in one 13-year-old patient dispite maximal 20 mA and 10 ms stimulus strength, depleted stimulator battery in 2 infants with SVT and insufficient shortening of the pacing cycle length in the fourth. All these failures occurred early in our experience (within the first 25 trials) and most likely can be avoided by improved attention to technique. Reason for failure of conversion of atrial flutter by this technique has been reviewed previously.[6] Conversion of SVT was achieved with pacing cycle length of 78% of the SVT cycle length. The pacing cycle length required to convert the patients with atrial flutter was slightly shorter at 71% of the atrial flutter cycle length. The threshold for capture was not related to the patients' age or size, the catheter used or the tachyarrhythmia converted, and did not differ between 2 separate episodes of tachyarrhythmia within a single patient with multiple episodes. Likewise, successful conversion was not related to the presence or absence of heart disease either as a whole or within either tachyarrhythmia groups[5-7] or to the presnce or absence of concurrent digoxin therapy.

All verbally expressive children stated, when asked, that they felt a sensation of "heartburn" (substernal discomfort) with each pacing discharge.[5-7] In no patient did this sensation require termination of the procedure. No complications were noted in the infants and children in whom the 4Fr soft bipolar electrode catheter was used. Passage of the catheter into the trachea occurred in a 13-year-old girl at which point the catheter was withdrawn and correctly placed with successful conversion. One 15-year-old girl bit through the fine wire of the pill electrode resulting in inadvertent pacing of her tongue. The pill was withdrawn, and exchanged for an endocardial pacing catheter with successful conversion. The next day she required repeat conversion and the pill was used successfully. One 19-year-old girl with a dual chamber pacemaker required programming of the pacemaker to the asynchronous (fixed rate) ventricular mode during conversion of atrial flutter to avoid inhibition of the pacemaker and ventricular asystole. One 5-year-old boy experienced inadvertent intermittent ventricular pacing during an unsuccessful at-

tempt in converting atrial flutter; no adverse effect was noted. Two 17-year-old boys immediately regurgitated the pill electrode after swallowing (they are not included in the 43 study patients).

Arrhythmias generated as a result of the technique occurred in 8 patients, all with atrial flutter. Three patients (2 with transposition/Mustard) were converted from atrial flutter to atrial fibrillation; the fibrillation persisted from 30 seconds to 45 minutes before self-extinguishing into sinus or a stable junctional rhythm. Three patients, all with transposition/Mustard, were converted from atrial flutter to atrial fibrillation or a faster flutter; these patients then received transthoracic direct current cardioversion under general anesthesia. No patient experienced hemodynamic deterioration or a ventricular response during atrial fibrillation faster than that observed during the original 2:1 atrioventricular block of atrial flutter. One patient with preexcitation but in atrial flutter was converted to SVT; the latter tachycardia was immediately converted to sinus rhythm. The final patient is the one with inadvertent ventricular pacing; no sustained arrhythmia was initiated. Thus, in none of the patients did an adverse arrhythmia develop and, importantly, in 3 patients conversion to a stable rhythm was achieved by a transition through a period of nonsustained atrial fibrillation.

These data indicate that transesophageal atrial pacing easily, predictably and safely converts reentrant supraventricular tachyarrhythmias to normal sinus rhythm. Although we and others have reported similar pediatric experience previously,[5-9] this more comprehensive serial study underscores the usefulness and safety of this technique especially in infants. Many authorities suggest that the first-line therapy for supraventricular tachycardia in infants and children is digoxin, and that if the patient is hemodynamically impaired, transthoracic direct current cardioversion.[10-12] Our data indicate that the delay inherent in digoxin or propranolol therapy, the risk of intravenous verapamil therapy and the transthoracic electrical discharge often requiring general anesthesia can frequently be avoided by transesophageal atrial pacing.

Our experience outlines several special applications of this technique in the young. First, although the time required to achieve access to the atria through the transesophageal route was not recorded, passage of the nasoesophageal catheter appeared to be quicker, simpler and less traumatic in an infant than establishing an intravenous route for pharmacologic agents. This difference in access is heightened by the potentially deleterious response to intravenous verapamil in the infant. Second, the use of a pill electrode requires, and may even encourage, a cooperative, participatory attitude in a reluctant older child or adolescent. The youngest patient to swallow the pill, which was used in all patients older than 10 years, was 8 years old. Third, the successful conversion of 74% of atrial flutter episodes suggests that this technique—perhaps because of the theoretical advantage of overdrive pacing for intraatrial reentrant arrhythmias when compared with most antiarrhythmic agents, and the smaller atrial size of young subjects—may be particularly suitable for children with atrial flutter.[6] Finally these data address the role of transesophageal atrial pacing in conversion of repeated episodes of either supraventricular tachycardia or atrial flutter in a single patient. Clearly, burst pacing through any route is an acute therapeutic technique and not a prophylactic one. Yet only 1 infant and two 8-year-old girls who were easily converted by transesophageal pacing immediately (within seconds) resumed the tachycardia. On the other hand, 19 of the 43 children required 1 or more repeat conversions at an interval of several hours to 3 years. Importantly, 4 of the 10 infants required repeat converison during their initial hospitalization while drug treatment was under evaluation. Although this study did not randomly assign to the patient episode or type of SVT transesophageal atrial pacing, drug trials or direct current cardioversion, it is nonetheless clear that atrial pacing through the esophagus offers at least equally prompt and safe therapy compared with the other forms of converison, especially in the infant.

Aortic regurgitation (AR) has been found with varying frequency in patients with systemic hypertension (SH).[1] The degree of AR in this clinical setting is usually mild.[2,3] Although it has been suggested that AR occurs in patients with SH as a consequence of the anatomic changes of aortic cusps, which are in turn related to both duration and severity of SH,[3] no recent study has investigated this.

From January to June 1987, we studied 98 consecutive patients with stable SH, 52 male and 46 female, mean age 56 ± 14 years, by color and pulsed-wave Doppler. Each patient had had SH for at least 3 years and had been diagnosed according to World Health Organization criteria. Patients referred for aortic valve disease (regurgitation or stenosis) were excluded from the study. Twenty-seven healthy normotensive subjects, 15 male and 12 female, mean age 57 ± 14 years, constituted the control group. Two-dimensional echocardiographic and Doppler studies were obtained using the Aloka SDS 860 color Doppler system, with 2.5- and 3.5-MHz transducers, by 2 observers unaware of clinical findings. AR was classified as mild and more than mild, according to whether diastolic regurgitant turbulence in both long-axis parasternal and 4-chamber or right anterior equivalent apical views[4] extended only to left ventricular outflow tract or further into the left ventricle (Figure 1A). Diastolic turbulence below the aortic cusps was considered suggestive of AR if it lasted the whole diastole, as confirmed by pulsed-wave Doppler analysis (Figure 1B).[5] Doppler findings were related to the following clinical data: length of history of SH and highest measurements of systolic and diastolic blood pressure, as reported by patient's physician; systolic and diastolic blood pressure and audibility of AR diastolic murmur at the time of Doppler studies. The following 2-dimensional echocardiographic data were considered: aortic anulus size, aortic root size and aortic cusp thickening (1 or more normally motile echo-dense leaflets). Concentric left ventricular hypertrophy was considered to be present if both left ventricular posterior wall and ventricular septum thickness exceeded 12 mm. Isolated hypertrophy of ventricular septum, which may occur in patients with SH,[6] was also noted.

AR was found in 37 of 98 patients with SH (38%) and 3 of 27 control subjects (11%) ($p < 0.001$). AR was

mild in 28 and more than mild in 9 patients with SH. AR was mild in all 3 control subjects. AR diastolic murmur was audible in 10 patients with SH and Doppler-defined AR, including all the 9 with more than mild Doppler AR, and in none of the control subjects. Clinical and 2-dimensional echocardiographic findings in patients with SH and control subjects, with and without Doppler AR, are listed in Table I. Thickening of aortic cusps was found in 34 of 37 patients with SH and Doppler AR (92%), 35 of 61 patients with SH and without Doppler AR (58%) and 8 of 27 control subjects (30%) ($p < 0.001$). All 3 control subjects with Doppler AR had aortic cusp thickening.

Our data show that AR can be frequently found by color and pulsed-wave Doppler in patients with long-standing SH, even if an AR murmur is not audible for the mild degree of regurgitation or emphysema. Prevalence of AR by Doppler was greater in our patients with SH than in normotensive control subjects of comparable age range. Confirming previous clinical studies,[1,2] we found that AR is usually mild in patients with SH. Because the assessment of AR by jet length method may be relatively inaccurate,[7] other Doppler methods, such as the estimate of regurgitant orifice width by color Doppler[7] or AR pressure half-time by continuous-wave Doppler,[8] might have provided further information on the real severity of AR in patients with SH. In some patients, continuous-wave Doppler is the only way of recording AR.[8] Then, with a combined use of pulsed- or color and continuous-wave Doppler, a higher prevalence of AR might have resulted in patients with SH than found in our study. We observed that aortic cusp thickening was more common in patients with SH and AR than in those without AR. Moreover, aortic cusp thickening was found in all 3 normotensive control subjects with AR. These data suggest a relation between Doppler AR and morphologic changes of aortic leaflets. Recently, Fisher and Henselman[9] found mild AR, using Doppler, in 7% of a geriatric population with a mean age of 76 years. Fibrosis and calcium deposits on the aortic cusps may be the result of the aging process induced by mechanical wear and tear.[10] We suggest that SH may accelerate this process and determine the occurrence of AR, usually mild and frequently clinically silent, 1 or 2 decades before its appearance in normotensive subjects. In contrast to others,[1,2] we were not able to find in patients with SH any relation between evidence of AR and aortic anulus or root size, duration and severity of SH and presence of left ventricular hypertrophy, concentric or limited to the subaortic portion of ventricular septum.[6] In patients with severe SH, aortic root dilation, by stretching the aortic cusps and hindering their diastolic coaptation, may determine significant AR.[3] This mechanism is probably less important in patients with SH and only mild AR. Transient AR may occur during acute elevation of blood pressure or circulatory overload, particularly in patients with renal failure.[11] Apparently, this mechanism did not influence our findings, because blood pressure was not different at the time of Doppler studies in SH patients with and without AR.

Early Results of Balloon Angioplasty of Native Aortic Coarctation in Young Adults

IHAB M. ATTIA, MD
ZUHDI A. LABABIDI, MD

Balloon angioplasty of aortic recoarctation has been established as an effective alternative to surgery in young children.[1,2] In spite of several international reports of successful balloon angioplasty of native aortic coarctation,[3-6] there are still controversial opinions regarding its value and long-term results. We report our experience with balloon angioplasty in managing 8 young adults with native aortic coarctation.

From 1983 to 1986, 8 consecutive young adults ranging in age from 19 to 30 years (mean 25 ± 5) with native aortic coarctation underwent balloon angioplasty. One 27-year-old patient has been previously reported.[6] All patients had localized aortic coarctations as confirmed by physical examination, 2-dimensional and Doppler echocardiography. Balloon coarctation angioplasty was performed as described in previous reports.[5,6] The diameter of the balloon was chosen to be equal to or 1 to 2 mm smaller than that of the descending thoracic aorta at the level of the diaphragm. The balloons used ranged in diameter from 15 to 20 mm and were 40 mm long. After confirming the exact location of the balloon by observing its hourglass shape during initial inflation (Figure 1A), the balloon was fully inflated until the hourglass shape disappeared (Figure 1B). In patient 2, follow-up cardiac catheterization was performed 21 months after the angioplasty procedure. The rest of the patients were followed up by physical examination, blood pressure measurement and Doppler echocardiography at an average period of 1 year.

Balloon angioplasty was performed with no significant complications in any of the 8 patients. Minor bleeding at the groin occurred at the time of the procedure. There were no arrhythmias, loss of femoral pulses, cerebrovascular accidents or spinal cord injuries. Table I lists the hemodynamic data obtained for all the patients before and after balloon angioplasty, as well as at follow-up. There was an appreciable decrease in the peak systolic gradient across the coarctation (Figure 2), as well as an increase in the diameter of the coarcted segment in all patients after the procedure (Figure 3). The initial results are promising and the follow-up catheterization performed 21 months later on patient 2 showed a further 8-mm Hg decrease in the gradient. At the 1-year follow-up examination, the residual gradient measured by pulsed-wave Doppler did not exceed 16 mm Hg in any patient. The blood pressure differential between the arms and the legs also did not exceed 15 mm Hg.

Our study showed that early results of balloon angioplasty for coarctation of the aorta in young adults can be as satisfactory as those previously reported in children, provided that meticulous care and appropriate choice of balloon size are undertaken to avoid overdistention of the media of the aortic segments adjacent to the coarctation. The maximum diameter of the balloon should be equal to or 1 to 2 mm less than the diameter of the descending thoracic aorta at the level of the diaphragm, as measured on the video monitor after correction for magnification. The ascending aorta, aortic isthmus and the area just distal to the coarctation are not suitable as a guide for balloon choice because of their marked variability in different patients. Careful manipulation of the guidewire is required at all times after balloon inflation to avoid intimal dissection. The option of balloon angioplasty for adults with

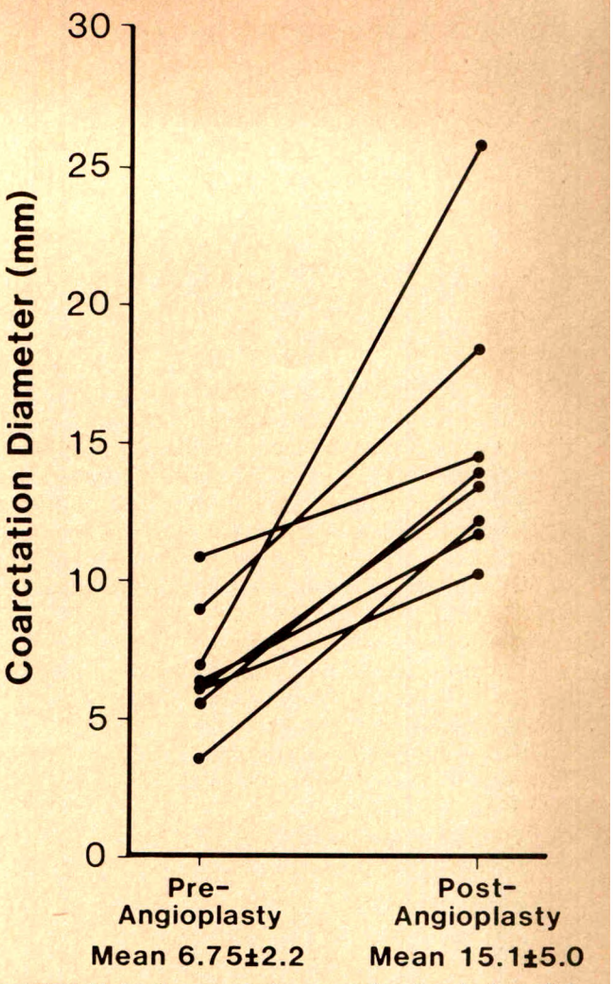

FIGURE 3. Marked increase in the coarctation diameter immediately after balloon coarctation angioplasty.

native aortic coarctation is worthy of consideration and provides the established advantages of balloon angioplasty over surgery. The frequent occurrence of an aneurysm at the site of surgical coarctation repair, several years after the various types of surgical repair of coarctation of the aorta, poses a challenge to the future long-term results of balloon angioplasty for native aortic coarctation. Thus, further studies involving adults with native aortic coarctation should be undertaken. Our initial experience is encouraging and long-term follow-up studies are required.

Effects of Repeated Increments in Right Atrial Pressure on Secretion of Atrial Natriuretic Factor

MATHIAS C. HAUFE, MD
JOCHEN WEIL, MD
RUPERT GERZER, MD
JOHANNA E. ERNST
KARL THEISEN, MD

It has been demonstrated that an acute increase in right atrial (RA) pressure and paroxysmal supraventricular tachycardias induce the release of atrial natriuretic factor (ANF).[1-4] In a previous study that allowed a selective or combined increase in heart rate and RA pressure by intracardiac pacing, we showed that acute increment in RA pressure is the determinant factor for ANF secretion.[5] Hollister et al[3] demonstrated that, in subjects with elevated ANF levels due to a high salt diet, ANF release caused by atrial pressure increment was higher compared with subjects with normal baseline ANF. These data suggest that under chronically stimulated ANF secretion, there might be a higher sensitivity of ANF release to additional secretory stimuli. However, it is unknown whether there is an adaptation of the ANF release to repetitive secretion stimuli. We therefore investigated the ANF response to repeated identical atrial pressure increments.

Eight patients (7 men, 1 woman, ages 38 to 63 years) with moderate coronary artery disease were studied before a diagnostic right- and left-sided heart catheterization. All patients had normal ventricular and atrial pressures, a left ventricular ejection fraction >40% and stable sinus rhythm at rest. Nitrates, β blockers and calcium antagonists were terminated at least 48 hours before the examination. None of the patients was taking digitalis. All patients had given their informed consent.

As previously reported,[5] right ventricular pacing in patients with sinus rhythm results in an asynchronous contraction of the right ventricle and atrium and leads to an acute increment in RA pressure and subsequently to ANF release.

All patients underwent right ventricular pacing at 150 beats/min for a period of 4 minutes (stimulation I). After a 15-minute interval, the identical stimulation was repeated (stimulation II). RA pressure and systemic blood pressure were continuously measured through catheters placed in the right atrium and the femoral artery. A bipolar lead and a programmable external pacemaker were used for stimulation. The electrocardiogram was monitored throughout the whole study.

Arterial blood samples were taken in ice-water-cooled Ethylene-diaminotetraacetate tubes before and after stimulation I and stimulation II, and immediately separated by centrifugation at 2°C and 2,800 rounds/min and stored at −70°C until assayed. Plasma ANF concentration was measured after extraction through octadecyl-silane cartridges (Sep-pak C18). The absorbed ANF was eluted with 86% ethanol in 4% acetic acid. After evaporation and lyophilization the dry residue was dissolved in radioimmunoassay

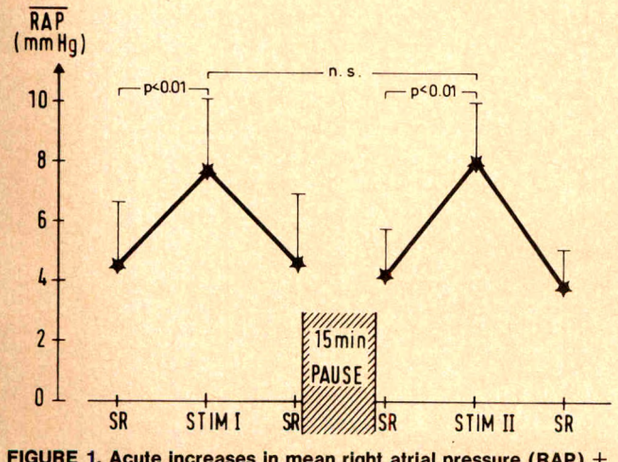

FIGURE 1. Acute increases in mean right atrial pressure (RAP) ± standard deviation by right ventricular stimulation I and II (Stim I, Stim II, both at 150 beats/min). NS = not significant; SR = sinus rhythm.

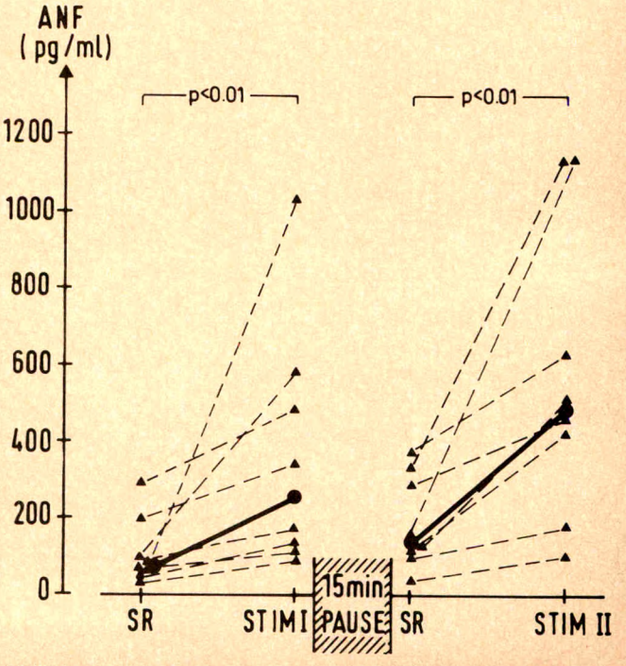

FIGURE 2. Atrial natriuretic factor (ANF) plasma concentrations during stimulations I and II (Stim I, Stim II) for each patient. *Dots* are median values. SR = sinus rhythm before both stimulations.

buffer for determination of ANF using an incubation time of 48 hours at 4°C. Separation of free from antibody-bound iodine-125-α-ANF was achieved by a double-antibody method. The inter- and intraassay variation was 15% and 11%, respectively. In 86 control subjects (ages 20 to 45 years), the plasma ANF levels ranged from 30 to 125 pg/ml (median 74).

Plasma levels of cyclic guanosine monophosphate were measured by radioimmunoassay of ethanol extracted samples.[2]

For statistical analysis the Wilcoxon test was used. P values <0.05 were considered significant.

Figure 1 illustrates the increment in mean RA pressure. Mean RA pressure increased from 4.5 ± 2.3 mm Hg at control (sinus rhythm) to 7.7 ± 2.5 mm Hg ($p < 0.01$) during stimulation I and dropped immediately after termination of stimulation I to control values. Stimulation II increased mean RA pressure comparably from 4.2 ± 1.7 to 7.9 ± 2.2 mm Hg ($p < 0.01$). Control values at sinus rhythm before and the amount of RA pressure increments during both stimulations did not differ (difference not significant). Mean systemic blood pressure remained stable throughout the whole protocol.

Figure 2 shows ANF levels during stimulation I and II. The median of control values before stimulation I was 79 pg/ml (range 46 to 299) and increased significantly ($p < 0.01$) to 258 pg/ml (range 96 to 1,045). At the end of the 15-minute interval, ANF values had decreased almost to control values (difference not significant). Median ANF before stimulation II was 140 pg/ml (range 42 to 375) and was significantly ($p < 0.01$) increased by stimulation II up to 488 pg/ml (range 107 to 1,145).

The statistically different ANF secretion in both stimulations is shown in Figure 3. Median ANF increase during stimulation I was 116 pg/ml (range 44 to 974) compared with 290 pg/ml (range 65 to 989) during stimulation II; i.e., the amount of ANF released by stimulation II was 2.5-fold higher than by stimulation I ($p < 0.02$).

Median cyclic guanosine monophosphate levels (Figure 4) showed a similar trend and increased from 3.1 to 4.9 pmol/ml after stimulation I and from 5.4 to 8.5 pmol/ml after stimulation II. There was a significant and linear correlation between control cyclic guanosine monophosphate and ANF levels ($r = 0.79$, $p < 0.05$).

Our results indicate, for the first time, that repeated stimulation of the ANF secretory system enhances ANF release. The myoendocrine cells are apparently capable of a fast upward regulation of their response to adequate secretory stimuli.

RA pressure modulates the ANF secretion. Diseases as well as maneuvers, which induce RA pressure increment, lead to enhanced ANF levels.[2-6] As previously shown, rapid ventricular pacing in patients with sinus rhythm provokes immediate and reproducible increases in RA pressure and ANF release.[5]

Up to now, no studies have investigated the ANF response to repeated secretory stimuli. From other hormone systems it is known that there is no uniform response. Insulin, for example, shows an enhanced release[7] after repeated stimulation. In the present study, while RA pressure was identically increased in both stimulations, the amount of ANF secretion after the second stimulation was significantly larger than the ANF release that followed the first stimulation. As expected from the known half-time of ANF, ANF levels had markedly dropped in the 15-minute interval before the second stimulation. There was no statistically significant difference between ANF levels before the first and the second stimulation.

The correlation between baseline cyclic guanosine monophosphate and ANF levels that we found in this

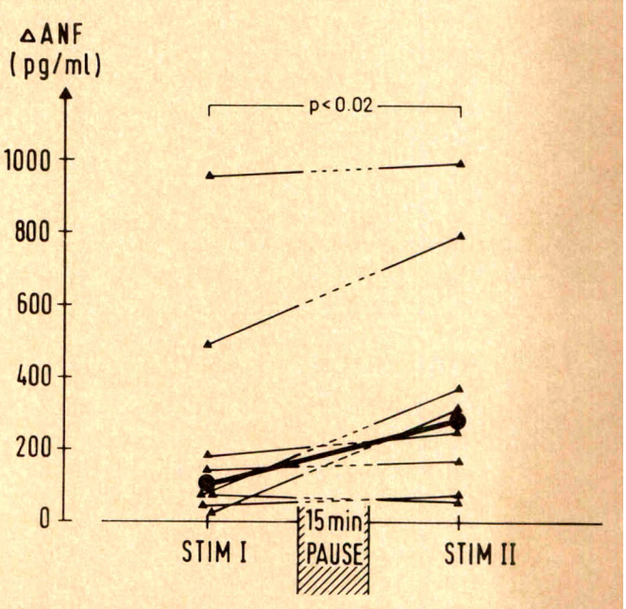

FIGURE 3. Increases (Δ values) in atrial natriuretic factor (ANF) plasma concentrations during stimulations I and II (Stim I, Stim II) for each patient. *Dots* are median values. SR = sinus rhythm before both stimulations.

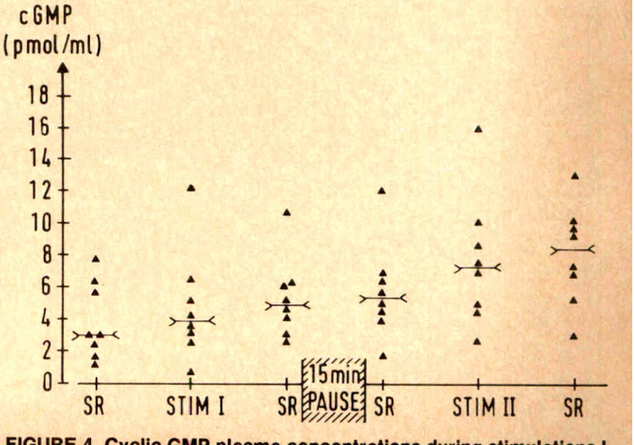

FIGURE 4. Cyclic GMP plasma concentrations during stimulations I and II (Stim I, Stim II). *Horizontal lines* are median values. SR = sinus rhythm before both stimulations.

study is comparable to data recently reported.[8] Increases in median cyclic guanosine monophosphate levels were 1.8 pmol/ml after the first stimulation and 3.1 pmol/ml after the second stimulation and corresponded to the higher release of ANF after the second stimulation. Between both stimulations, cyclic guanosine monophosphate had not decreased, which can be explained by a time difference between peaks of ANF and cyclic guanosine monophosphate, and a markedly longer half-time of cyclic guanosine monophosphate of about 30 minutes, as demonstrated in a previous study.[9]

According to our results, the first secretory stimulus, RA pressure increment, appears to have a "priming effect" on the ANF release caused by an identical second stimulus. According to published reports, a correlation between ANF concentrations and its biologic effects can be anticipated.[9]

In addition, the increase in cyclic guanosine monophosphate, known as the second messenger of ANF,[10] confirmed the primed ANF secretion measured after the second stimulation.

The myoendocrine cells appear to be quickly adaptable to a higher secretion. Possible underlying mechanisms, i.e., propagation of granular exocytosis, enhanced intracellular conversion from progranules to granules or increased ANF reduplication, have to be resolved in further studies.

Lipoprotein Profiles of Elite Veteran Endurance Athletes

ROBIN J. NORTHCOTE, MD
GORDON C. CANNING, MRCP
IAIN C. TODD, BSc, MRCP
DAVID BALLANTYNE, MD

The long-term effect of exercise training on plasma lipoproteins has not been described, although the short-term effects of exercise have shown an improvement in the lipoprotein profile with regard to coronary artery disease (CAD) risk.[1] We report our findings in a group of veteran endurance runners.

Three groups of subjects were studied. Group 1 consisted of 20 male endurance runners recruited from the Scottish Veteran Harriers Club. These men were recruited on the basis of a minimum age of 45 years, minimum running experience of 15 years and minimum weekly training of 30 miles. All athletes had not run for at least 2 days before study. Group 2 consisted of 20 men who undertook light physical activity in the form of golf, bowls or walking. All subjects in groups 1 and 2 were healthy with no history of cardiovascular disease, cigarette smoking, heavy alcohol consumption, renal or hepatic disease or diabetes mellitus and none was on a special diet or took dietary supplements, stimulants or other medication. Group 3 consisted of 20 matched male patients recruited from a cardiac clinic with symptomatic CAD (New York Heart Association grade II to III) confirmed by selective coronary angiography (n = 12) or exercise electrocardiography (n = 8). No subject was taking medication at the time of study, apart from sublingual triceryl trinitrate for episodes of chest pain. Eight of

CAD = coronary artery disease; HDL = high density lipoprotein; LDL = low density lipoprotein; VLDL = very low density lipoprotein.

these men were previously known to have had a myocardial infarction at least 1 year before this study. Percentage of body fat was calculated by incorporating tricepts, scapular and abdominal skin-fold thickness into the equation devised by Lohman.[2]

Blood was withdrawn from all subjects in the sitting position after an overnight fast (14 to 16 hours). No vigorous exercise was performed in the previous 48 hours.

Lipoprotein subfractions were separated using the technique of preparative ultracentrifugation and heparin/magnesium chloride precipitation followed by lipid analysis of the resultant fractions. The cholesterol and triglyceride concentration in the fractions A (very low density lipoprotein [VLDL]), B (low density lipoprotein [LDL]) and C (high density lipoprotein [HDL]) were measured. The concentration of LDL was obtained by subtracting the HDL cholesterol concentration from that in fraction B. Plasma total triglycerides were estimated by a fully enzymatic method on a Technicon auto-analyzer (second generation). Plasma total cholesterol was estimated by an enzymatic colorimetric method using a modified Lieberman-Burchard reaction. HDL was further subfractioned into the components HDL and HDL_3 by rate zonal ultracentrifugation. Lipoprotein subfractions are expressed in mg/dl followed by mmol/liter.

Results are expressed as mean ± standard deviation. Both Student's paired t test and Wilcoxon's signed rank test were applied to the lipoprotein results. The most conservative estimates of significance are reported.

The 3 groups were closely matched in terms of age (Table I). Predictably, both resting heart rate, body mass (Quetelet index) and percentage of body fat were lower in the athletic group. Group 1 consisted of an elite group of veteran runners with excellent performances in marathons (Table I) of national and international scope.

The results of the lipoprotein analyses are listed in Table II. Total triglyceride was significantly higher in both control subjects and those patients with CAD, but total cholesterol was higher in both athletes (difference not significant) and CAD patients ($p < 0.05$) compared with control subjects. VLDL cholesterol was significantly higher in both control subjects (group 2) and those patients with CAD (group 3) but LDL was only higher in CAD patients ($p < 0.01$); the level in the athletes was higher than those found in healthy control subjects (difference not significant). Both total HDL and HDL_2 were significantly lower in control subjects and those patients with CAD ($p < 0.001$). The ratios of HDL_2 to HDL_3 and HDL to total cholesterol were significantly higher in the athletes.

The veteran endurance athletes in this study had a remarkably higher HDL_2 level: 37% higher than their lean sedentary peers. This indicates an approximately 2.5-fold increased greater risk for the latter group compared with athletes of developing CAD according to Framingham data,[3] independent of other risk factors. The athletes had levels 250% higher than those patients with proven CAD. The groups involved in the study were closely matched in physical terms but it could be argued tht the difference in lipoproteins reflected differences in body composition. The athletes had a significantly lower percentage of body fat than their sedentary peers but no significant relation was found between HDL_2 levels and percentage of body fat. Thus the higher HDL and HDL_2 concentrations appear to be a direct result of lifelong running rather than body composition. Previously, differences in HDL concentrations between trained and sedentary individuals have not been related to differences in diet. In this study, no participant was on a special or unusual diet. Thus, although dietary analyses were not part of the study it is unlikely that any difference in dietary habit substantially altered the results.

Previous studies have reported significantly higher total HDL cholesterol levels in individuals taking part in an exercise training program,[1,4–7] but none has measured the HDL subfractions. It is probable that the acute effect of exercise training on the lipoprotein profile reported by others[6] is sustained and results in a substantial reduction in CAD risk if continued throughout life. The mechanism whereby exercise increased total HDL and HDL_2 is not known; however, Kantor et al[8] demonstrated a substantial increase in post-heparin plasma lipoprotein lipase activity in marathon runners for up to 2 days following a 42-km race.

This may explain the increase in total HDL and reduction in triglycerides that they demonstrated, and would be consistent with our results.

Idioventricular Rates in Early and Late Phases of Acute Myocardial Infarction

JAOK HAN, MD, PhD
MYUNG S. YOON, MD
GEORGE H. DERSHAM, PhD

Two distinct phases of ventricular arrhythmias are observed after coronary artery occlusion in the dog.[1] An early arrhythmic phase begins almost immediately and persists up to a few hours; then, a late phase begins at 12 to 24 hours and lasts approximately 24 hours. Experimental data seem to indicate that the early arrhythmias result from reentry associated with abnormal conduction in the ischemic myocardium, whereas the late arrhythmias are due to enhanced automaticity of Purkinje fibers.[2,3] The present study compares the degrees of ventricular automaticity during the early and late phases of acute myocardial infarction in dogs with complete atrioventricular (AV) block and idioventricular escape rhythm.

From the Department of Medicine (Cardiology), Albany Medical College of Union University, and the Electrocardiography Laboratory, Albany Medical Center Hospital, Albany, New York. This study was supported by a grant from the American Heart Association (New York State Affiliate), and by the Cardiology Research Fund of Albany Medical College, Albany, New York. Manuscript received September 8, 1987; revised manuscript received December 7, 1987, and accepted December 8.

Experiments were performed on 10 mongrel dogs anesthetized by an intravenous injection of sodium pentobarbital (30 mg/kg). The dogs were ventilated by artificial respiration through an endotracheal tube. A bipolar electrode catheter was introduced into the right femoral vein and advanced to the region of His bundle. The His bundle electrogram was recorded along with lead II electrocardiogram on an Electronics for Medicine recorder at a paper speed of 100 mm/s. After the stable His electrogram was secured, ablation of the His bundle was attempted by way of the His bundle electrode catheter. The cathodal output of a standard defibrillator unit was connected to the distal pole of the His electrode catheter and the anodal output was connected to the paddle placed over the left precadium. A high-energy discharge of 200 to 300 joules was delivered to the His bundle electrode to obtain the stable AV block which resulted in idioventricular escape rhythm. This was repeated in some dogs to secure long-standing complete AV block. Figure 1 illustrates lead II electrocardiograms and His bundle electrograms recorded before and after the successful His bundle ablation. After the stable idioventricular escape rhythm was established, the chest was opened by left thoracotomy and the pericardium was opened to expose the proximal and mid portions of the left anterior descending artery for later ligation. The idioventricular rate was determined as a measure of baseline ventricular automaticity. The left anterior

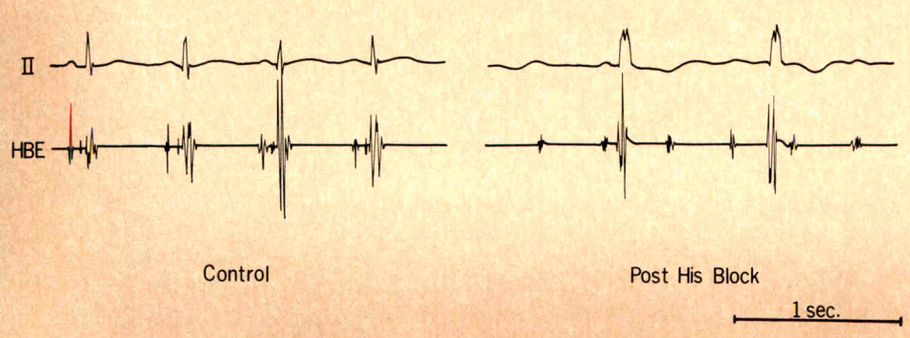

FIGURE 1. Lead II electrocardiograms and His bundle electrograms before (control) and after the His bundle ablation (block). HBE = His bundle electrogram.

descending artery was then occluded above the diagonal branch by the Harris 2-stage ligation technique.[1] The idioventricular rate was again determined at 15 to 45 minutes after coronary occlusion. The pericardium and the thorax were subsequently closed and an airtight seal maintained while the dogs were allowed to recover from the anesthesia. After 24 hours the dogs were reanesthetized, their chests were reopened and ventricular automaticity was again assessed using the same methods as those used on the previous day.

Figure 2 shows the mean idoventricular rates in the control state, at 15 to 45 minutes and at 24 hours after coronary occlusion. The mean rates were 86 ± 7/min in the control state and 85 ± 7/min at 15 to 45 minutes after coronary occlusion. The difference was not statistically significant. The mean rate was increased to 171 ± 9/min at 24 hours after coronary occlusion and this increase was statistically significant ($p < 0.001$) compared with the mean rate during the control state or at 15 to 45 minutes after coronary occlusion. The increased idioventricular rate at 24 hours after coronary occlusion was predominantly due to acceleration of the rhythm of the same QRS morphology in 5 of the 10 dogs. An example of such a rate increase in the same QRS pattern is shown in Figure 3. In the remaining 5 dogs, the QRS morphology at 24 hours after coronary occlusion was different from that of either the control state or at 15 to 45 minutes after coronary occlusion. As depicted in Figure 4, the QRS patterns were often multiform.

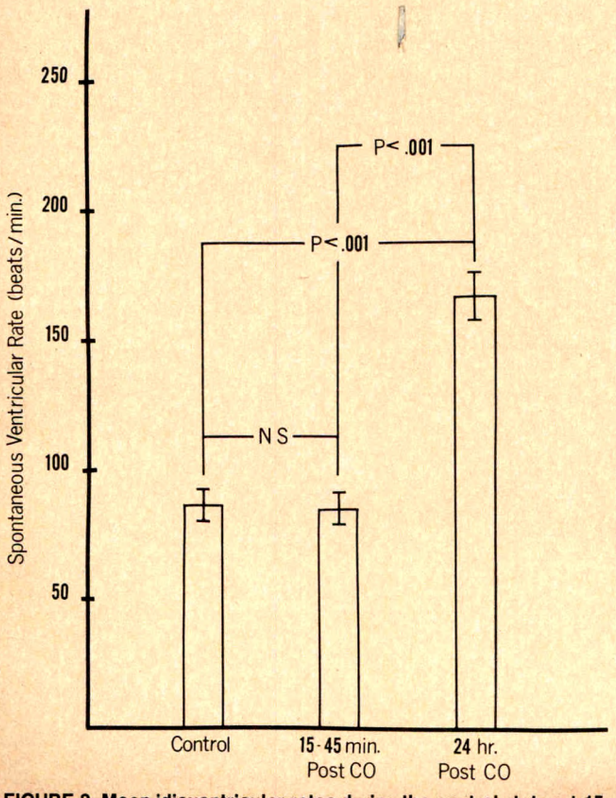

FIGURE 2. Mean idioventricular rates during the control state, at 15 to 45 minutes and at 24 hours after coronary occlusion (CO). NS = not significant.

Our present knowledge of the electrophysiologic mechanisms of ventricular arrhythmias has been largely obtained from canine experiments. It has been generally accepted that the early arrhythmias result from reentry and the late ones are due to enhanced automaticity.[2,3] The early arrhythmic phase in the dog could be related to the prehospital phase of arrhythmias seen during acute myocardial infarction in humans, while the late arrhythmic phase may be similar to the in-hospital arrhythmias. In the present study, the idioventricular rates were assessed in the early and late phases of acute myocardial infarction using the same dogs and with each dog serving as its own control. The results showed that the mean idioventricular rate does not change significantly during the early

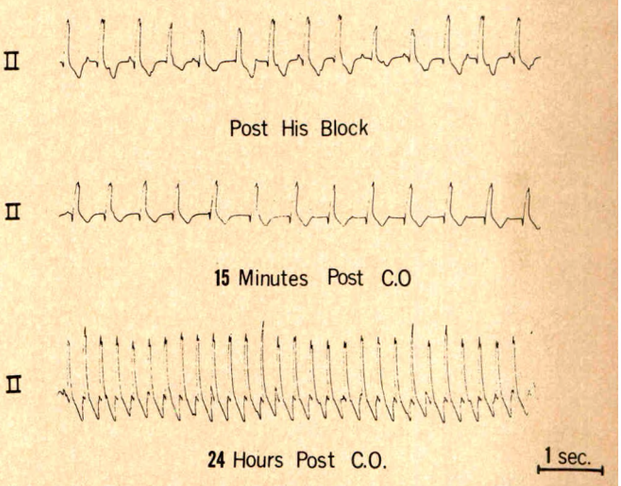

FIGURE 3. Lead II electrocardiograms from 1 of the experiments after the His block before coronary occlusion, at 15 minutes and at 24 hours after coronary occlusion (C.O.).

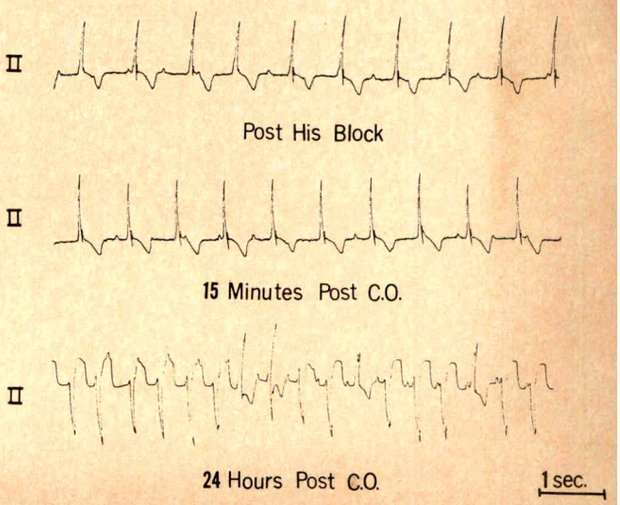

FIGURE 4. Lead II electrocardiograms from another experiment shows multiform QRS patterns.

phase of acute myocardial infarction but is significantly increased during the late phase. These observations are in agreement with earlier dog experiments in which the ventricular Purkinje fibers remained intact for approximately 10 to 12 hours and the structural changes began to appear at 12 to 24 hours after coronary occlusion.[3,4] The damaged Purkinje fibers showed abnormal electric activity, such as reduced resting membrane potential and spontaneous diastolic depolarization.[4,5] These spontaneously depolarizing Purkinje fibers may result in increased automaticity and ventricular arrhythmias. Indeed, the present study indicates that enhanced automaticity is of little importance in the genesis of early ventricular arrhythmias but may play a significant role in the development of late arrhythmias during acute myocardial infarction. Other possible mechanisms for the late arrhythmias are reentry and triggered activity arising from damaged Purkinje tissues.[3]

The AJC in April 1963

WILLIAM C. ROBERTS, MD

The AJC in April 1963 contained 20 articles, occupying 133 pages, and they included 8 major studies, 2 experimental studies, 1 historic study and 9 case reports. Five of the 8 major studies and 8 of the 9 case reports concerned patients with congenital heart disease. This piece will comment on 4 of the 20 articles.

Moncada and associates[1] from Chicago, Illinois, described left ventricular angiographic findings in 35 infants and children with ventricular septal defect (VSD). The angiograms demonstrated shunting of the contrast material into the right ventricle in all 35 patients. The defect was "membraneous" in 21, "high muscular" in 9 and "low muscular" in 4. The authors concluded that left ventricular angiography was useful in indicating the presence, location, size and number of VSDs, and the existence of associated intracardiac anomalies of the left side of the heart.

Karnegis and Wang[2] from Minneapolis, Minnesota, measured the interval between the onset of the Q wave on the electrocardiogram and the first heart sound on the phonocardiogram (Q-1 interval) in 13 patients with VSD and found the interval to be relatively proportional to the size of the shunt through the VSD—the larger the shunt, the longer the interval.

Elliott and associates[3] from Minneapolis, Minnesota, described clinical and necropsy findings in 3 patients with single ventricle, normally related ascending aorta and pulmonary trunk, and obstruction to pulmonary flow. Most patients with single ventricle have transposed great arteries and no obstruction to pulmonary flow.

Samet and associates[4] from Miami Beach, Florida, illustrated indicator dilution curves following injections of indocyanine green in complicated atrial septal defect (Ebstein's anomaly of the tricuspid valve, total anomalous pulmonary venous connection, tricuspid valve atresia and anomalously connected left pulmonary vein).

Coronary Artery Spasm, Cardiac Arrest, Transient Electrocardiographic Q Waves and Stunned Myocardium in Cocaine-Associated Acute Myocardial Infarction

ELIZABETH K. ASCHER, MD
JEAN-CHRISTOPHE E. STAUFFER, MD
WILLIAM H. GAASCH, MD

Recreational cocaine use has recently been recognized as a cause of acute myocardial infarction (AMI), even in patients with normal coronary arteries.[1-11] The pharmacologic effects of this drug are sympathomimetic; they include peripheral potentiation of catecholamine activity, inhibition of monoamine oxidase activity and direct central medullary stimulation. In previous reports relating nasal or intravenous cocaine use to AMI, angiography has frequently shown little or no fixed obstructive coronary artery disease.[2-5,8,10,11] Although ergonovine testing has been negative in reported cases,[4,5,8,10,11] cocaine-induced coronary artery spasm has been presumed to be responsible for AMI in these patients. We describe a cocaine user who had an AMI, in whom unprovoked coronary artery spasm was documented.

A 47-year-old white man was admitted to the hospital with severe chest pain beginning 15 hours after the intake of undetermined quantities of cocaine (intranasal), alcohol (oral) and marijuana (inhaled). He was a longstanding cigarette smoker, but had no known history of cardiovascular disease, diabetes mellitus or hyperlipidemia. The admission electrocardiogram showed significant Q waves and 3-mm ST elevation in leads V_2 through V_4 (Figure 1A). Within 30 minutes of admission, the patient developed ventricular fibrillation and immediately underwent successful cardioversion. Shortly thereafter, the chest pain resolved, and a repeat electrocardiogram revealed only ST-segment depression in V_4; the Q waves were no longer present (Figure 1B). Serum creatine kinase levels peaked at 1,053 (IU/liter) with a 15% MB-isoenzyme fraction 18 hours after admission. On the day after admission, an echocardiogram showed extensive left ventricular wall motion abnormality (anteroseptal and apical akinesis). The left ventricular ejection fraction by radionuclide ventriculogram was 29%. Initial treatment with metoprolol (25 mg orally 2 times daily) and aspirin (325 mg orally once daily) was begun.

Five days after admission, left ventriculography showed anterior, apical and inferior wall akinesis

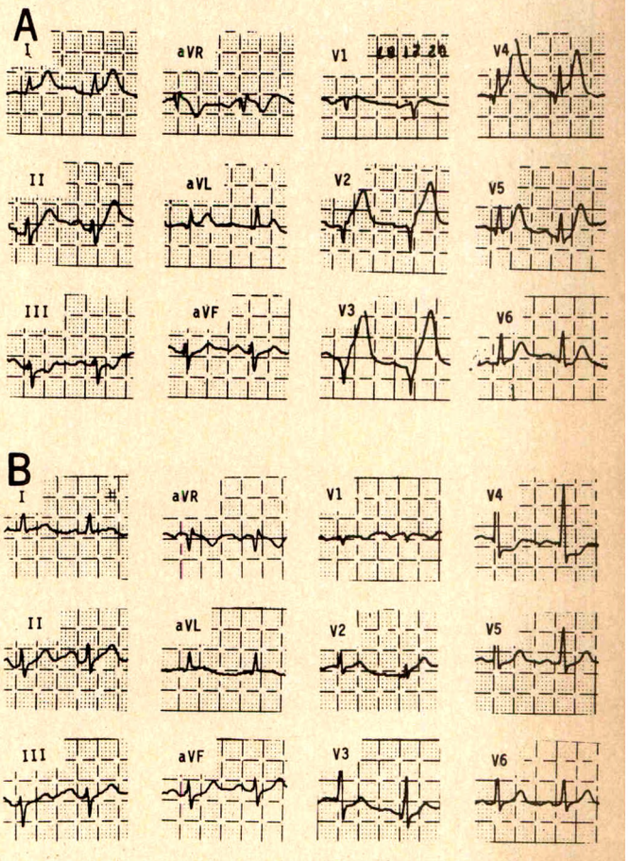

FIGURE 1. Electrocardiogram from a patient with cocaine-associated myocardial infarction. In *A*, the electrocardiogram shows Q waves and ST elevation in leads V_2 through V_4 consistent with acute myocardial infarction. In *B*, taken after cardioversion, the electrocardiogram shows resolution of the infarct pattern; ST-segment depression persists and later showed evolution consistent with a non-Q-wave myocardial infarction.

From the Department of Medicine (Cardiology), Tufts University School of Medicine, and the Boston Veterans Administration Medical Center, Boston, Massachusetts. Manuscript received October 6, 1987; revised manuscript received and accepted December 12, 1987.

with an ejection fraction of 45%. Selective coronary arteriography revealed <20% diameter narrowing of the mid-left anterior descending coronary artery. Spontaneous spasm at this site resulted in diameter narrowing of the lumen by 80% (Figure 2A). This dynamic narrowing resolved after administration of sublingual nitroglycerin (0.4 mg) (Figure 2B). Metoprolol was discontinued, and the patient was treated with diltiazem (30 mg orally 4 times daily); he remained asymptomatic thereafter.

On exercise testing before discharge, the patient had no clinical or electrocardiographic evidence of myocardial ischemia at a heart rate of 98 beats/min during stage 4 of the Naughton protocol. A radionuclide ventriculogram 1 month after discharge showed normal left ventricular wall motion; the systolic ejection fraction was 59%. A second echocardiogram 2 months after discharge showed normalization of the previously observed wall motion abnormality; the global ejection fraction appeared normal.

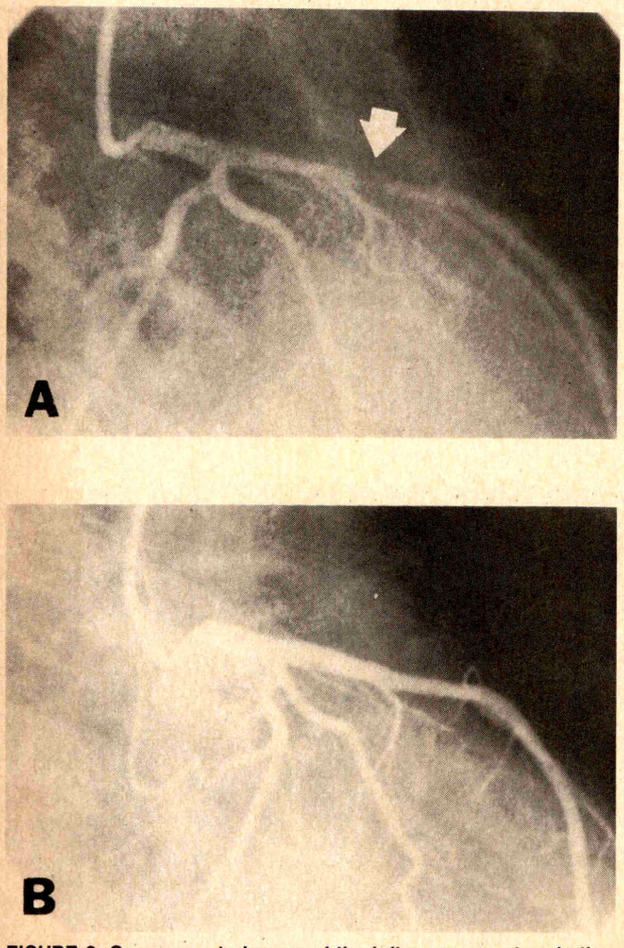

FIGURE 2. Coronary arteriogram of the left coronary artery in the right anterior oblique projection. In *A*, there is a near-total occlusion (spasm) of the proximal left anterior descending coronary artery (*arrow*). In *B*, the left anterior descending artery (filmed after nitroglycerin administration) appears nearly normal.

Cocaine-induced increases in the left ventricular pressure-rate product and myocardial oxygen demand represent a predictable risk for patients with underlying coronary artery disease. In patients with normal coronary arteries, mechanisms that can explain AMI include coronary artery spasm or in situ thrombosis. Our case is the first report of AMI with cocaine use in which coronary spasm of the infarct-related artery was documented by angiography; this extends the likelihood that cocaine-induced coronary spasm was the cause of AMI.

In concurrence with 38 previous case reports of AMI associated with cocaine use, our patient was relatively young and had no risk factors for coronary artery disease aside from cigarette smoking.[1-11] More important, he had no previous symptoms to suggest an underlying vasospastic syndrome such as Prinzmetal's variant angina, nor was he using ergonovine or drugs known to produce or exacerbate spasm.

Evidence that focal coronary spasm was the inciting event in this patient's illness is provided by his clinical course. On admission, the electrocardiogram suggested severe transmural ischemia; abruptly, he developed ventricular fibrillation, followed by resolution of chest pain and the near-normalization of electrocardiographic abnormalities. This sequence is consistent with reperfusion of ischemic myocardium after relief of dynamic coronary obstruction. Transient abnormal Q waves, as seen in this case, have been described during episodes of ischemia in both classic angina and Prinzmetal's variant angina. The mechanism of this phenomenon is felt to be reversible loss of electrical activity due to localized alterations in the cell membranes in severely ischemic but still viable tissue.[12]

Coronary vasospasm, in the presence or absence of coronary atherosclerosis, can cause a wide spectrum of clinical syndromes ranging from transient myocardial ischemia to irreversible infarction with permanent ventricular dysfunction. In between these 2 extremes, our patient manifested reversible postischemic left ventricular dysfunction, with enzymatic evidence of myocardial necrosis. Heart muscle that exhibits prolonged but reversible contractile dysfunction after coronary occlusion has been termed "stunned."[13] Although originally described as dysfunction that persists without evidence of necrosis, "stunning" apparently may also occur, as in our patient, in the surviving myocardium adjacent to, or within, a necrotic area after infarction.[14] As illustrated by this case, the presence of severe left ventricular dysfunction early after AMI may not be permanent.

Sudden Death in Hemochromatosis After Closed-Chest Catheter Ablation of the Atrioventricular Junction

ROBERT LEMERY, MD
PEDRO BRUGADA, MD
MICHAEL HAVENITH, MD
DEBORAH BARBOUR, MD
WILLIAM C. ROBERTS, MD
HEIN J.J. WELLENS, MD

In patients with supraventricular tachycardia refractory to antiarrhythmic drugs or antitachycardia pacemakers, closed-chest catheter ablation of the atrioventricular (AV) junction is an alternative to surgery.[1,2] We report clinical and necropsy findings in a patient who died suddenly 1 week after catheter ablation of the AV junction.

A 47-year-old man with hemochromatosis since age 25 had evidence of congestive heart failure since age 44 and paroxysmal atrial fibrillation with recorded heart rates of up to 160 beats/min since age 45. He had been unsuccessfully treated with digitalis, disopyramide, propafenone and amiodarone. The ejection fraction by echocardiography was 24%. No family members had hemochromatosis and he had never received blood transfusions. Serum ferritin was 5,430 μg/liter (normal 34 to 310 μg/liter); hemoglobin, 7.4 mmol/liter and potassium 5.1 mmol/liter.

Catheter ablation of the AV junction was performed 1 day after admission. Atrial fibrillation was present. The electrogram of the His bundle measured 0.4 mV (Figure 1). Four shocks were given, but atrial fibrillation returned immediately after ablation. A second session 4 days later, using 6 shocks (300 J each), failed to produce complete heart block. The serum creatine kinase rose to 332 U/liter (3% MB) after the first session and to 365 U/liter after the second. Following the second ablation session, paroxysmal atrial fibrillation was present with episodes of escape beats at 40 beats/min when the pacemaker was turned off. A permanent rate-responsive pacemaker was implanted 3 days after the second ablation session. That same day, however, recurrent episodes of paroxysmal atrial fibrillation with rates of up to 140 beats/min prompted therapy with sotalol (160 mg/day) and digitalis (0.375 mg/day). Electrocardiographic monitoring showed a 3-beat run of ventricular tachycardia (Figure 2A) at 180 beats/min (Holter monitoring before the present admission had revealed ventricular couplets). Continuous monitoring revealed no further ventricular ectopic activity (Figure 2B). No abnormal pacemaker

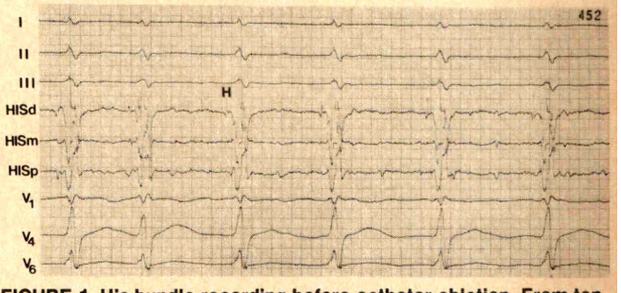

FIGURE 1. His bundle recording before catheter ablation. From top to bottom: standard electrocardiographic leads I, II, III, unipolar recordings from each electrode of a tripolar catheter positioned in the region of the His bundle and precordial leads V_1, V_4, and V_6. The amplitude of the His electrogram measured 0.4 mV and the rhythm is atrial fibrillation.

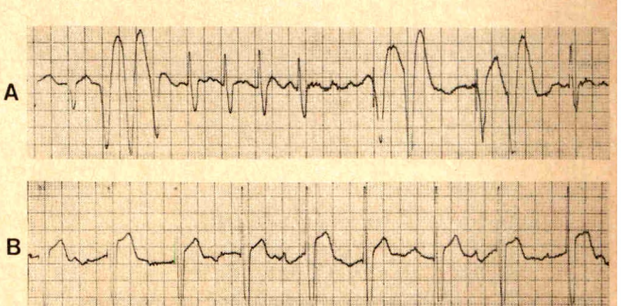

FIGURE 2. *A* shows a 3-beat run of nonsustained ventricular tachycardia, 3 days after catheter ablation. *B* shows sinus rhythm with first-degree atrioventricular block, taken 10 hours before death.

From the Departments of Cardiology and Pathology, University of Limburg, University Hospital, Maastricht, the Netherlands, and the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received June 8, 1987; revised manuscript received and accepted November 25, 1987.

behavior was observed and electrocardiographic monitoring was discontinued during the evening of his tenth day in the hospital. The patient was found dead in bed 7 hours later.

Necropsy disclosed heavy iron deposits in the liver (weight 2,650 g), spleen (350 g), thyroid gland and pancreas. The heart weighed 530 g. The coronary arteries were normal. Foci of subendocardial hemorrhage were present in the area of the AV bundle. Iron deposits were present in numerous myocardial cells in the walls of all 4 chambers, but heaviest in the left ventricular wall. No grossly visible foci of myocardial necrosis or fibrosis were seen.

A total of 3,140 sections were cut from the AV node and bundle area. Every twentieth section was stained with hematoxylin and eosin, and every two hundredth was stained with Prussian blue. The iron deposits were far less extensive in the conducting tissue than in the "working" myocardium. The myocardial cells in the area of the AV bundle and in the subendocardial portion of the ventricular septum, right ventricular aspect, were lysed and some inflammatory cells were present. The AV node and bundle were intact. The junction between the AV bundle and the right bundle branch was interrupted (Figure 3).

Sudden death has been reported in approximately 2% of patients after catheter ablation.[3] Detailed histopathologic studies have been reported in single patients dying at 6 weeks,[4] 5 months[5] and 5.5 months,[6] respectively, after catheter ablation. Histopathologic changes in patients dying after catheter ablation have shown replacement of AV nodal tissue by fibrous tissue.[4–6] The caudal part of the AV bundle and the bun-

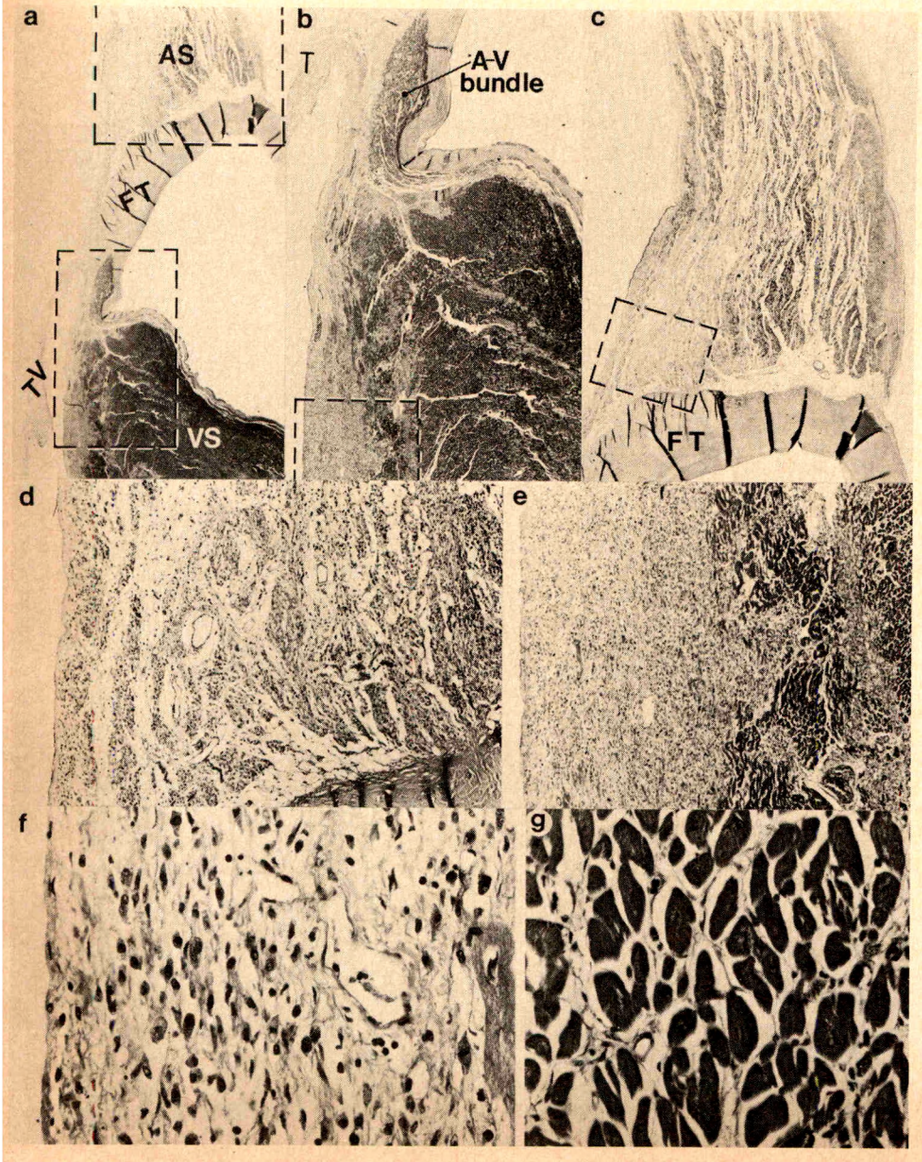

FIGURE 3. Photomicrographs from the area of the atrioventricular (AV) bundle in the patient. All sections were stained by hematoxylin and eosin. *A*, low-power (× 6.5) view of the atrial septum (AS) and the fibrous trigone (FT), within which is the AV bundle and to which is attached the septal leaflet of the tricuspid valve (TV) and the ventricular septum (VS) below. *B*, a closer view (× 16) of one of the areas in brackets shown in *A*. The myocardium beneath the mural endocardium on the right ventricular aspect of the ventricular septum is extensively damaged and a close-up (× 54) of a portion of this damaged myocardium in brackets in *B* is shown in *E*. The connection between the AV bundle and the left bundle branch is intact, but the connection between the AV bundle and the right bundle branch is interrupted. *C*, closer view (× 11.5) of the atrial septum above the fibrous trigone. A portion of this area also is visible in the brackets in *A*. An even closer view (× 54) of the area in brackets in *C* is shown in *D*. The myocardial fibers are extensively damaged. *F*, a high-power view (× 430) of a portion of the damaged myocardial fibers shown in *E*. The myocardial fibers have disappeared. *G*, a high-power view (× 430) of preserved or undamaged myocardium of the ventricular septum for comparison to *F*.

dle branch showed no abnormalities in 2 of the previously reported patients.[5,6] Both had received a single shock (280 J in 1 patient[5] and 275 J in the other[6]). In the report by Bharati et al,[4] the patient received 2 shocks of 500 J each and damage was present in the left and right bundle branch, with scarring seen in the summit of the muscular ventricular septum. In our patient, the AV node was spared and the AV bundle was interrupted at the take-off of the right bundle branch. The continuity of the AV bundle and left bundle branch is in agreement with the symptomatic recurrence of AV conduction in our patient.

The cause of our patient's sudden death is uncertain. Nonsustained ventricular tachycardia occurs occasionally after catheter ablation of the AV junction. Our patient received a new antiarrhythmic agent 3 days before death and its proarrhythmic effect could have contributed to his death.

Transient Entrainment of Pacemaker Circus Movement Tachycardia

IVO E. KERSSCHOT, MD
PEDRO BRUGADA, MD
KAREL den DULK, MD
WILLEM R.M. DASSEN, PhD
HEIN J.J. WELLENS, MD

The circus movement tachycardia, involving anterograde conduction through the normal atrioventricular (AV) conduction system and retrograde conduction using an accessory AV bypass tract, is 1 of the best understood human models of reentrant tachycardia.[1] The observations made during transient entrainment of many tachycardias[2–6] have supported reentry as the underlying mechanism. In the present report we describe our observations during transient entrainment of pacemaker circus movement tachycardia (PCMT), where the retrograde limb of the circuit is provided by retrograde ventriculoatrial conduction and the anterograde limb by triggering a ventricular pacemaker response to a sensed retrograde P wave. In the first part of the study, entrainment of PCMT is studied in a patient with a DDD pacemaker, whereas an analogous situation is simulated in the second part by a computerized model of the heart's conduction system.

A bipolar dual chamber pacemaker (Medtronic Symbios 7006) was implanted in a 67-year-old man because of symptomatic sinus node dysfunction. The pacemaker was programmed with a short postventricular atrial refractory period of 155 ms, an AV interval of 200 ms and an upper rate limit of 150 beats/min. Sustained episodes of PCMT could be induced after implantation using asynchronous chest wall stimuli. A temporary bipolar pacing lead in the right ventricle was used to study the effects of synchronized overdrive pacing at different pacing rates. The temporary lead tip was located at the lower right ventricular septum, while the ventricular lead tip of the dual chamber pacemaker was in the right ventricular apex.

The effect of ventricular overdrive pacing during PCMT was studied in a computerized model of the conduction system of the heart previously described.[7] DDD pacemaker software was incorporated into the model with the following parameters: lower rate 80/min, upper rate 175/min, AV interval 200 ms, postventricular atrial refractory period 235 ms. Timed premature depolarizations or ventricular pacing at different rates could be programmed at the left ventricular apex in order to initiate or entrain PCMT. The conduction and refractoriness of the different points and segments were analyzed and displayed by a computer at 1-ms intervals.[7] The exact timing of events of interest is referred to in the text and schematically depicted in the corresponding figures, according to absolute timing markers.

The effects of synchronized ventricular pacing during PCMT are shown in Figures 1, 2 and 3. The first 3 ventricular complexes in Figure 1A represent PCMT with a cycle length of 480 ms before overdrive pacing. Arrows 1 and 2 indicate retrograde P waves. The fourth pacing artifact is followed by the fusion of QRS complexes from the pacing pulses of the implanted pacemaker and of the external stimulator which was pacing with a cycle length of 470 ms (arrow 3). This can be explained by the synchronization of the external stimulator to the preceeding ventricular pacing pulse of the implanted pacemaker with a slightly shorter (10 ms) coupling interval than that of the pacemaker. As a consequence, the fourth ventricular complex represents a fusion beat and results in an advancement of the retrograde P wave and subsequent internal pacemaker stimulus (arrow 4). The fifth ventricular complex consists in another fusion morphology, which remains constant during subsequent paced beats except for the last entrained beat (Figure 1B, asterisk), being similar to the native PCMT complex.

From the Department of Cardiology, Clinical Electrophysiology Laboratory, University of Limburg, Annadal Hospital, Maastricht, the Netherlands. Manuscript received April 28, 1987; revised manuscript received November 17, 1987, and accepted November 22.

Figure 2 shows entrainment at a cycle length of 450 ms. The retrograde P wave after the fourth ventricular complex is advanced by means of the same mechanism as that in Figure 1. A look at the QRS morphology shows that the subsequent impulses have a constant and shorter interval between stimulator and pacemaker stimuli in comparison with Figure 1, resulting in a different fusion morphology except, again, for the last entrained beat (Figure 2B, asterisk). Pacing at a cycle length of 440 ms results in the complete inhibition of the implanted pacemaker by the stimulator artifacts (Figure 3), because the stimulator stimuli are delivered before each expected pacemaker stimulus. The last entrained beat (Figure 3B, asterisk) is similar to the native PCMT complex. Further reduction of the pacing cycle length only prolongs retrograde conduction time, as can be appreciated from the last entrained pacing interval, obviously unchanged in ventricular complex morphology (Figure 4A). During pacing at a cycle length of 370 ms, a retrograde conduction block occurs. Now, if any of the burst stimuli is not conducted retrogradely to the atria, the next stimulus will be recognized by the implanted pacemaker as a ventricular premature beat and the postventricular atrial refractory period of the DDD pacemaker will be extended to 400 ms automatically. The subsequent retrograde P wave (if it occurs at all) will not be sensed because it will occur within the atrial refractory period, and the next paced ventricular complex will be recognized as a premature complex again. By this mechanism, the automatic extension of the atrial refractory period can persist to the last paced complex of the burst and PCMT is interrupted (Figure 4B).

The different symbols used subsequently in the computerized model of PCMT are explained in Figure 5A. Figure 5B shows the initiation of PCMT by 2 ventricular premature beats delivered from the left ventricular apex at 3,200 and 3,600 ms. The sensed retrograde atrial activation at time 3,893 ms initiates PCMT with a cycle length of 493 ms and a ventricular complex duration of 90 ms. The panel C of Figure 5 (continuous with panel B), shows the pacing start from the left ventricle with a cycle length of 480 ms at time 5,572 ms. This ventricular beat is a fusion complex, as can be seen from the activation from both stimuli (the first from the overdriving stimulator at the left ventricular apex, the second from the implanted pacemaker at the right ventricular apex). Note that the stimuli from the stimulator, in contrast with our patient model, did not inhibit the DDD pacemaker. The next ventricular complex at 6,039 ms has a different degree of fusion as compared with the previous one, and remains constant from now on. From this point all parts of the tachycardia have the same interval as the entraining pulse train (480 ms). The last entrained pulse at 15,177 ms (asterisk, Figure 5D) shows absence of fusion and is followed by resumption of PCMT at the initial cycle length of 493 ms. The ventricular complex duration during entrainment at a cycle length of 480 ms was 55 ms.

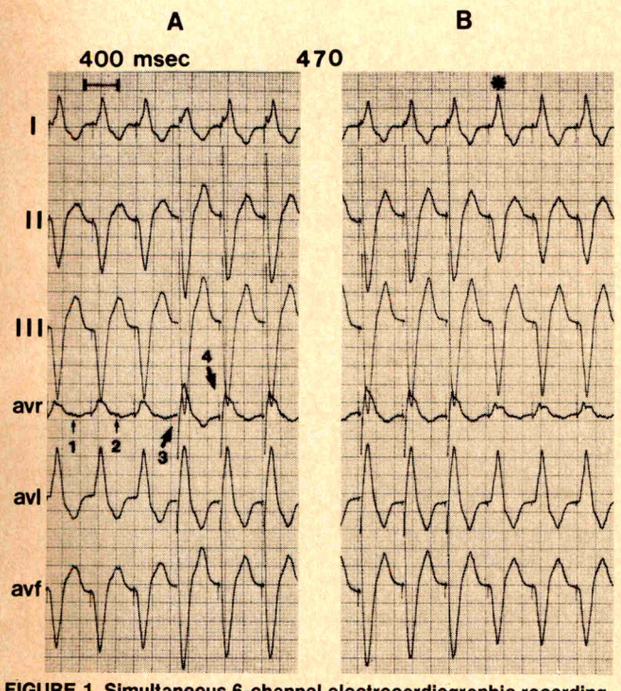

FIGURE 1. Simultaneous 6-channel electrocardiographic recording at the start (*A*) and end (*B*) of overdrive pacing with a cycle length of 470 ms. Pacing artifacts of the implanted pacemaker are best seen in lead I, whereas the large stimuli of the external pacemaker can easily be appreciated in the other leads. The asterisk denotes the last entrained beat occurring at the entrained interval and showing no fusion.

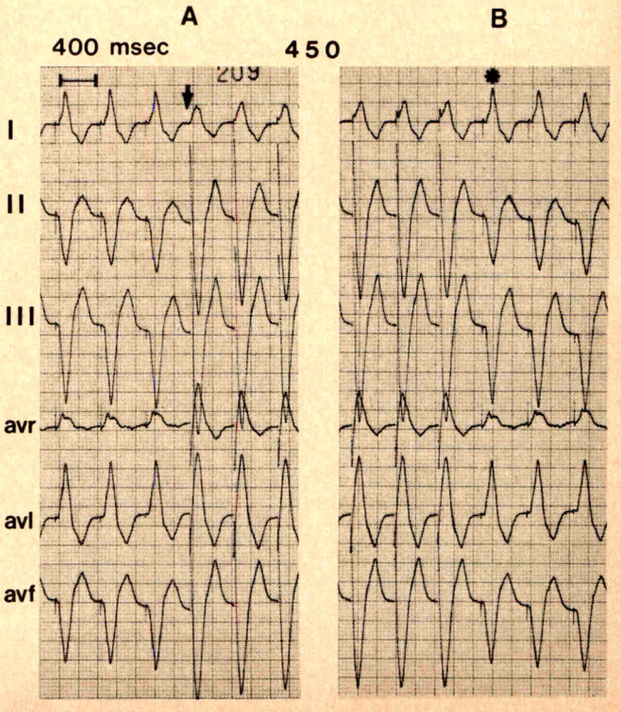

FIGURE 2. Entrainment of PCMT with a pacing cycle length of 450 ms. *Arrow* points to start of overdrive pacing.

Ventricular pacing with a cycle length of 440 ms similarly demonstrates transient entrainment with resumption of the PCMT at the initial rate after sensing the last retrograde P wave (now shown). The ventricular complex duration during pacing at 440 ms was 70 ms.

Ventricular pacing at an interval of 420 ms results in complete inhibition of the internal pacemaker (Figure 5E) because the tissue segment at the right ventricular apex is depolarized by the wavefront from the left ventricular apex (in the computer model the pacemaker is inhibited by the wavefront but not by the stimulation artifact). Furthermore, the tachycardia is interrupted after the last stimulator pulse at 13,405 ms (Figure 5F). Retrograde atrial activity occurred at 13,777 ms (open arrow), and the ventriculoatrial interval, as measured from the stimulator pulse, was therefore 372 ms. The stimulator wavefront from the left ventricle reached the right ventricular apex by conduction at 13,569 ms (i.e., 164 ms later) and only at this time was the pacemaker pulse inhibited and the postventricular atrial refractory period started. The retrograde P wave occurred 208 ms later, during the postventricular atrial refractory period of 235 ms.

Transient entrainment of a tachycardia has been defined as an increase of the tachycardia to a faster

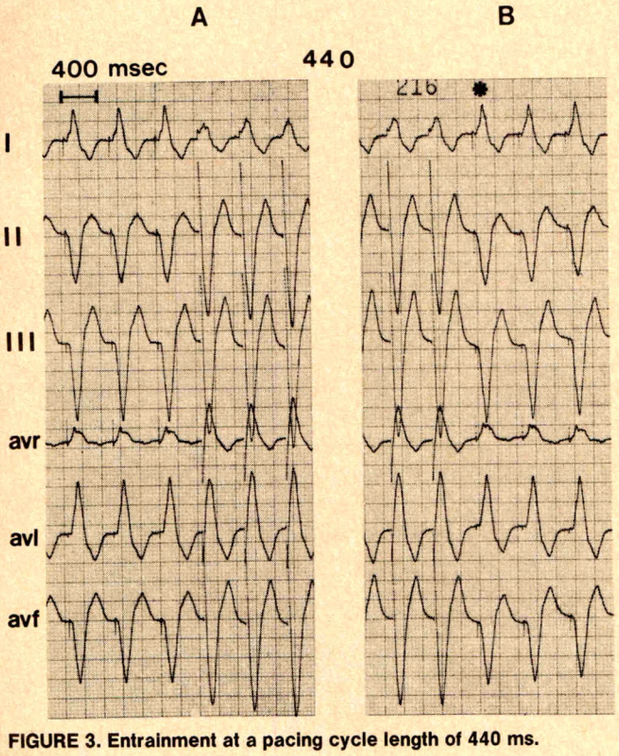

FIGURE 3. Entrainment at a pacing cycle length of 440 ms.

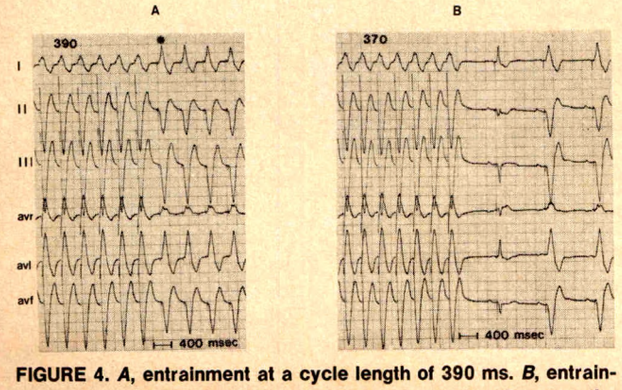

FIGURE 4. *A*, entrainment at a cycle length of 390 ms. *B*, entrainment at a cycle length of 370 ms. PCMT is terminated because the last entrained impulse was not followed by a sensed retrograde P wave.

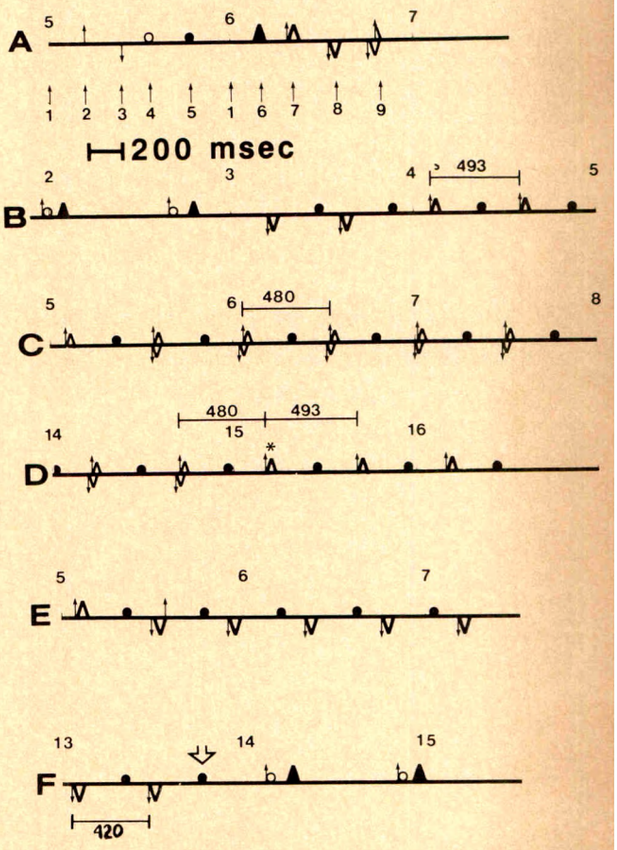

FIGURE 5. *A*, symbols used in subsequent panels to illustrate findings during entrainment of PCMT in the computer model include 1 = absolute timing markers at 1-second intervals; 2 = pacing pulse delivered by the dual chamber pacemaker (either atrial or ventricular); 3 = pacing pulse delivered by the external stimulator; 4 = anterograde atrial depolarization; 5 = retrograde atrial depolarization; 6 = spontaneously conducted ventricular complex; 7 = pacing pulse of the dual chamber pacemaker, followed by ventricular capture; 8 = pacing pulse delivered by the stimulator, followed by ventricular capture; 9 = fusion complex between 7 and 8. *B*, initiation of PCMT by 2 ventricular premature complexes. *C*, entrainment of the tachycardia is started, resulting in an increase in the rate of the tachycardia to the pacing rate. *D*, interruption of pacing and termination of entrainment. The asterisk denotes the last entrained beat, still occurring at the pacing interval. *E*, entrainment of PCMT with pacing at a cycle length of 420 ms. After entrainment, PCMT is interrupted (*F*). The *open arrow* indicates the last entrained P wave, which is not sensed by the atrial amplifier of the pacemaker.

pacing rate, with resumption of the tachycardia at the intrinsic rate upon either abrupt cessation of pacing or slowing of the pacing rate below the rate of the tachycardia.[2-5] Careful observations made during transient entrainment of many tachycardias[2-8] have led to additional criteria: constant fusion during the period of transient entrainment except for the last entrained beat and progressive fusion, consisting of different degrees of fusion at different pacing rates. At a critical rate, localized conduction block followed by activation of that site from a different direction and with a shorter conduction time (as was evident from intracardiac recordings), resulted in interruption of the tachycardia. These findings were most easily explained by reentry as the underlying mechanism of the tachycardia. On the other hand, overdrive pacing during a reentrant tachycardia does not necessarily imply that all the aforementioned criteria will be fulfilled.[8-9] If pacing is performed in close proximity to a small reentrant circuit or just distally to the area of slow conduction in a macroreentrant pathway, it can be anticipated that any fusion at all will be difficult to demonstrate, let alone progressive fusion. Both the PCMT of our patient and the computer model fulfilled the criteria for entrainment.

Surgical Removal of the Intracoronary Portion of a Fractured Angioplasty Guidewire

LISA C. BACHENHEIMER, MD
CURTIS E. GREEN, MD
DOUGLAS R. ROSING, MD
ROBERT B. WALLACE, MD

Successful percutaneous removal of a foreign body from the aorta and coronary artery has been reported,[1] and surgical removal has been reported in 1 patient.[2] In the latter patient, laceration and dissection of the left anterior descending coronary artery occurred and at operation the wire tip was found to have passed through the arterial wall and into the epicardial fat. Intracoronary wire fracture also has occurred once in our medical center and surgery was required.

A 57-year-old man with unstable angina pectoris underwent cardiac catheterization in August 1984. A 75 to 90% luminal diameter narrowing of the left anterior descending coronary artery proximal to the origin of the first diagonal branch and a 75 to 90% narrowing of the first obtuse marginal branch of the left circumflex coronary artery were found. Percutaneous transluminal angioplasty was performed the next day. The left anterior descending angioplasty was successful with a residual 30% stenosis. With considerable difficulty an 0.014 inch high-torque floppy guidewire (Advanced Cardiovascular System) was then passed across the narrowing in the first obtuse marginal branch, but attempts to advance the balloon dilatation catheter resulted in the distal tip of the guidewire breaking off and remaining coiled within the lumen of this obtuse marginal branch distal to the stenosis (Figure 1). Flow in this artery was poor. Emergency aorto-coronary bypass grafting was performed. On opening the parietal pericardium, the heart appeared normal.

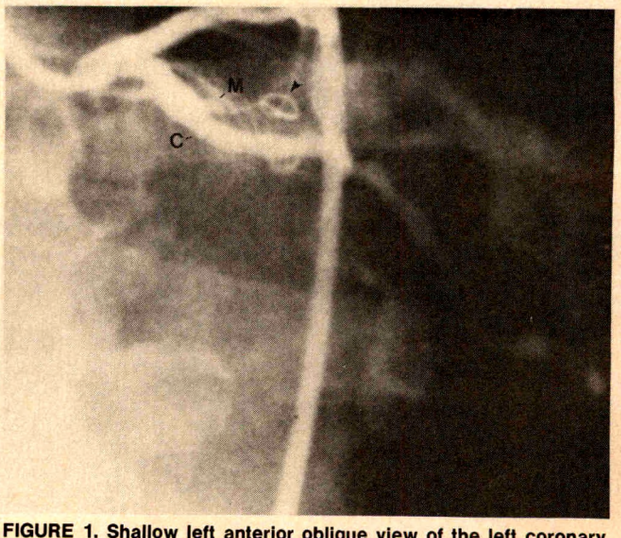

FIGURE 1. Shallow left anterior oblique view of the left coronary artery showing the guidewire (*arrowhead*) coiled in the occluded first obtuse marginal branch (M) of the circumflex coronary artery (C).

From the Departments of Surgery, Radiology and Cardiology, Georgetown University Hospital, Washington, DC 20007. Manuscript received November 6, 1987, and accepted November 13.

Extracorporeal whole body perfusion was established and the patient's core body temperature was lowered to 30°C. A saphenous vein graft was placed from the aorta to the second obtuse marginal. The first obtuse marginal was then exposed proximally and a longitudinal arteriotomy incision was made in it. A thrombus was removed and after extension of the arteriotomy the guidewire was retrieved. The aorto-second obtuse marginal graft was then anastamosed to the first obtuse in a side-to-side fashion. The severe narrowing in the left anterior descending coronary artery also was bypassed using saphenous vein. The patient was rewarmed and weaned from bypass without difficulty. His postoperative course was complicated by a small acute myocardial infarction documented by a peak creatine kinase level of 1,127 IU/liter with an MB fraction of 87 IU/liter. He continues to do well at home 2 years after the cardiac operation.

There have not been enough reported cases of wire fracture to draw any conclusions implicating a particular type of wire as being prone to fracture. In our patient, the wire may have been subjected to increased mechanical stress by being coiled in the artery distal to the severe narrowing. In some cases of wire fracture it may be possible to remove the foreign body without surgery by using a snare.

Bioprostheses in Tricuspid and Mitral Valve Positions for 100 Months with Heavier Calcific Deposits on the Left-Sided Valve Followed by New Bioprostheses in Both Positions for 95 Months with Heavier Calcific Deposits on the Right-Sided Valve

BENJAMIN N. POTKIN, MD
CHARLES L. McINTOSH, MD, PhD
RICHARD O. CANNON III, MD
WILLIAM C. ROBERTS, MD

Previous reports describing results of simultaneously implanted and explanted bioprostheses in the mitral and aortic valve positions and in the mitral and tricuspid positions usually, but not always, have shown greater degeneration of the bioprostheses in the mitral position than in either the aortic or tricuspid valve position, presumably because of the higher closing pressure on the bioprosthetic cusps in the mitral position.[1-4] Herein, we describe a patient who had simultaneous bioprosthetic replacement of both mitral and tricuspid valves. Later replacement of both bioprostheses revealed heavier calcific deposits on the bioprosthesis in the mitral position after the first bioprosthetic replacement and heavier calcific deposits on the bioprosthesis in the tricuspid valve position after the second bioprosthetic replacement.

From the Pathology, Surgery and Cardiology Branches, National Heart, Lung, and Blood Institute, National Institues of Health, Bethesda, Maryland 20892. Manuscript received October 15, 1987; revised manuscript received and accepted November 13, 1987.

E.V., a 62-year-old white woman with systemic hypertension and diabetes mellitus, had 4 cardiac valve operations (Table I). Congestive heart failure developed during her second pregnancy and 1 year later, at age 35, she underwent closed mitral commissurotomy for mitral stenosis. She was nearly asymptomatic for 2 years thereafter and then congestive heart failure and atrial fibrillation developed. Because of worsening congestive heart failure, at age 46 she had simultaneous replacement of both native mitral and tricuspid valves with Hancock no. 29 and 31 glutaraldehype processed bioprostheses, respectively. She was asymptomatic for the next 8 years when congestive heart failure reappeared at age 54. Left ventricular cineangiogram now demonstrated 4+/4+ mitral regurgitation and a 22 mm Hg mean diastolic pressure gradient across the bioprosthesis in the mitral position. At age 54, the 2 bioprostheses, each of which had been in place for 100 months, were excised along with the diffusely thickened, purely regurgitant aortic valve and all 3 were replaced with Hancock bioprostheses. The excised bioprosthesis in the mitral position had heavier calcific deposits than did the bioprothesis in the tricuspid valve position (Figure 1). Postoperatively, she again was asymptomatic. Catheterization, 7 months later, disclosed a 11 mm Hg mean diastolic pressure gradient across the bioprosthesis in the mitral position. Pulmonary hypertension persisted. Congestive heart failure recurred at age 61 years, 86 months after the last operation. Nine months later or 3 days before death the 3 bioprosthetic valves were replaced because of refractory congestive heart failure. The bioprosthesis that had been in the tricuspid valve position had heavier calcific deposits than that present on the bioprostheses that had been in either the mitral or aortic valve position (Figure 2).

This patient is unique in that 2 prostheses had each been in place for 100 months and 3 other bioprostheses had each been in place for 95 months. When the initially inserted 2 bioprostheses were explanted, heavier

calcific deposits were present in the bioprosthesis that had been in the mitral valve position compared with the one that had been in the tricuspid valve position. When these malfunctioning bioprostheses were excised and replaced with other bioprostheses that were in place for nearly the same amount of time, namely 95 months, heavier calcific deposits developed in the bioprosthesis that had been in the tricuspid valve position compared with that occurring in either bioprosthesis located on the left side of the heart.

The explanation for the reversal of the heavier calcific deposits in the tricuspid and mitral valve positions during the 2 time frames (100 months with the initially inserted bioprostheses and 95 months with the replaced bioprostheses) is unclear. It is likely that during much of the postoperative period after the initial double valve replacement the right ventricular systolic pressure, which represents the closing pressure on the bioprosthesis in the tricuspid valve position, was only mildly elevated (37 mm Hg). In contrast, after the bioprostheses in the tricuspid and mitral valve positions were replaced, the right ventricular systolic pressure remained elevated (65 mm Hg), probably during the entire 95-month period. During this latter 95-month period of high right ventricular systolic pressures, heavier calcific deposits developed on the cusps of the bioprosthesis in the tricuspid valve position than on the cusps of the bioprosthesis in the mitral valve position. The closing pressure, i.e., the left ventricular systolic pressure, on the bioprosthesis in the mitral position, however, was always considerably higher than was the closing pressure on the bioprosthesis in the tricuspid valve position: 160 vs 37 mm Hg after the first

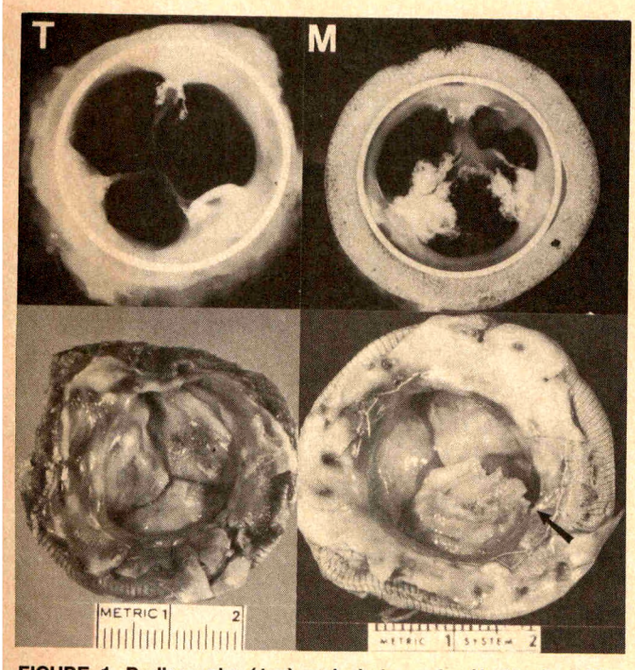

FIGURE 1. Radiographs (*top*) and photographs (*bottom*) of bioprostheses that had been in place in the tricuspid (T) and mitral (M) valve positions for 100 months. Heavier calcific deposits are present in the prosthesis that had been in the mitral valve position. Additionally, 1 cusp of the prosthesis in the mitral position was torn (*arrow*) and this bioprosthesis was severely regurgitant.

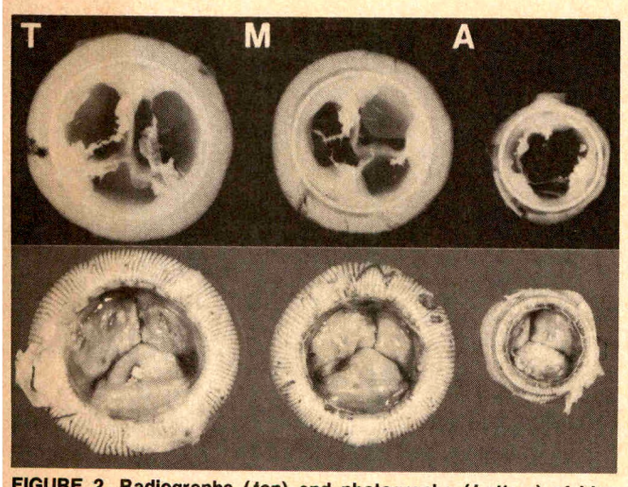

FIGURE 2. Radiographs (*top*) and photographs (*bottom*) of bioprostheses explanted 3 days before death and which had been in place in the tricuspid (T), mitral (M) and aortic (A) valve positions for 95 months. Heavier calcific deposits are present in the bioprosthesis in the tricuspid valve position than in the bioprosthesis in either the mitral or aortic valve positions.

TABLE I Patient's Hemodynamic Data

Month/year	5/1970	8/1971	6/1979	1/1980	8/1986
Age (yr)	45	46	54	55	61
NYHA FC	III	I	III	I	III
SA (s/d)	160/95	150/90	112/70	205/90	137/76
RA V (mean)	25 (18)	14 (10)	26 (22)	16 (13)	22 (20)
RV (s/d)	60/9	37/7	75/16	65/7	67/20
PA (s/d)	60/30	37/20	80/40	65/28	68/28
PAW V (mean)	34 (25)	26 (20)	47 (38)	40 (28)	34 (25)
LV (s/d)	155/16	160/12	117/16	210/25	158/17
CO/CI	5.4/3.1	6.3/3.8	2.2/1.4	5.2/3.3	4.0/2.5
LV-SA psg	0	10	0	5	21
PAW-LV mdg	13	8	22	11	10
RA-RV mdg	6	7	8	7	6
MVA/MVI	*0.8/0.5	2.8/1.7	†	2.1/1.3	1.3/0.8
TVA/TVI	—	2.2/1.3	1.4/0.9	1.4/0.9	1.4/0.9
AR by AA cine (0 to 4+)	0	0	2+/4+	0	1+/4+
MR by LV cine (0 to 4+)	1+/4+	0	4+/4+	0	0

All pressures are in mm Hg. All valve replacements were with Hancock bioprosthesis (size in parenthesis): mitral commissurotomy, 1959; MVR (29) and TVR (31), 2/1971; MVR (27), TVR (31) and AVR (19), 6/1979.

* Calculated valve area underestimated because of mild mitral regurgitation.

† Not possible to calculate valve area because of severe mitral regurgitation.

AA = ascending aorta; AR = aortic regurgitation; AVR = aortic valve replacement; CI = cardiac index (liters/min/m^2); Cine = cineangiography; CO = cardiac output (liters/min); LV = left ventricular; mdg = mean diastolic gradient; MR = mitral regurgitation; MVA = mitral valve area; MVI = mitral valve index; MVR = mitral valve replacement; NYHA FC = New York Heart Association functional class; PA = pulmonary artery; PAW = pulmonary artery wedge pressure; psg = peak systolic gradient; RA = right artial; RV = right ventricular; SA = systemic artery; s/d = systolic/diastolic; TVA = tricuspid valve area; TVI = tricuspid valve index; TVR = tricuspid valve replacement.

valve replacements and 210 vs 65 mm Hg after the bioprosthetic replacements. Thus, factors other than bioprosthetic closing pressures must have played a role in determining which bioprosthesis in the atrioventricular valve positions contained the heavier calcific deposits.

Left Isomerism with Left-Sided Systemic Venous Return and Ventriculoarterial Concordance: Six-Year Follow-Up After a "Mirror Image" Mustard Operation

SYLVAIN CHAUVAUD, MD
LAURENT FERMONT, MD
DANIELLE BENSASSON, MD
ALAIN CARPENTIER, MD

Left atrial isomerism is usually associated with other complex cardiac abnormalities.[1,2] The atrioventricular connection is ambiguous.[2] When venous returns are inverted and the ventricular arterial connection is concordant, the physiology is that of complete transposition of the great arteries. Surgical correction requires a "modified mirror-image" Mustard procedure. We report a patient who had left atrial isomerism, systemic venous return to the left-sided atrium, partial atrioventricular septal defect, common atrium, azygos continuation of the inferior vena cava and abdominal situs inversus. We emphasize the surgical problems of the mirror image operation regarding venous returns and conductive tissue.

From the Service de Chirurgie Cardiovasculaire, Hôpital Broussais, 96 Rue Didot, 75674 Paris Cedex, France. Manuscript received August 26, 1987; revised manuscript received November 30, 1987, and accepted December 4.

The patient was a 3.5-year-old girl who weighed 14 kg and was cyanotic since birth. No cardiac murmur was present. The liver was situated on the left side and was enlarged. The electrocardiogram disclosed sinus rhythm with first-degree atrioventricular (AV) block (PR interval 0.20 second). Episodes of complete AV block were documented. Chest x-ray showed increased pulmonary vascularity, dextrocardia, a cardiothoracic ratio of 0.67 and a right-sided stomach. Splenic scintigraphy revealed only 1 spleen on the right side. Hemoglobin concentration was 16.3 g/dl. Cardiac catheterizaiton was performed at the age of 24 months. There was an azygos continuation of the inferior vena cava (left sided) to a left superior vena cava. "Right" ventricular and pulmonary pressures were normal. There was complete mixing of oxygenated and deoxygenated blood at the atrial level. Angiocardiography revealed a D-loop with a right-sided and trabeculated ventricle from which the pulmonary artery originated. The subaortic ventricle was morphologically left and left sided. AV valve function was normal on both sides. The aorta was posterior and to the left of the pulmonary artery (Figure 1). Cross-sectional echocardiography demonstrated a common atrium (Figure 2) and an intact ventricular septum. The preoperative diagnosis was situs inversus, ventriculoarterial concordance, common atrium, partial atrioventricular septal defect and intact ventricular septum.

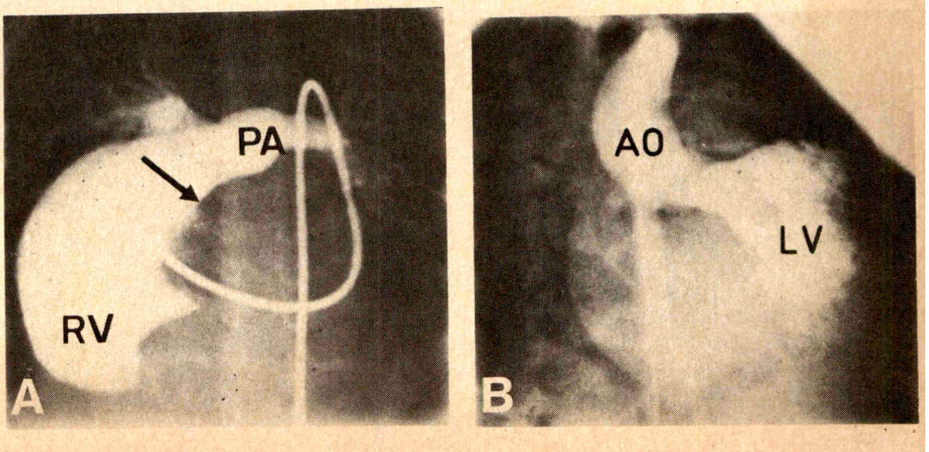

FIGURE 1. *A*, preoperative angiogram with opacification of the right-sided morphologically right ventricle. The catheter is passed in the left inferior vena cava, in the azygos vein and in the left superior vena cava. Ventricular pulmonary discontinuity is shown with an arrow. RV = right ventricle; PA = pulmonary artery. *B*, preoperative angiogram with opacification of the left-sided morphologically left ventricle. Note the deformity of the left ventricular outflow tract, "goose neck," during diastole. LV = left ventricle; AO = aorta.

Surgical repair was performed in May 1981 when the child was 3.5 years old. Extracorporeal circulation was performed between the aorta and 2 venous canulae. The superior venous canula was placed in the superior vena cava. The inferior venous canula was placed in the confluence of the hepatic veins, which were situated on the left side of the atria. Intracardiac lesions were inspected through the appendage situated on the left side. "Left" atriotomy was oblique and directed to the right. There was a left appendage with absence of a crista terminalis, which led to the diagnosis of left atrial isomerism. The atrial septum was absent and a typical partial AV defect was found. An intraatrial transposition of the venous return using a "mirror image" Mustard procedure was performed. A pericardial patch was used such that the superior vena cava and the confluence of the hepatic veins were connected to the tricuspid valve. The coronary sinus was left in to drain into the caval channel. Localization of the His bundle was not performed but superficial stitches were placed in the coronary sinus area (Figure 3). The systemic AV valve was typical of a partial AV defect with a 3-leaflet configuration. The septal commissure was partially closed. The atria receiving the pulmonary veins was enlarged with a pericardial patch. Pressures at the end of the procedure were: mean left atrial 16 mm Hg; mean right atrial 13 mm Hg; aorta 100/50 mm Hg; and pulmonary artery 32/15 mm Hg. The immediate postoperative course was uneventful. AV conduction disturbances remained as they were preoperatively. A permanent pacemaker was inserted on the thirteenth postoperative day with epicardial electrodes. A venous angiogram was performed on the twentieth postoperative day (Figure 4).

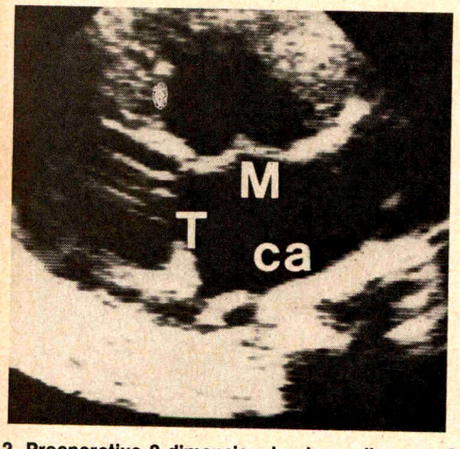

FIGURE 2. Preoperative 2-dimensional echocardiogram. Common atrium is clearly shown. The systemic atrioventricular valve is anterior to the venous atrioventricular valve. Ca = common atrium; M = mitral; T = tricuspid.

Six years after the surgical procedure the child returned for follow-up. Her physical condition was normal; she was not receiving any treatment and had no clinical sign of cardiac failure or valvular incompetence. The heart was still large (cardiothoracic ratio 0.60); pulmonary arterial and venous vascularization were normal. The AV block was still present. The pacemaker and the electrodes were functioning with normal threshold. Cross-sectional echocardiography demonstrated no stenosis of the systemic or pulmonary venous channels and the hepatic veins did not appear to be dilated. The ventricular wall was hypertrophied on both sides. Ventricular function was excellent. The ejection fraction of the systemic ventricle was 62%. The subaortic pathway was normal. On echocardiographic Doppler examination, the "right" AV valve had a trivial incompetence, and the "left" AV valve was normal.

The association of azygos continuation of inferior vena cava, common atrium and left atrial isomerism was pointed out by Macartney et al.[1] In our patient visceral situs was inverted as confirmed by spleen scintigraphy, and polysplenia was excluded. Thoracic situs was not studied with tomography. Atrial situs was much more difficult to establish. Hepatic veins were on the left side of the common atrim leading to the diagnosis of thoracic situs inversus[3] before the opera-

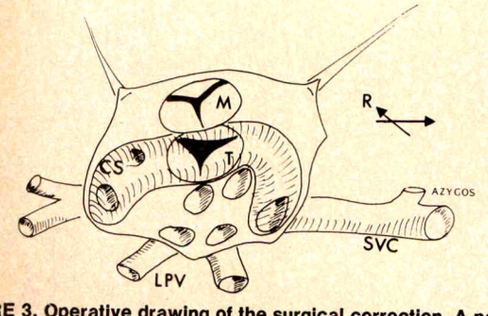

FIGURE 3. Operative drawing of the surgical correction. A pericardial patch is placed in order to connect the orifices of superior vena cava (SVC) and hepatic veins to the tricuspid valve (T). The left atrioventricular valve is typical of a partial atrioventricular defect with 3 leaflets. A partial closure of the commissural cleft was performed. CS = coronary sinus; LPV = left pulmonary veins; M = mitral valve.

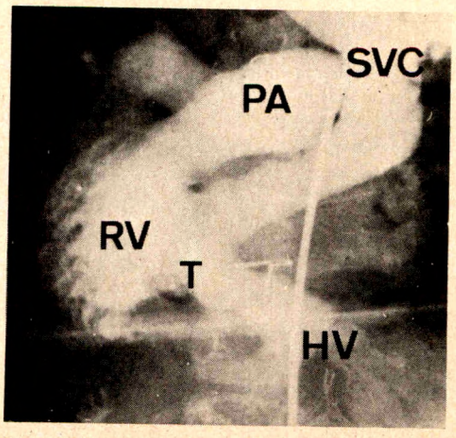

FIGURE 4. Postoperative angiogram of the right chambers. Dye was injected in the superior channel. Opacification of the intraatrial baffle is seen. HV = hepatic veins; other abbreviations as in Figures 1 and 3.

tive examination. Internal morphology of the left appendage revealed a smooth endocardium without a crista terminalis and was of the left atrial type. The presence of left atrial isomerism associated with a common atrium led to the diagnosis of ambiguous AV connection. Surgical correction involved rerouting the systemic venous return to the tricuspid valve. This was achieved with a "mirror image" Mustard operation. The Senning operation was not indicated because of a lack of tissue in the atrial septum.

Localization of the conductive tissue is difficult. Two AV nodes may be present.[4] A similar pattern is found in AV and ventricular discordance (corrected transposition). The posterior node is hypoplastic, and the His bundle originates from the anterior node. Anderson et al[5] showed that the posterior node could be connected with the His bundle. In situs inversus the posterior node is predominant, but not always so. A sling of conductive tissue could be found with fibers around the anterior and posterior margins of the ventricular septal defect.

Uncertainty of the correct location of the conducting tissue explains the high frequency of complete AV dissociation following surgical repair when an AV septal defect is present.[6] Suturing the interatrial baffle into place with a beating heart could help to avoid damage to the His bundle; however, in small patients, as was ours, this can be difficult to achieve.

Aortic Aneurysms After Subclavian Angioplasty Repair of Coarctation of the Aorta

MONICA M. MARTIN, MD
ROBERT H. BEEKMAN, MD
ALBERT P. ROCCHINI, MD
DENNIS C. CROWLEY, MD
AMNON ROSENTHAL, MD

It has been over 10 years since aortic aneurysms after synthetic patch repair of coarctation of the aorta were first reported. More recent studies suggest that late aneurysm formation after synthetic patch angioplasty may occur in up to 38% of patients.[1,2] These aneurysms typically occur in the aortic wall opposite the synthetic patch, perhaps resulting from stress exerted on abnormal tissue in that portion of the aorta. As is the case with synthetic patch repair, the aortic wall of the coarctation and periductal area is not excised in the subclavian angioplasty procedure. Late aneurysm formation might therefore be expected to occur after subclavian angioplasty as well. In this report we describe 3 children who developed aortic aneurysms following left subclavian angioplasty repair of coarctation.

Case 1: An infant presented during the second week of life with Turner syndrome, congestive heart failure, a discrete thoracic coarctation and severe valvar aortic stenosis. At 12 days of age the coarctation was repaired using the left subclavian angioplasty procedure. An intraluminal web at the site of the coarctation was excised and the subclavian flap was sutured with running 7-0 prolene. At the end of the procedure the patient was normotensive and had no residual coarctation gradient. A surgical aortic valvotomy was performed at 2 months of age. At age 4.5 years a chest x-ray revealed a prominence of the aorta in the area of the coarctation repair (Figure 1). Although an echocardiogram disclosed no abnormality of the aortic

TABLE I Findings After Subclavian Angioplasty Repair of Coarctation of the Aorta

Pt	Age (yrs)	Ratio of Repair to DS Aorta	Aneurysm Extension	Identified by CXR	Identified by Echo
1	4.5	1.5	P,L,M	+	0
2	3	1.6	P,L	0	0
3	2	2.8	A,L,M	+	+

A = anterior; CXR = chest x-ray; DS = descending; L = lateral; M = medial; P = posterior.

FIGURE 2. Anteroposterior left ventricular angiogram demonstrating an aortic aneurysm in a 3-year-old girl who underwent left subclavian angioplasty 21 months earlier (case 2).

arch, a computerized tomographic chest scan suggested the presence of a small aneurysm of the coarctation repair site. A cardiac catheterization revealed aneurysmal dilatation of the repair site, no residual coarctation gradient and mild aortic stenosis. Angiography revealed that the aneurysm diameter was 150% of the aortic diameter at the diaphragm (Table I).

Case 2: A 15-month-old girl presented with heart failure, a severe thoracic coarctation and supravalvar mitral stenosis. The coarctation was repaired with resection of a 3-mm long stenotic segment and end-to-end anastomosis using posterior running and anterior interrupted 7-0 prolene sutures. When an intraoperative residual gradient of 35 mm Hg was noted, a longitudinal incision was made across the anastomosis and a left subclavian angioplasty was performed using running 7-0 prolene sutures. The coarctation gradient was reduced to 5 mm Hg and the patient was normotensive after the operation. A cardiac catheterization at age 3 years revealed an aneurysmal dilatation at the repair site and no residual coarctation gradient. The diameter of the aneurysm by angiography was 160% of the diameter of the aorta at the diaphragm (Figure 2). The aneurysm had not been detected by echocardiogram or chest x-ray.

Case 3: A boy with Taussig-Bing anomaly and discrete thoracic coarctation presented in early infancy with congestive heart failure and cyanosis. At 6 weeks

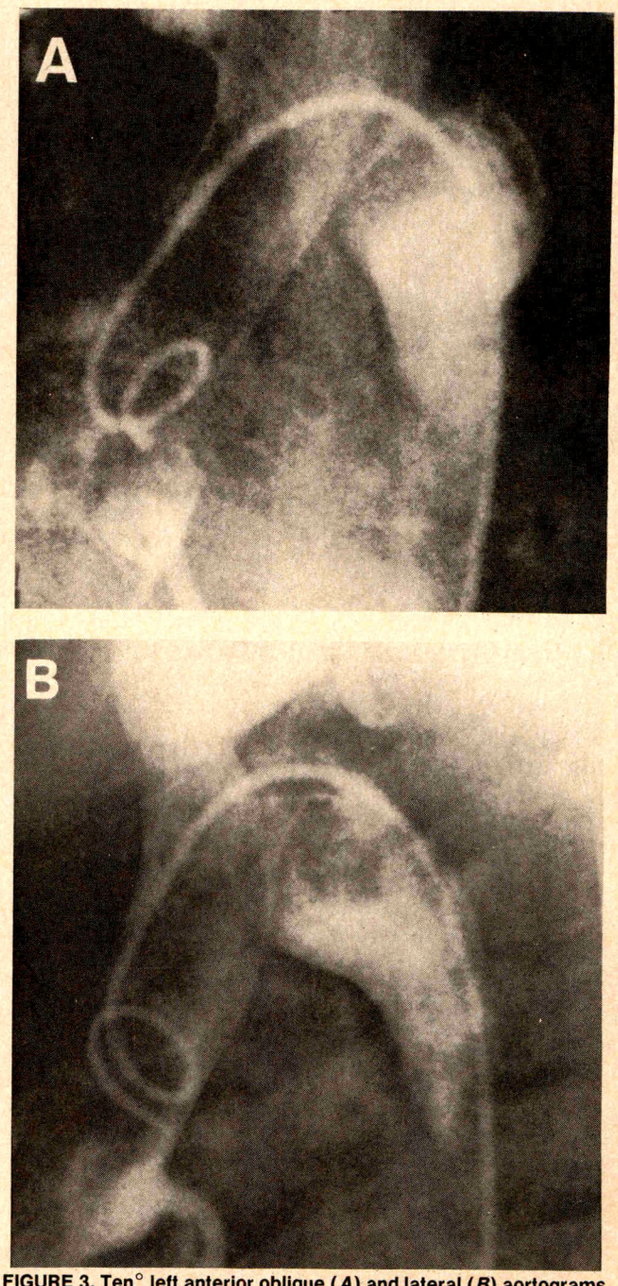

FIGURE 3. Ten° left anterior oblique (*A*) and lateral (*B*) aortograms confirming the presence of a large circumferential aneurysm in a 2-year-old boy who had left subclavian repair of a coarctation at age 6 weeks (case 3).

of age he underwent a left subclavian angioplasty repair of the coarctation and pulmonary artery banding. The subclavian flap was sutured with 7-0 prolene. After the operation there was no residual coarctation gradient and the patient was normotensive. At age 2 years an echocardiogram suggested the presence of an aortic aneurysm and a cardiac catheterization was performed. Angiography revealed aneurysmal dilatation at the coarctation repair site, the diameter of which was 280% of the aortic diameter at the diaphragm (Figure 3). No residual coarctation gradient was present.

Subclavian angioplasty, introduced in 1966 by Waldhausen and Nahrwold,[3] has been recommended by some as the surgical procedure of choice for repair of coarctation of the aorta in infancy. Because the procedure avoids a circumferential suture line and uses viable tissue as a patch, it has been hoped that it would avoid the late problems documented after other types of repair, namely restenosis (after resection and end-to-end anastomosis) and aneurysm formation (after synthetic patch aortoplasty). As long-term follow-up data are acquired, however, the early enthusiasm for the subclavian angioplasty repair may prove to be unwarranted. Recent data suggest that recurrent coarctation may develop more often after subclavian angioplasty than previously suspected.[4] And now, we report instances of aortic aneurysms occurring at the site of a subclavian angioplasty repair.

The synthetic patch aortoplasty technique for coarctation repair was first described by Vosschulte in 1957.[5] As is now the case with subclavian angioplasty, aneurysms occurring at the repair site were not described until nearly 20 years later. In 1976, aortic aneurysms were described in 5 patients from Vosschulte's original series.[6] Late aneurysm formation has since been reported to be as high as 38% after a synthetic patch repair of coarctation.[1,2] Although most of the previous reports have not explicitly defined what constitutes an aneurysm in the absence of pathologic material, fusiform dilatation of the repair site with a diameter ≥150% of the patient's descending aorta correlates well with the presence of an aneurysm.[2] This criterion (comparing the diameter of the dilated vessel to that of the adjacent uninvolved vessel) has also been used to define aneurysms of other muscular arteries as, for example, coronary arteries in Kawasaki disease,[7] and has been applied in the present report.

The mechanism of aneurysmal aortic dilatation after synthetic patch repair of a coarctation may relate to increased tension transmitted by the patch to the more elastic abnormal aortic wall opposite the repair. It was suggested by Moulton in 1983 that late aneurysm formation may be expected regardless of whether the patch is a synthetic material or subclavian artery tissue, since abnormal tissue of the coarctation and periductal area is not excised in either repair.[8] The first aneurysms after subclavian angioplasty have now been documented, lending support to Moulton's concept. It is of interest that in case 2 an aneurysm developed despite coarctation resection before subclavian angioplasty; it may be that a suture line is as vulnerable to excessive wall stress opposite a patch as is native aortic tissue.

Because no patient in this series underwent aneurysm resection, we do not have pathologic data regarding the nature and location of the lesions. We intend to follow these children closely and recommend resection if evidence of progressive aneurysmal dilatation is found. Nevertheless, the clinical data presented indicate that children who have undergone subclavian angioplasty, much the same as those who have had a synthetic patch repair, warrant long-term serial evaluation for possible development of an aneurysm at the coarctation repair site. Long-term studies are necessary to accurately define the incidence and natural history of late aneurysm formation after the subclavian angioplasty procedure.

Reduction of Nitroglycerin and Isosorbide Dinitrate by Hemodialysis in Refractory Angina Pectoris After Acute Myocardial Infarction

TAKUROH IMAMURA, MD
KAZUO TAMURA, MD
TOSHIFUMI TAGUCHI, MD
MASARU MINODA, MD
MASASHI SEITA, MD

Dosage adjustment of drugs is important to achieve safe and effective therapy in patients undergoing chronic hemodialysis. If drugs are removed by hemodialysis, supplemental drug administration is required to ensure adequate therapeutic plasma levels. Currently, intravenous nitroglycerin[1] and oral administration of isosorbide dinitrate[2] are commonly used in patients with coronary artery disease. However, there are no available pharmacokinetic data of these drugs in patients who undergo hemodialysis. We describe a patient with refractory angina after acute myocardial infarction whose plasma nitroglycerin and isosorbide dinitrate concentrations were measured during hemodialysis.

A 43-year-old man, who had been on hemodialysis for 3 years, was transferred to our hospital on January 14, 1986, because of retrosternal chest pain that had persisted over 17 hours before admission. The electrocardiogram showed anteroseptal myocardial infarction. Hemodynamic study demonstrated elevated mean pulmonary artery wedge (35 mm Hg) and pulmonary artery pressures (38/28 mm Hg), and normal cardiac index (4.0 liters/min/m²). Nitroglycerin, sustained-release isosorbide dinitrate and diltiazem were started soon after he was placed in the coronary care unit. Chest pain at the time of admission was soon relieved with this treatment. However, anginal attacks occurred frequently, especially during hemodialysis, despite stable blood pressure and heart rate. During the anginal attacks electrocardiogram showed ST-segment elevations associated with peaked T' waves in anterior precordial leads.

Hemodialysis was performed 4 times a week using hollow fiber dialyzers, RENAK-A 10M (Kawasumi Laboratories, Inc.) containing cellulose acetate membranes of 11 μ. It was usually started around 9:00 A.M. and lasted 4 hours. Blood samples were obtained from the inflow and outflow portions of the hemodialysis system to measure plasma nitroglycerin and isosorbide dinitrate concentrations. Blood flow was maintained at about 150 ml/min and transmembrane pressure at about 250 mm Hg throughout hemodialysis unless hypotension or profound general weakness developed. On the thirty-fifth hospital day, blood samples were obtained at 9:30 and 11:00 A.M. and 1:00 P.M., i.e., 30 minutes, 120 minutes and 240 minutes after hemodialysis was started, respectively. Intravenous nitroglycerin was infused at a rate of 100 μg/min into the right atrium through a Swan-Ganz catheter. Sustained-release isosorbide dinitrate, 40 mg, and diltiazem, 90 mg, were given by mouth every 6 hours starting at 6:00 A.M. Nitroglycerin concentrations in the dialysates were also measured at the same time (Table I). This demonstrated a 16 to 29% reduction in plasma nitroglycerin concentrations after transit of the blood through the dialyzer. The plasma isosorbide dinitrate concentrations were more significantly reduced by 44 to 60% after the blood was dialyzed (Table II). Despite oral administration of isosorbide dinitrate at noon, the plasma isosorbide dinitrate level at 1 P.M. (240 minutes on dialysis) was low. A possible explanation for this low concentration is that the isosorbide dinitrate used in this patient was a sustained-release preparation and, therefore, plasma concentration might not have increased sufficiently 60 minutes after the last dose of isosorbide dinitrate was given. The nitroglycerin and isosorbide dinitrate concentration assays were performed by gas-chromatography mass spectrometer JMS-DX300 (JEOL) and gas-chromatography 9AM (Shimadzu), respectively.

Subsequently coronary arteriography was performed showing a 99% diameter stenosis in the proximal portion of the left anterior descending coronary artery and a 75% diameter stenosis in the left circumflex coronary artery. The right coronary artery was normal. Left ventriculography demonstrated anteroseptal wall hypokinesis. Percutaneous transluminal

TABLE I Nitroglycerin Concentration (Infusion Rate of 100 μg/min)

Time after the Start of HD (min)	NTG Concentration (ng/ml)			Extraction (%)
	Inflow	Outflow	Dialysate	
30	49	35	5.6	29
120	58	49	7.9	16
240	56	42	7.4	25

Extraction = (inflow − outflow)/inflow × 100.
HD = hemodialysis; Inflow = inflow portion of the dialyzer; NTG = nitroglycerin; Outflow = outflow portion of the dialyzer.

TABLE II Isosorbide Dinitrate Concentration

Time after the Start of HD (min)	Time after the Last Dose of ISDN (min)	ISDN Concentration (ng/ml)			Extraction (%)
		Inflow	Outflow	Dialysate	
30	210	87	49	8.4	44
120	300	56	31	4.0	44
240	60	51	20	4.7	60

Dr. Imamura's present address: The First Department of Internal Medicine, Miyazaki Medical College, 5200 Kihara Kiyotake, Miyazaki 889-16, Japan.

angioplasty or coronary artery bypass surgery was recommended, but the patient was not willing to undergo these procedures. Doses of isosorbide dinitrate and diltiazem were increased to 200 mg and 450 mg, respectively. In addition, propranolol was added, but it had to be discontinued because of profound hypotension during hemodialysis. Although we were able to gradually decrease the dose of intravenous nitroglycerin, it was still required to control the patient's anginal attack during hemodialysis. It took 3 months to withdraw the patient from intravenous nitroglycerin during hemodialysis. Subsequently his anginal attacks were controlled with oral medications. He was discharged home and has been doing well under outpatient hemodialysis without intravenous nitroglycerin.

Nitroglycerin and isosorbide dinitrate were dialyzed by hemodialysis. The molecular weights of nitroglycerin and isosorbide dinitrate are 227.09 and 236.14, respectively. These are small enough to pass through a semipermeable membrane of the dialyzer. Nitroglycerin[3] and isosorbide dinitrate[4] are reported to be bound to the polyvinyl chloride tubes used in intravenous infusion sets, and the loss of the drugs appeared to be dependent on the flow rate. Although polyvinyl chloride tubes are used in this hemodialysis system, blood flow is so fast that binding of nitrate to these tubes may be negligible. This is suggested by the fact that significant amounts of nitrate were found in the dialysates, although the possibility of binding nitrate to the tubes and the dialyzer could not be completely ruled out. It has been reported that diltiazem is not removed by hemodialysis.[5] In summary, various factors, including the reduction of plasma nitroglycerin and isosorbide dinitrate concentration by hemodialysis, may precipitate myocardial ischemia during hemodialysis. The dosage of these agents must be adjusted to maintain therapeutic plasma concentrations.

Reversal of ST Depression and Low Maximal Oxygen Uptake After Verapamil with Normal Coronary Arteries and Pulmonary Disease

ILEANA L. PINA, MD
ELIZABETH V. SMITH, RN
MERCEDES FUGUET, CVT
HORST J. BAIER, MD
ROBERT J. MYERBURG, MD

Exercise-induced ST-segment depression in the absence of coronary artery disease has been described in many conditions and circumstances, such as digitalis use, electrolyte abnormalities, left ventricular hypertrophy and cardiomyopathy.[1] The present report describes ST depression and ventricular arrhythmias in a patient free of coronary artery disease but with pulmonary disease.

A 58-year-old man presented with recent onset of angina on exertion without concomitant dyspnea. He had been in good health, had no prior history of systemic hypertension, diabetes mellitus or heart disease and was not receiving medication. The patient had a history of cigarette smoking (30 packs/year), had worked as a window and glass door installer and was accustomed to heavy labor. His blood pressure was 140/70 mm Hg and his heart rate 60 beats/min with regular rhythm. The lungs were clear and an S_4 gallop was audible at the apex. The resting electrocardiogram was normal.

A treadmill exercise test with thallium scintigraphy was performed using a Bruce protocol (test 1). At 7 minutes of exercise, 3 mm of horizontal ST depression was recorded in leads II, III, aVF, V_5 and V_6 and ventricular ectopy developed in patterns of triplets and couplets. The ST changes lasted 10 minutes into recovery (Figure 1). Thallium imaging demonstrated normal perfusion. Coronary angiography revealed normal coronary arteries. Pulmonary function testing was compatible with moderate hypoxemia at rest (pO_2 65.5 mm Hg) and mild obstructive changes. A repeat exercise test (test 2) was performed using a Medical Graphics 2001 metabolic cart. At 9 minutes, the patient developed chest pressure and diffuse wheezing. Exer-

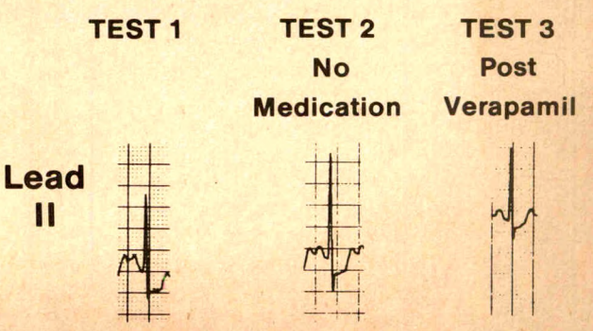

FIGURE 1. Representative QRS (lead II) with ST-segment changes.

TABLE I Exercise Hemodynamics Before and After Verapamil

	Before	After
Duration (min)	9.0	9.0
Rest standing heart rate (beats/min)	74	65
3-minute heart rate	105	90
6-minute heart rate	123	108
Peak heart rate (9 minutes)	154	142
Predicted maximum heart rate (%)	96	89
Rest standing blood pressure (mm Hg)	125/70	110/80
3-minute blood pressure	160/80	120/75
6-minute blood pressure	185/76	140/76
Peak blood pressure (9 minutes)	190/78	170/95
Double product-peak exercise*	29.26	24.14
Double product-onset ST depression*	16.0	22.6
VO_2 Max (ml/min)	1,666	2,267 ($p < 0.001$)
VO_2 Max/kg (ml/min/kg)	21 (6 MET)	29 (8 MET)
O_2 pulse (VO_2/max HR) (ml)	10	16

* Double product expressed as beats-mm Hg/min × 1,000.
HR = heart rate; MET = 3.5 ml oxygen uptake/min/kg; VO_2 max = peak oxygen uptake.

cise hemodynamics are shown in Table I. Peak O_2 uptake was 1.66 liter/min with an O_2 pulse of 10, and a peak double product of 29.26 × 10^3 beats-mm Hg/min. The ST depression noted previously was reproduced (Figure 1) with an onset at a double product of 16.0 × 10^3 beats-mm Hg/min. One hour after the oral administration of 80 mg of verapamil, the exercise test was repeated in the same manner (test 3). At 9 minutes, peak O_2 uptake was 2.27 liter/min with an O_2 pulse of 16 and a peak double product of 24.14 × 10^3 beats-mm Hg/min. There was no evidence of exercise-induced wheezing. Upsloping ST depression (onset at a double product of 22.6 × 10^3 beats-mm Hg/min) of 1 mm was recorded at peak exercise, returning to baseline 4 minutes into recovery.

The ST-segment depression with exercise was horizontal, lasted 10 minutes in recovery and was accompanied by symptoms and ventricular arrhythmias. Peak O_2 uptake was low. The patient lacked any other condition or circumstance generally associated with ST depression representing a false-positive test for ischemia. Improvement after verapamil prompts several hypotheses.

Because hypoxemia was present at rest, a further decrease in pO_2 would account for exercise-induced ischemia. Kurihara et al[2] predicted pO_2 during exercise in patients with chronic pulmonary disease using diffusing capacity and a known peak O_2 uptake and found a high correlation with actual measurements of pO_2. With this formula, our patient would have a pO_2 of >100 mm Hg. To further corroborate this, we employed ear oximetry during exercise and found no evidence of desaturation.

Henriquez et al[3] found that patients with chronic bronchitis and severe exercise intolerance (VO_2 max <2.1 liter/min) had elevated pulmonary resistance at rest, with the highest values in those subjects whose O_2 pulse was <11 ml and whose maximal heart rate was >95% predicted. ST depression may represent right ventricular pressure overload to high pulmonary resistances. Calcium antagonists can dilate the pulmonary vascular bed[4] and inhibit exercise-induced bronchospasm.[5,6]

Finally, a defective subendocardial vasoregulatory system could account for microscopic (albeit electrocardiographically significant) ischemia not detected grossly by thallium scintigraphy. Inadequate coronary vasodilator responses in patients with normal coronary arteries have been described.[7] Moreover, calcium antagonists have reduced angina frequency and improved exercise tolerance in such patients.[8] Exercise duration was unchanged in our patient. A more significant change, i.e., an increase in maximal O_2 uptake at a lower heart rate, occurred after verapamil administration, which implies improvement in stroke volume because maximal A-V O_2 difference is physiologically limited to 15 to 17 vol%.[1] The onset of ST depression occurred at a higher double product suggesting an increase in flow. In the absence of physical training, these changes can only be attributed to the effect of verapamil. At this time it could not be determined whether improvement in vasoregulation or enhancement of ventricular relaxation produced the changes described.

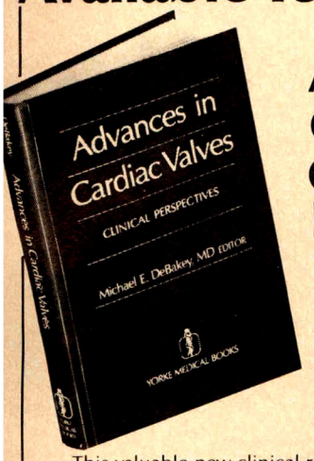
The Most Extensive Compilation of Information on Heart Valve Replacement Available Today!



Advances in Cardiac Valves
Clinical Perspectives

edited by
Michael E. DeBakey, MD

0-914316-40-0, November 1983, 274pp., $35.00

This valuable new clinical reference provides a detailed update on many aspects of mechanical heart valve prostheses, including hemodynamics, clinical results, results in children, non-invasive assessments, special indications, and implant techniques. Each topic is presented in an easily understood style and format which facilitate the comprehension of recent developments in heart valve replacement for the busy clinician.

Each chapter is written by internationally respected physicians and medical scientists each of whom is pre-eminent in his field. All of this information has been co-ordinated by Dr. DeBakey to produce a very readable and informative volume on the state-of-the-art of heart valve replacement with mechanical prostheses. No cardiologist, cardiovascular surgeon, internist, or bioengineer can afford *not* to be knowledgeable about the information in this book.

About $3 billion a year is spent on business press advertising—yet amazingly little concrete evidence has existed to show whether it really works.

Research to actually prove the effectiveness of trade and industrial advertising has been unconvincing and inconclusive.

Till now.

Finally. New research proves business press advertising dramatically increases sales and profits.

It's comprehensive. This landmark research study took more than three years to complete at a cost of over $390,000.

It's impartial—the study was conducted entirely by the independent Advertising Research Foundation.

No longer will increasing your ad budget be an act of faith.

It's reliable. The new study tracked ads for four totally different products. Was based on real-time data carefully accumulated as the ads ran. And employed state-of-the-art data analysis techniques.

It's conclusive. It links higher levels of advertising with significant increases in sales, plus increased profits. Considering the competitive crunch of today's marketplace, these kinds of results mean increasing your advertising is no longer an act of faith—but an act of survival.

Shoot down your old notions, and put the research to work.

Armed with these new, easy-to-understand facts and figures, you can now have powerful decision support for increasing your trade magazine ad budget.

For your copy of the "Summary of the Findings", write on your letterhead to: Marketing Services, Association of Business Publishers, 205 E. 42nd Street, New York, NY 10017.

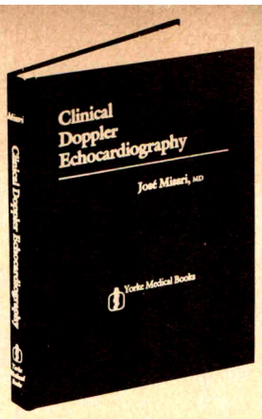
...a comprehensive text emphasizing the clinical aspects of Doppler echocardiography



Clinical Doppler Echocardiography

by José Missri, MD
0-914316-51-6 256 pp., April 1986, 175 illustrations, $55.00

The development and refinement of Doppler echocardiography represent a major advance in the diagnostic applications of ultrasound in heart disease.

Dr. Missri has written *Clinical Doppler Echocardiography* to provide clinical cardiologists, postdoctoral fellows and "echo" technologists with practical information on cardiac Doppler applied to acquired and congenital disease.

Clearly written, logically presented, generously illustrated—including 4-color examples of Doppler color-flow mapping—and thoroughly indexed, *Clinical Doppler Echocardiography* is a must addition for personal and medical center libraries.

Table of Contents (in brief)

INTRODUCTION TO DOPPLER ECHOCARDIOGRAPHY
PRINCIPLES OF DOPPLER ECHOCARDIOGRAPHY AND INSTRUMENTATION
DOPPLER EXAMINATION OF THE HEART AND GREAT VESSELS
DOPPLER EVALUATION OF MITRAL VALVE DISEASE
DOPPLER EVALUATION OF AORTIC VALVE DISEASE
DOPPLER EVALUATION OF RIGHT SIDED LESIONS AND PULMONARY HYPERTENSION
DOPPLER ASSESSMENT OF PROSTHETIC VALVES
DOPPLER ECHOCARDIOGRAPHY IN THE EVALUATION OF CONGENITAL HEART DISEASE
EVALUATION OF CARDIAC FUNCTION AND ASSESSMENT OF CARDIOMYOPATHY BY DOPPLER ECHOCARDIOGRAPHY
SELECTED CASE STUDIES AND DOPPLER COLOR-FLOW MAPPING

K-DUR™ Microburst Release System™
(potassium chloride) Sustained Release Tablets

INDICATIONS AND USAGE: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage or perforation.

K-DUR tablets contain micro-crystalloids which disperse upon disintegration of the tablet. These micro-crystalloids are formulated to provide a controlled release of potassium chloride. The dispersibility of the micro-crystalloids and the controlled release of ions from them are intended to minimize the possibility of a high local concentration near the gastrointestinal mucosa and the ability of the KCl to cause stenosis or ulceration. Other means of accomplishing this (e.g., incorporation of potassium chloride into a wax matrix) have reduced the frequency of such lesions to less than one per 100,000 patient years (compared to 40–50 per 100,000 patient years with enteric-coated potassium chloride) but have not eliminated them. The frequency of GI lesions with K-DUR tablets is, at present, unknown. K-DUR tablets should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

PRECAUTIONS: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Laboratory Tests: Regular serum potassium determinations are recommended. In addition, during the treatment of potassium depletion, careful attention should be paid to acid-base balance, other serum electrolyte levels, the electrocardiogram, and the clinical status of the patient, particularly in the presence of cardiac disease, renal disease, or acidosis.

Drug Interactions: Potassium-sparing diuretics; see **WARNINGS.**

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies in animals have not been performed.

Pregnancy Category C: Animal reproduction studies have not been conducted with K-DUR. It is also not known whether K-DUR can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. K-DUR should be given to a pregnant woman only if clearly needed.

Nursing Mothers: The normal potassium ion content of human milk is about 13 mEq per liter. Since oral potassium becomes part of the body potassium pool, so long as body potassium is not excessive, the contribution of potassium chloride supplementation should have little or no effect on the level in human milk.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: One of the most severe adverse effects is hyperkalemia (see **CONTRAINDICATIONS, WARNINGS,** and **OVERDOSAGE).** There have also been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration, and perforation (see **CONTRAINDICATIONS** and **WARNINGS);** other factors known to be associated with such conditions were present in many of these patients.

The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by taking the dose with meals or reducing the dose.

Skin rash has been reported rarely.

OVERDOSAGE: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see **CONTRAINDICATIONS** and **WARNINGS**). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-waves, depression of S-T segment, and prolongation of the QT-interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10–20 units of insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

ONCE-A-DAY

Calan® SR

(verapamil HCl) 240 mg

SUSTAINED-RELEASE CAPLETS

- **Convenient one-caplet, once-a-day dosing regimen:* Start with one 240—mg caplet in the morning with food. (Starting dosages of 120 mg/day, ½ caplet, may be suitable for the elderly or those of small stature.)**
- **Favorably priced—similar in cost to beta blockers**

*Some patients may require *b.i.d.* dosing.

BRIEF SUMMARY

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block (if no pacemaker is present).

Warnings: Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure and in patients with significant ventricular dysfunction if they are receiving a beta-adrenergic blocker. Control milder heart failure with optimum digitalization and/or diuretics before Calan SR is used. Verapamil may occasionally produce a decrease in blood pressure below normal levels, which may result in dizziness or symptomatic hypotension. Elevations of liver enzymes have been reported. Several cases of hepatocellular injury have been demonstrated to be produced by verapamil. Periodic monitoring of liver function in patients on verapamil is prudent. Some patients with paroxysmal and/or chronic atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) have developed an increased antegrade conduction across the accessory pathway bypassing the AV node, producing a very rapid ventricular response or ventricular fibrillation after receiving I.V. verapamil (or digitalis). The effect of verapamil on AV conduction and the SA node may cause asymptomatic 1st-degree AV block and transient bradycardia, sometimes with nodal escape rhythms. PR-interval prolongation is correlated with verapamil plasma concentrations especially during initial titration. Higher degrees of AV block are infrequent (0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil.

Precautions: Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Verapamil may decrease neuromuscular transmission in patients with Duchenne's muscular dystrophy and may prolong recovery from the neuromuscular blocking agent vecuronium. It may be necessary to decrease verapamil dosage in patients with attenuated neuromuscular transmission. Studies in a small number of patients suggest that concomitant use of Calan and oral beta-adrenergic blockers may be beneficial in certain patients with chronic stable angina or hypertension. Combined therapy can also have adverse effects on cardiac function; therefore patients should be closely monitored. A decrease in metoprolol clearance may occur with concurrent use of verapamil and metoprolol. Chronic verapamil treatment increases serum digoxin levels by 50% to 75% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient reassessed. Verapamil used concomitantly with oral antihypertensive agents will usually have an additive effect on lowering blood pressure that in some cases may be excessive; therefore patients should be monitored appropriately. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Quinidine levels may increase during verapamil therapy. Clearance of verapamil may be reduced in concomitant use with cimetidine. Concomitant use of verapamil and lithium may result in decreased serum lithium levels. Verapamil therapy may increase carbamazepine concentrations during combined use. Therapy with rifampin may markedly reduce oral verapamil bioavailability. Concomitant use of inhalation anesthetics and calcium antagonists needs careful titration to avoid excessive cardiovascular depression. Verapamil may potentiate the activity of neuromuscular blocking agents (curare-like and depolarizing); dosage reduction may be required. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Another study in rats showed no evidence of carcinogenicity. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. Verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. Safety and efficacy in children under 18 have not been established.

Adverse Reactions— oral verapamil: Constipation (8.4%), dizziness (3.5%), nausea (2.7%), hypotension (2.5%), edema (2.1%), headache (1.9%), CHF/pulmonary edema (1.8%), fatigue (1.7%), bradycardia: HR <50/min (1.4%), AV block: total 1°, 2°, 3° (1.3%)/3rd-degree (0.8%), flushing (0.1%); elevations of liver enzymes have been reported (see *Warnings*). The following reactions, reported in 1.0% or less of patients, occurred under circumstances where a causal relationship is not certain: angina pectoris, chest pain, claudication, myocardial infarction, palpitations, purpura (vasculitis), syncope, diarrhea, dry mouth, gastrointestinal distress, gingival hyperplasia, ecchymosis or bruising, cerebrovascular accident, confusion, equilibrium disorders, insomnia, muscle cramps, paresthesia, psychotic symptoms, shakiness, somnolence, dyspnea, arthralgia, rash, exanthema, hair loss, hyperkeratosis, macules, sweating, urticaria, blurred vision, gynecomastia, impotence, increased urination, spotty menstruation.

Instructions to Authors

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY, that upon submission, they become the property of the Publisher, that the work has not been previously published, and that the data in the manuscript have been reviewed by all authors, who agree with the analysis of the data and the conclusions reached in the manuscript. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced without the written permission of the Publisher. Statements in articles are the responsibility of the authors.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 7960 Old Georgetown Road, Suite 2C, Bethesda, Maryland 20814. Please include the corresponding author's phone number. The covering letter should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make (for example, the elimination of 1 or more figures or tables or a portion of the text) to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The names of investigators considered unlikely by the authors to give nonbiased reviews of their work also may be submitted, and this request is honored.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page, which should include the title, the full names and academic degrees of the authors, and the institution and city and state or city and country from which the work originated; (2) second title page, with only the title of the article (page not numbered); (3) abstract; (4) text; (5) acknowledgment; (6) references; (7) figure legends; (8) miniabstract for Table of Contents that includes the full title and names (without academic degrees) of the authors (page not numbered); and (9) tables. Number the title page as 1, abstract page as 2, and so forth. (Leave the second title page and the miniabstract page unnumbered.) Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25-mm (1-inch) margins.

The second title page, on which the names and institutions of the authors are omitted, gives the Editor in Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be solicited. The authors should state which type of review they wish in the covering letter; this request is honored.

TITLE PAGE, TABLE OF CONTENTS, ABSTRACT AND MINIABSTRACT: For the **complete title page**, include the full first or middle and last names of all authors. Provide a short running title of 3 to 6 words. List the institution and address from which the work originated, and provide information about grant support if necessary. If the work described is supported by a grant from a pharmaceutical company, that fact should be stated on the title page. Add at the bottom the phrase, "Address for reprints:" followed by full name and address with zip code. Limit the **abstract** to 250 words and the Table of Contents **miniabstract** to 150 words. List 2 to 6 **key words** for subject indexing at the end of the abstract.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as the Methods, Results and Discussion. **Abbreviations** are permitted, but no more than 3 per manuscript, and then they must be used on every page of the manuscript after they are initially spelled out (followed by the abbreviation) in both abstract and introduction. Abbreviations are best limited to phrases in the article's title. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence, but try not to begin sentences with numbers. Use symbols for less than (<), greater than (>) and percent (%). Indent for paragraphs except the first one in both abstract and introduction. Consult the Uniform Requirements for Manuscripts Submitted to Biomedical Journals, published in *The Annals of Internal Medicine* June 1982;96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association.*

REFERENCES: List all authors, year, volume and inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts, but if they are used, indicate them as such by the abbreviation (abstr) after the title. Do not use periods after authors' initials or after abbreviations for titles of journals. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications, unpublished observations, and manuscripts submitted but not yet accepted for publication do not constitute references.

Journal: Harvey W, Heberden W, Withering W, Stokes W, Murrell W, Einthoven W, Osler W. Anomalies and curiosities of cardiology and of cardiologists. Reflections of famous medical Williams. Am J Cardiol 1984;53:900–915.

Chapter in Book: Cabot RC, White PD, Taussig HB, Levine SA, Wood P, Friedberg CK, Nadas AS, Hurst JW, Braunwald E. How to write cardiologic textbooks. In: Hope JA, ed. A Treatise on Disease of the Heart and Great Vessels. London: Yorke Medical Books, 1984;175–200.

Book: Carrel A, Cutler EC, Gross RE, Blalock A, Craffoord C, Brock RC, Bailey CP, DeBakey ME. The Closing of Holes, Replacing of Valves and Inserting of Pipes, or How Cardiovascular Surgeons Deal with Knives, Knaves and Knots. New York: Yorke University Press, 1984:903.

FIGURES: Submit 3 glossy unmounted prints of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all charts (line drawings). Make decimals, broken lines, and so on, clear enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by title of the article; omit the authors' names so that blinded reviews can be obtained. Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figures. Limit figures to the number necessary to present the message clearly. Type **figure legends** on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author.

TABLES: Place each table on a separate page, typed double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating numbers of patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate "positive" or "present", a zero (0) for "negative" or "absent," and dash (—) for "no information available" or "not done." Do not use "yes" or "no" or "more."

BRIEF REPORTS: Brief Reports must be limited to no more than 4 text pages (including the title page) and 6 references. Longer ones may be returned without review. Neither an abstract nor a Table of Contents miniabstract is required for a Brief Report. Subheadings are not used.

LETTERS (For Publication): The author who submits a letter for consideration for publication should provide a covering letter on his/her own stationery to the Editor in Chief stating why the letter should be published. The letter for consideration for publication should be typed, double-spaced, on a separate sheet of plain white paper and limited, with few exceptions, to 2 pages. The original and 2 xerographic copies should be submitted. A title for the letter should be provided at the top of the page. At the end of the letter, the writer's full name and city and state (or country if outside the United States) should be provided. The author's title and institution should not be included. The word "References" does not appear above the list of references in published letters. References should be double-spaced. A letter concerning a particular article in the *Journal* must be received (from authors within the United States) within 2 months of the article's publication.

REPRINTS: Price schedules and order cards for reprints are mailed to the author upon publication of the article. Individual reprints must be obtained through the author.

PERMISSIONS: Permission to reproduce figures published in the Journal is obtained by writing to: Managing Editor, THE AMERICAN JOURNAL OF CARDIOLOGY, 249 West 17th St., New York, NY 10011.

LETTERS*

TERMINATION OF VENTRICULAR TACHYCARDIA WITH TRANSCUTANEOUS CARDIAC PACING

The case report by Rosenthal et al,[1] which reported on the termination of ventricular tachycardia (VT) with transcutaneous pacing, is similar to our previous publication.[2] Several additional points should be made.

The termination of VT with transcutaneous pacing is limited by the patient's stability and the type of transcutaneous pacemaker. Transcutaneous pacing's advantage over low energy cardioversion is that anesthesia can be avoided. For the unconscious patient the best method is low energy cardioversion. Transcutaneous pacing is best used for the conscious patient whose VT rate is slow, who has not responded to simple medical therapy such as intravenous lidocaine and in whom a transvenous wire is not in place. The Zoll transcutaneous pacemaker's maximum pacing rate is 180/min,[1] which limits overdrive transcutaneous termination with this pacemaker to VTs with a rate below 160 beats/min. This limitation is not common to all transcutaneous pacemakers, however, as our pacemaker (Transpace, model 25, Micromedical Devices Inc.) paces up to rates of 300/min.

The largest population of conscious patients, who require an intervention to terminate a fast heart rhythm, are those with supraventricular tachycardia. Transcutaneous pacing appears to affect atrial rhythm, as illustrated in our case,[2] where a short period of an irregular supraventricular rhythm followed the termination of the patient's VT with transcutaneous pacing. The possible danger of inducing rapidly conducting atrial fibrillation in a patient with an accessory pathway is remote and is easily corrected with an electrical cardioverter. VT or ventricular fibrillation might also be induced, and again, should respond quickly to cardioversion. The danger of inducing a ventricular arrhythmia could be decreased by using R-wave triggered pacing (DVT mode[3]). Simultaneous transvenous atrial and ventricular pacing is used to treat patients with recurrent supraventricular tachycardia,[4] and simultaneously transcutaneous pacing will probably terminate some forms of supraventricular tachycardia.

Transcutaneous pacing could prove to be fast, simple and safe for the termination of tachyarrhythmias, especially supraventricular tachycardia. In addition to higher rates, transcutaneous pacemakers should provide new synchronization modes to suit them to tachycardia termination. Research should be done to determine the optimal positions for the pacing electrodes and the safest and most effective pacing protocols for transcutaneous pacing termination of tachycardias.

FETAL DOPPLER ECHOCARDIOGRAPHY

I read with interest the article by Hata et al,[1] who performed 65 continuous-wave Doppler ultrasonographic examinations on 57 normal fetuses. Their experience was similar to previously published data.[2,3] However, I object to the use of continuous-wave ultrasound particularly in normal fetuses because continuous-wave Doppler exposes the fetus to higher intensities of ultrasound energy than the pulse-wave mode. This, coupled with loss of range resolution makes it less favorable for use in normal fetuses especially since maximal velocities recorded are still within the range of the pulse-Doppler technique. Moreover, the Aloka SSD-730 system used by the investigators allows for either pulsed or continuous-wave Doppler modes. Thus, it is prudent and probably safer to use pulse-wave Doppler techniques in fetal studies in general and in normal fetuses in particular and limit the energy output of the system to the minimum necessary for adequate examination with signal intensity usually maintained at or below 100 mW/cm^2. The continuous-wave modality should be reserved for occasional use only and in selected cases.

3. Huhta JC, Strasburger JF, Carpenter RJ, Reiter A, Abinader E. *Pulsed Doppler fetal echocardiography. J Clin Ultrasound 1985;13:247–254.*

REPLY: We also think that it is prudent and probably safer to use the Doppler equipment with low signal intensity in fetal studies. An Aloka SSD-730 used in our study is applicable for either pulsed or continuous-wave modes. In the continuous-wave Doppler mode, the spatial average-temporal average (SATA) intensity was 24 mW/cm^2, and the spatial peak temporal average (SPTA) intensity 120 mW/cm^2. Therefore, the SATA intensity was within the limited value of theFDA (94 mW/cm^2), and the SPTA intensity was slightly higher than the value of 100 mW/cm^2. The continuous-wave Doppler mode is very useful to record the maximal velocity along the Doppler beam, and the scanning time is very brief. In order to prevent an unnecessary Doppler exposure to the fetus, the scanning time of Doppler recordings was limited to 2 minutes, and the gain control was reduced to the minimum necessary to record adequate blood flow velocity waveform in our study. Moreover, all fetuses were subsequently delivered at Shimane Medical University Hospital without apparent fetal abnormalities.

DOPPLER PREDICTION OF TRANSVALVULAR GRADIENT AND STENOTIC ORIFICE AREA

Requarth et al[1] have studied the theoretical relation between pressure and flow, and used an in vitro model to verify a formula for valve area determination. This formula is based on the Gorlin equation[2] but applied to flow velocity measurements using ultrasound Doppler.[3] Unfortunately, they came up with some results, and especially interpretations, that are questionable and may create confusion regarding the hydraulic conditions at a stenotic valve. Their article has been quoted by others, and we feel that a clarification is necessary. It is partly possible to clarify some dubious interpretations of results, because the original data were fortunately published in the article. Because, however, quite some time has passed since this article was published, we will first summarize their model and the conclusions drawn from it. We will then comment on questionable results and present an alternative interpretation of some of their data.

To represent the flow situation at a stenotic valve, Requarth et al constructed a model where interchangeable orifices separated 2 tubes between which fluid streamed. The pressure p_1 was measured upstream to the orifice and p_2 immediately downstream. The fluid velocity through the orifice was obtained in 3 different ways: (1) velocity at the presumed vena contracta measured with pulsed ultrasound Doppler, (2) velocity ob-

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

tained from measured volume flow measured orifice area assuming a value of 0.62 for the discharge coefficient and (3) velocity at vena contracta calculated from the simplified Bernoulli relation. Two areas were used: a true measured area and an area calculated from measured volume flow and ultrasound Doppler velocity assuming a discharge coefficient of 0.62. The 2 areas are compared.

We would like to comment on a misinterpretation in their Figure 2. It is apparent from the theory presented by Requarth et al that there is a square root relation between pressure gradient and flow. However, in the figure straight lines are fitted to the data points, which could indicate that they expected a linear relation. A major problem in their paper is the conclusions drawn from their data regarding the size of the discharge coefficient and the accuracy of the orifice area calculations. In their calculations of the area they used a theoretical value of 0.62 for the discharge coefficient. This theoretical value is a value for ideally sharp-edged orifices and may not be appropriate in this experimental situation.[4] For a specific orifice arrangement the real discharge coefficient has to be determined empirically. The data presented allows us to calculate real discharge coefficients as

$$C_d = Q/A_{true}\ vel_p$$

where Q is the measured volume flow and A_{true} the actual area of the orifice and vel_p the velocity at vena contracta calculated from the simplified Bernoulli relation. Our calculations give mean values of the discharge coefficient of 0.72, 0.77 and 0.85 for orifices with diameters of 10.4, 8.5 and 6.1 mm, respectively. Compared with other reported experimental data, we notice that the values 0.77 and 0.83 are high for this type of orifice. The reason for these discrepancies cannot fully be explained from the data presented and measurement errors cannot be excluded. Requarth et al do not discuss how the results are influenced by the fact that the flow velocity proximal to the hole is ignored and do not comment on errors of pressure measurements due to the location of the pressure tap.

Requarth et al found, using the discharge coefficient 0.62, that the calculated area was larger than the true area for the tested holes. For the smallest hole this overestimation was 27 to 40%. If one instead calculates the area using the measured discharge coefficient and the velocity measured by ultrasound Doppler, the calculated area will be in the range of −19% to +7% of the true area.

In the discussion section of this article, the deviations between actual and predicted orifice area at high flow rates through the smallest orifice were explained by limitations of the theoretical model. They claim that the real discharge coefficient might be larger than unity due to the spray effect distal to the orifice. The discharge coefficient, however, can by definition never be larger than unity, because that would violate basic physical principles like the first law of thermodynamics.

The too high orifice areas calculated by Requarth et al can definitely not be explained by a discharge coefficient larger than unity. The area of a fluid jet spray is associated with phenomena that cannot be described with a discharge coefficient concept. The explanation to the Requarth et al results lies in the use of a discharge coefficient deviating from the true one and in limitations of their experimental model.

DECREASED HEART RATE VARIABILITY AND BETA BLOCKERS AFTER ACUTE MYOCARDIAL INFARCTION

Kleiger et al[1] recently reported the results of a large multicenter study. The major finding was that decreased heart rate (HR) variability—a predominant feature of impaired parasympathetic nervous function—assessed from Holter tapes was associated with an increased mortality after acute myocardial infarction (AMI). This finding is in accordance with previous reports on HR variability and HR and its association with mortality.[2,3] Experimental studies have also shown that dogs with a healed myocardial infarction and reduced levels of cardiac vagal activity are prone to exercise-induced ventricular fibrillation and subsequent increases in vagal activity protect against it.[4]

According to their Table VI the effect of blunted HR variability on mortality was partially neutralized by β-blocker treatment. The mortality of patients with decreased HR variability (<50 ms) was 37% compared with 8% in patients with normal HR variability (>100 ms) in the patient group not using β blockers. In the β blocker group the corresponding figures were 26% and 13%. This preliminary finding is in agreement with a previous report which showed that the favorable prognostic effect of β blocker treatment after AMI is related to the achieved HR reduction.[5] Heart rate is namely inversely related to HR variability.[1]

The association of diminished HR variability with the effectiveness of β blockade may be explained by the fact that the parasympathetic nervous system interacts with the sympathetic nervous system and can buffer the deleterious effects of a sympathetic storm on ventricular fibrillation threshold.[6] Thus, intact vagal function may protect the heart as does β blockade. On the basis of simple bedside tests impairment of parasympathetic nervous function is, however, common in coronary artery disease.[7]

The selection of patients who will probably benefit from long-term β-blocker treatment after AMI is an everyday problem. These findings of Kleiger et al suggest that assessing the vagal activity from Holter records or using simple bedside tests might give additional information in this decision-making.

CARDIAC RHYTHM IN ATRIAL ISOMERISM

Although Wren and colleagues make a solid contribution to understanding the clinical expression of atrial isomerism,[1] there is a conceptual flaw in their definition of sinus rhythm: "Sinus rhythm was recorded if the PR interval was normal regardless of the P-wave axis." This is a curious definition of sinus rhythm, since the PR interval is created virtually entirely by the delay in the atrioventricular node.[2] Indeed, the P-wave axis was superior in 49% of patients with left isomerism. At least the −30° to −90° range was loosely known as "coronary sinus rhythm" based on Katz's criteria; as in their patients the leftward orientation of the pacemaker was frequently transient.[3] Moreover, Massumi and colleagues have shown that P-wave polarity was not a reliable guide to the site of the pacemaker.[4] Perhaps the authors chose to define sinus rhythm by the PR interval because in left atrial isomerism the sinus node is hypoplastic or absent and may be situated on the lateral wall of the atrium.[1]

LONG-TERM FOLLOW-UP OF VALVULAR FUNCTION AFTER ORTHOTOPIC CARDIAC TRANSPLANTATION

In the June 1987 issue of the *Journal*, Lewen et al[1] describe the occurrence of tricuspid regurgitation (TR) after orthotopic heart transplantation, and suggest it to be an original observation. In fact, before Lewen's work had been submitted for publication to the *Journal* (January 5, 1986), this finding, and its relation to pulmonary hypertension, was published elsewhere,[2] and an article from our laboratory appeared in a November 1986 issue describing that valve regurgitation after heart transplantation involved the 4 cardiac valves and was transient in most patients.[3] Long-term follow-up of these patients indicates that tricuspid, mitral, aortic and pulmonary regurgitation suffers a gradual reduction in both their prevalence and importance (Table I).

The mechanism of such regurgitation can be ascribed to valve edema, and myocardial edema could also contribute[3]; certainly pulmonary hypertension contributes to both the presence and degree of TR.

One year after heart transplantation valve function is normal in most patients. Mild TR seen 1 year after the operation cannot be ascribed to a tricuspid valve abnormality as it is frequently observed in normal individuals.

CORRECT NOMENCLATURE FOR THE CARDIOMYOPATHIES

In his "From the editor" column Dr. Roberts is brief and succinct. One can agree or disagree with his statements—it is all put very clearly. In contrast to this it is rather irritating and frustrating that some Americans cannot or will not stick to the rules of nomenclature of cardiomyopathy. The topic ends up smothered—not debated. In 1980 the WHO Task Force Group on the Definition and Classification of Cardiomyopathy[1] (a group including a prominent American cardiologist) defined what was to be called cardiomyopathy, and what was to be called specific heart muscle disease. There is *no* such entity as ischemic cardiomyopathy although Americans continue to use this terminology (the latest example I have seen is Eisenberg et al[2]). I don't think I am a fusspot and my point is definitely not to discuss whether or not the definition of cardiomyopathy is an appropriate one. Simply put, my point is if you are playing (American) football the rules of soccer or baseball will not do. One has to stick to the rules until new and better ones have been decided upon. Emphasizing the American angle may be a little unfair as other nationalities are known to have broken the rules in the past, too. But it counts heavily when Americans are as influential in cardiology as they are in this case.

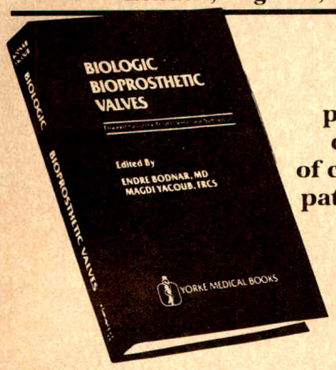
Biologic & Bioprosthetic Valves

Proceedings of the Third International Symposium London, England, May 21-23, 1985



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

edited by Endre Bodnar, MD, and Magdi Yacoub, FRCS
ISBN 0-914316-49-4, 920 pp., May, 1986, $125.00

To order your copy of this important new book use the order form below.

The Third International Symposium on Cardiac Bioprostheses was held May 21-23, 1985, at the Grosvenor House Hotel, London. Six years have passed since the first meeting of this kind was held in Munich and 3 years since the second conference in Rome. The reassessment of the state of the art with biologic and bioprosthetic valves seems to have become a regular 3-yearly fixture reflecting the fast development of these devices, as well as the desire of surgeons and academics working in this field to share experiences, exchange ideas, and to resolve problems together.

The London meeting brought together surgeons, cardiologists, pathologists, engineers, and basic scientists, and the 3-day program accommodated 96 formal presentations with nearly 7 hours of discussion. It is a credit to the session chairmen and participants that the discussions were frank, outspoken, but fair and always to the point, and they have been added to this volume, and they certainly enhance its value.

This volume incorporates the work of the best specialists in the field, and should not be missing from your own professional library.

The Editors are eminently qualified to do this book, Dr. Bodnar is with the Cardiothoracic Institute, London, England, and Mr. Yacoub is with Harefield Hospital, Middlesex, England.

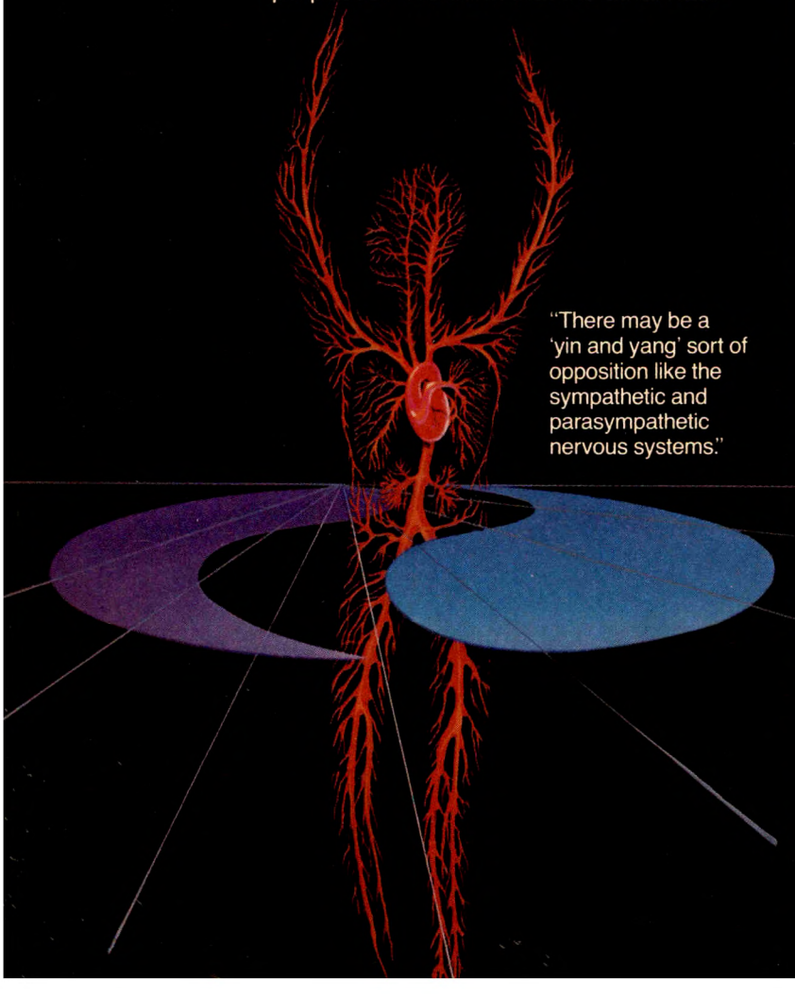
THE NEW VISION OF

"We are trying to readjust the entire cardiovascular system to operate at a new control point."

"Many hormones and other types of mediators of cardiovascular function could be altered for therapeutic benefit."
"The hormonal system of cardiovascular control uppermost in people's minds at this time is the renin-angiotensin-aldosterone (RAA) axis. The reason is its central role in the pathogenesis of hypertension and congestive heart failure (CHF).

"What's the next likely target—the next system we might alter for therapeutic purposes? We think that the atrial natriuretic or atrial peptide system has a lot of potential for treatment of CHF, hypertension, renal failure, and perhaps other cardiovascular disorders."



"There may be a 'yin and yang' sort of opposition like the sympathetic and parasympathetic nervous systems."

"Several years ago I suggested that the atrial peptide and RAA systems might be functional antagonists."
"And you can cite a number of areas where they are. Angiotensin constricts blood vessels; atrial peptides relax them. Angiotensin stimulates aldosterone production; atrial peptides inhibit it. The RAA system causes sodium retention—the atrial peptides cause natriuresis. And the atrial peptides inhibit renin release.

"Both angiotensin and atrial peptides are also present in the CNS, but it's not clear what they do. We have put atrial peptides into the CNS and shown they inhibit vasopressin release. Angiotensin appears to stimulate thirst, while atrial peptides antagonize angiotensin-induced water intake. There may be a 'yin yang' sort of opposition like the sympathetic and parasympathetic nervous systems."

"We are looking for the essence of cardiovascular control."
"If we can understand the natural physiologic controls, we may be able to alter them without stimulating counterregulatory mechanisms as occurs with diuretics and vasodilators. What we want to do is change the natural drives on the cardiovascular system so that the entire system readjusts back to a normal control point."

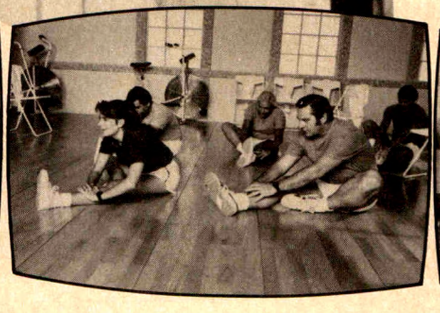
New Prescribed Video Programs For Cardiac Patients.

Special Offer For AJC Readers



Now available, the first take-home education and exercise video for cardiac patients. These four 60-minute videos extend rehabilitative care and meet the current standards of AHA and ACSM.

- Exercise videos feature increasing levels of intensity. Select the tape that's best for each patient. These video home programs encourage patient compliance.
- Patient exercise and activity log helps you audit progress during office visits.
- Available only on physician recommendation.

Prescription video orders can be filled at your office or rehab center for as low as $69-$89 each, depending on the module you prescribe.

VideoCare National Advisory Panel on Cardiac Rehabilitation

Physicians: Bruno Balke; Samuel M. Fox, III; Victor Froelicher, Peter Hanson; Herman K. Hellerstein; Terence Kavanagh; Arthur S.Leon; Henry S. Miller, Jr.; L. Kent Smith; C. Barr Taylor; Steven P. Van Camp.
Nurses: Kathy Berra; Nancy Houston Miller; Erika S. Sivarajan.
Exercise Physiologists: Carl Foster; Barry A. Franklin; William L. Haskell; Neil B. Oldridge; Michael L. Pollock; Paul M. Ribisl; Ray W. Squires.
Behavioral Scientist: James A. Blumenthal.
Physical Therapist: Elizabeth J. Protas.

Special AJC Offer

Normally $346, a complete VideoCare™ set can be obtained by AJC readers for only $300. Satisfaction guaranteed, credit cards accepted. **Call 1-800-338-1927.** Mention AJC for special offer.

we never stop asking "What if..."

HP's cardiograph won't decide for you. But it will help.

Sometimes ECGs are clear calls. Other times, judgement and an experienced eye are required to make the right decision. HP's new PageWriter II cardiograph can help by screening normal ECGs, automating measurements, highlighting abnormalities and producing clean copies for easier analysis. This advanced cardiograph analyzes 45% faster, is more reliable and is easier to use than our earlier models. Best of all, it costs less, so you can put PageWriters where you need them.

PageWriter II. Helpful, and new from Hewlett-Packard. For more information, contact your local HP representative.

HEWLETT PACKARD

©1988 Hewlett-Packard Co. MG03812

Tambocor is indicated for the treatment of documented life-threatening ventricular arrhythmias, such as sustained V-tach.

Tambocor is also indicated for the treatment of patients with symptomatic NSVT and frequent PVCs. Because of the proarrhythmic effects of Tambocor, its uses in these less severe arrhythmias should be reserved for patients in whom, in the opinion of the physician, the benefits of antiarrhythmic treatment outweigh the risks.

For most patients, the better choice.

Joan Borra's symptomatic PVCs and NSVT have been successfully controlled by Tambocor® (flecainide acetate) B.I.D. for almost a year, and she experienced none of the problems characteristic of arrhythmia therapy. Tambocor has proven to be highly effective in study after study. In a multicenter clinical trial against quinidine, for example, Tambocor produced greater than 95% suppression of NSVT in 86% of patients.[1] In a 12-month follow-up to this trial, 94% of patients who remained on Tambocor had 100% suppression of NSVT.[2]

Tambocor is so well tolerated by most patients that discontinuation due to noncardiac adverse effects in a major multicenter study was only 5.4%.[3] Tambocor also has convenient b.i.d. dosing, making it easier to comply with in long-term use.

Tambocor has a low incidence of cardiac side effects in patients with symptomatic PVCs and NSVT. In a study of 1,330 patients treated with Tambocor, the overall incidence of proarrhythmia was 6.8%. In patients with PVCs, the incidence was 1.7% (8/470); in NSVT patients, 3.8% (18/469).[4] However, Tambocor should be used with caution and dosed differently in patients with sustained V-tach, particularly those with congestive heart failure or myocardial dysfunction. The incidence of cardiac adverse effects has been found to be substantially higher in these patients. Please see full prescribing information.

This exceptional record of efficacy, safety and tolerance has been borne out in six years' experience with more than 300,000 patients worldwide. It's no wonder that many physicians prefer Tambocor for the treatment of symptomatic PVCs and NSVT.

Please see following page for brief summary of full prescribin information.

TAMBOCOR® B.I.D.
(flecainide acetate)

The one to start with, the one to stay with.

TAMBOCOR® B.I.D.
(flecainide acetate)

Brief Summary. Consult the package insert for full prescribing information.

CONTRAINDICATIONS:
TAMBOCOR is contraindicated in patients with preexisting second- or third-degree AV block, or with right bundle branch block when associated with a left hemiblock (bifascicular block), unless a pacemaker is present to sustain the cardiac rhythm should complete heart block occur. TAMBOCOR is also contraindicated in the presence of cardiogenic shock or known hypersensitivity to the drug.

WARNINGS:
Proarrhythmic Effects. TAMBOCOR, like other antiarrhythmic agents, can cause new or worsened arrhythmias. Such proarrhythmic effects range from an increase in frequency of PVCs to the development of more severe ventricular tachycardia, e.g., tachycardia that is more sustained or more resistant to conversion to sinus rhythm, with potentially fatal consequences. In studies of TAMBOCOR, three fourths of proarrhythmic events were new or worsened ventricular tachyarrhythmias, the remainder being increased frequency of PVCs or new supraventricular arrhythmias. In patients with complex arrhythmias, it is often difficult to distinguish a spontaneous variation in the patient's underlying rhythm disorder from drug-induced worsening, so that the following occurrence rates must be considered approximations. Proarrhythmic effects were reported in 7% of patients treated with TAMBOCOR. Their frequency appears to be related to dose and to the underlying cardiac disease.
Among patients treated for sustained ventricular tachycardia (who frequently also had heart failure, a low ejection fraction, a history of myocardial infarction and/or an episode of cardiac arrest), the incidence of proarrhythmic events was 13% when dosage was initiated at 200 mg/day with slow upward titration, and did not exceed 300 mg/day in most patients. In early studies in patients with sustained ventricular tachycardia utilizing a higher initial dose (400 mg/day) the incidence of proarrhythmic events was 26%; moreover, in about 10% of the patients treated proarrhythmic events resulted in death, despite prompt medical attention. With lower initial doses, the incidence of proarrhythmic events resulting in death decreased to 0.5% of these patients. Accordingly, it is extremely important to follow the recommended dosage schedule (see Dosage and Administration).
Patients with less serious arrhythmias (chronic PVCs and nonsustained ventricular tachycardia) have experienced a lower rate of proarrhythmic events, about 3%, with 0.1% being fatal.
The relatively high frequency of proarrhythmic events in patients with sustained ventricular tachycardia and serious underlying heart disease, and the need for careful titration and monitoring, requires that therapy of patients with sustained ventricular tachycardia be started in the hospital. Hospitalization should also be considered for other patients with underlying structural heart disease (see Dosage and Administration).
Heart Failure. TAMBOCOR has a negative inotropic effect and may cause or worsen congestive heart failure (CHF), particularly in patients with cardiomyopathy, preexisting severe heart failure (NYHA functional class III or IV) or low ejection fractions (less than 30%). New or worsened CHF which might be attributed to TAMBOCOR therapy occurred in approximately 5% of patients studied in various trials. CHF developed rarely (1%) in patients who had no previous history of CHF. Exacerbation of preexisting CHF occurred more commonly in studies which included patients with class III or IV failure than in studies which excluded such patients. TAMBOCOR should be used cautiously in patients who are known to have a history of congestive heart failure or myocardial dysfunction. The initial dosage in such patients should be no more than 100 mg bid (see Dosage and Administration) and patients should be monitored carefully. Close attention must be given to maintenance of cardiac function, including optimization of digitalis, diuretic, or other therapy. In cases where CHF has developed or worsened during treatment with TAMBOCOR, the time of onset has ranged from a few hours to several months after starting therapy. Some patients who develop evidence of reduced myocardial function while on TAMBOCOR can continue on TAMBOCOR with adjustment of digitalis or diuretics, others may require dosage reduction or discontinuation of TAMBOCOR. When feasible, it is recommended that plasma flecainide levels be monitored. Attempts should be made to keep trough plasma levels below 0.7 to 1.0 μg/ml.
Effects on Cardiac Conduction. TAMBOCOR slows cardiac conduction in most patients to produce dose-related increases in PR, QRS, and QT intervals.
The PR interval increases on average about 25% (0.04 seconds) and as much as 118% in some patients. Approximately one third of patients may develop new first degree AV heart block (PR interval ≥0.20 seconds). The QRS complex increases on average about 25% (0.02 seconds) and as much as 150% in some patients. Many patients develop QRS complexes with a duration of 0.12 seconds or more. In the study, 4% of patients developed new bundle branch block while on TAMBOCOR. The degree of lengthening of PR and QRS intervals does not predict either efficacy or the development of cardiac adverse effects. In clinical trials, it was unusual for PR intervals to increase to 0.30 seconds or more, or for QRS intervals to increase to 0.18 seconds or more. Thus, caution should be used when such intervals occur, and dose reductions may be considered. The QT interval widens about 8%, but most of this widening (about 60% to 90%) is due to widening of the QRS duration. The JT interval (QT minus QRS) only widens about 4% on the average. Significant JT prolongation occurs in less than 2% of patients. There has been one case of Torsade de Pointes-type arrhythmia associated with TAMBOCOR induced QT prolongation and bradycardia.
Clinically significant conduction changes have been observed at these rates: sinus node dysfunction such as sinus pause, sinus arrest and symptomatic bradycardia (1.2%), second-degree AV block (0.5%) and third-degree AV block (0.4%). An attempt should be made to manage the patient on the lowest effective dose in an effort to minimize these effects (see Dosage and Administration). If second- or third-degree AV block, or right bundle branch block associated with a left hemiblock occurs, TAMBOCOR therapy should be discontinued unless a temporary or implanted ventricular pacemaker is in place to ensure an adequate ventricular rate.
Sick Sinus Syndrome (Bradycardia-Tachycardia Syndrome). TAMBOCOR should be used only with extreme caution in patients with sick sinus syndrome because it may cause sinus bradycardia, sinus pause, or sinus arrest.
Effects on Pacemaker Thresholds. TAMBOCOR is known to increase endocardial pacing thresholds and may suppress ventricular escape rhythms. These effects are reversible if flecainide is discontinued. It should be used with caution in patients with permanent pacemakers or temporary pacing electrodes and should not be administered to patients with existing poor thresholds or nonprogrammable pacemakers unless suitable pacing rescue is available.
The pacing threshold in patients with pacemakers should be determined prior to instituting therapy with TAMBOCOR, again after one week of administration and at regular intervals thereafter. Generally threshold changes are within the range of multiprogrammable pacemakers and, when these occur, a doubling of either voltage or pulse width is usually sufficient to regain capture.
Electrolyte Disturbances. Hypokalemia or hyperkalemia may alter the effects of class I antiarrhythmic drugs. Preexisting hypokalemia or hyperkalemia should be corrected before administration of TAMBOCOR.

PRECAUTIONS:
Drug Interactions. TAMBOCOR has been administered to patients receiving digitalis preparations or beta-adrenergic blocking agents without adverse effects. During administration of multiple oral doses of TAMBOCOR to healthy subjects stabilized on a maintenance dose of digoxin, a 13% ± 19% increase in plasma digoxin levels occurred at six hours postdose.
In a study involving healthy subjects receiving TAMBOCOR and propranolol concurrently, plasma flecainide levels were increased about 20% and propranolol levels were increased about 30% compared to control values. In this formal interaction study, TAMBOCOR and propranolol were each found to have negative inotropic effects; when the drugs were administered together, the effects were additive. The effects of concomitant administration of TAMBOCOR and propranolol on the PR interval were less than additive. In TAMBOCOR clinical trials, patients who were receiving beta blockers concurrently did not experience an increased incidence of side effects. Nevertheless, the possibility of additive negative inotropic effects of beta blockers and flecainide should be recognized.
Flecainide is not extensively bound to plasma proteins. In vitro studies with several drugs which may be administered concomitantly showed that the extent of flecainide binding to human plasma proteins is either unchanged or only slightly less. Consequently, interactions with other drugs which are highly protein bound (e.g., anticoagulants) would not be expected. TAMBOCOR has been used in a large number of patients receiving diuretics without apparent interaction. Limited data in patients receiving known enzyme inducers (phenytoin, phenobarbital, carbamazepine) indicate only a 30% increase in the rate of flecainide elimination. In healthy subjects receiving cimetidine (1 gm daily) for one week, plasma flecainide levels increased by about 30% and half-life increased by about 10%.
When amiodarone is added to flecainide therapy, plasma flecainide levels may increase two-fold or more in some patients, if flecainide dosage is not reduced. (See Dosage and Administration.)
There has been little experience with the coadministration of TAMBOCOR and either disopyramide or verapamil. Because both of these drugs have negative inotropic properties and the effects of coadministration with TAMBOCOR are unknown, neither disopyramide nor verapamil should be administered concurrently with TAMBOCOR unless, in the judgement of the physician, the benefits of this combination outweigh the risks. There has been too little experience with the coadministration of TAMBOCOR with nifedipine or diltiazem to recommend concomitant use.
Carcinogenesis, Mutagenesis, Impairment of Fertility. Long-term studies with flecainide in rats and mice at doses up to about eight times the usual human dose of 8 mg/kg/day (assuming patient weight of 50 kg) have not revealed any compound-related carcinogenic effects. Mutagenicity studies (Ames test, mouse lymphoma and in vivo cytogenetics) did not reveal any mutagenic effects. A rat reproduction study at doses up to 50 mg/kg/day (seven times the usual human dose) did not reveal any adverse effect on male or female fertility.
Pregnancy. Pregnancy Category C. Flecainide has been shown to have teratogenic effects (club paws, sternebrae and vertebrae abnormalities, pale hearts with contracted ventricular septum) and an embryotoxic effect (increased resorptions) in one breed of rabbit (New Zealand White) but not in another breed of rabbit (Dutch Belted) when given in doses about four times (but not three times) the usual human dose (assuming a patient weight of 50 kg). No teratogenic effects were observed in rats and mice given doses up to 50 and 80 mg/kg/day, respectively; however, delayed sternebral and vertebral ossification was observed at the high dose in rats. Because there are no adequate and well-controlled studies in pregnant women, TAMBOCOR should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Labor and Delivery. It is not known whether the use of TAMBOCOR during labor or delivery has immediate or delayed adverse effects on the mother or fetus, affects the duration of labor or delivery, or increases the possibility of forceps delivery or other obstetrical intervention.
Nursing Mothers. Limited data suggest that flecainide is excreted in human milk. Because of the drug's potential for serious adverse effects in nursing infants, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use. The safety and effectiveness of TAMBOCOR in children less than 18 years of age have not been established.
Hepatic Impairment. Since flecainide elimination from plasma can be markedly slower in patients with significant hepatic impairment, TAMBOCOR should not be used in such patients unless the potential benefits clearly outweigh the risks. If used, frequent and early plasma level monitoring is required to guide dosage (See Plasma Level Monitoring); dosage increases should be made very cautiously when plasma levels have plateaued (after more than four days).

ADVERSE EFFECTS:
The most serious adverse effects reported for TAMBOCOR, described in detail in Warnings section, were new or exacerbated ventricular arrhythmias which occurred in 7% of patients, and new or worsened congestive heart failure which occurred in approximately 5% of patients. In some patients, TAMBOCOR treatment has been associated with episodes of unresuscitatable ventricular tachycardia or ventricular fibrillation. There have also been instances of second- (0.5%) or third-degree (0.4%) AV block. Patients have developed sinus bradycardia, sinus pause, or sinus arrest, about 1.2% altogether (see Warnings). The frequency of most of these serious adverse events probably increases with higher trough plasma levels, especially when these trough levels exceed 1.0 μg/ml.
There have been rare reports of isolated elevations of serum alkaline phosphatase and isolated elevations of serum transaminase levels. These elevations have been asymptomatic and no cause and effect relationship with TAMBOCOR has been established. In foreign postmarketing surveillance studies, there have been rare reports of hepatic dysfunction including reports of cholestasis and hepatic failure, and extremely rare reports of blood dyscrasias. Although no cause and effect relationship has been established, it is advisable to discontinue TAMBOCOR in patients who develop unexplained jaundice or signs of hepatic dysfunction or blood dyscrasias in order to eliminate TAMBOCOR as the possible causative agent.
Incidence figures for other adverse effects are based on a multicenter efficacy study, utilizing starting doses of 200 mg/day with gradual upward titration to 400 mg/day. Patients were treated for an average of 4.7 months, with some receiving up to 22 months of therapy. In this trial, 5.4% of patients discontinued due to non-cardiac adverse effects.

Table 1
Most Common Adverse Effects in Patients Treated With TAMBOCOR in the Multicenter Study

Adverse Effect	Incidence in All 429 Patients at Any Dose	Incidence by Dose During Upward Titration: 200 mg/Day (N=426)	300 mg/Day (N=293)	400 mg/Day (N=100)
Dizziness*	18.9%	11.0%	10.6%	13.0%
Visual Disturbance†	15.9%	5.4%	12.3%	18.0%
Dyspnea	10.3%	5.2%	7.5%	4.0%
Headache	9.6%	4.5%	6.1%	9.0%
Nausea	8.9%	4.9%	4.8%	6.0%
Fatigue	7.7%	4.5%	4.4%	3.0%
Palpitation	6.1%	3.5%	2.4%	7.0%
Chest Pain	5.4%	3.1%	3.8%	1.0%
Asthenia	4.9%	2.6%	2.0%	4.0%
Tremor	4.7%	2.4%	3.4%	2.0%
Constipation	4.4%	2.8%	2.1%	1.0%
Edema	3.5%	1.9%	1.4%	2.0%
Abdominal Pain	3.3%	1.9%	2.4%	1.0%

*Dizziness includes reports of dizziness, lightheadedness, faintness, unsteadiness, near syncope, etc.
†Visual disturbance includes reports of blurred vision, difficulty in focusing, spots before eyes, etc.

In a trial in ambulatory patients with frequent premature ventricular complexes and nonsustained ventricular tachycardia utilizing a starting dose of 400 mg/day and a maintenance dose of 400-600 mg/day, the incidence of these adverse experiences was similar, except for dizziness (32%) and visual disturbances (28%).
The following additional adverse experiences, possibly related to TAMBOCOR therapy and occurring in 1% to less than 3% of patients, have been reported in acute and chronic studies: *Body as a Whole*—malaise, fever; *Cardiovascular*—tachycardia, sinus pause or arrest; *Gastrointestinal*—vomiting, diarrhea, dyspepsia, anorexia; *Skin*—rash; *Visual*—diplopia; *Nervous System*—hypoesthesia, paresthesia, paresis, ataxia, flushing, increased sweating, vertigo, syncope, somnolence, tinnitus; *Psychiatric*—anxiety, insomnia, depression.
The following additional adverse experiences, possibly related to TAMBOCOR, have been reported in less than 1% of patients: *Body as a Whole*—Swollen lips, tongue and mouth; arthralgia, bronchospasm, myalgia; *Cardiovascular*—angina pectoris, second-degree and third-degree AV block, bradycardia, hypertension, hypotension; *Gastrointestinal*—flatulence; *Urinary System*—polyuria, urinary retention; *Hematologic*—leukopenia, thrombocytopenia; *Skin*—urticaria, exfoliative dermatitis, pruritus; *Visual*—eye pain or irritation, photophobia, nystagmus; *Nervous System*—twitching, weakness, change in taste, dry mouth, convulsions, impotence, speech disorder, stupor; *Psychiatric*— amnesia, confusion, decreased libido, depersonalization, euphoria, morbid dreams, apathy.

HOW SUPPLIED:
TAMBOCOR is supplied as white, round, scored tablets containing 100 mg of flecainide acetate and embossed with RIKER on one side and TR 100 on the other side.

Manufactured by:
Riker Laboratories, Inc./3M
St. Paul, Minnesota 55144

No two are exactly alike.

Because body chemistry differs from person to person, we often need a choice of drugs to treat the same illness.

You've heard it said that no two snowflakes are exactly alike. The variety is endless. Much the same is true of the human body.

Take the case of two patients suffering from hypertension. Both under the care of the same physician, who prescribes the same medication for each. One patient responds to the medication while the other reports unpleasant side-effects. Thanks to the diversity of drugs available to treat this illness, the doctor is able to prescribe another medicine that works without the side effects.

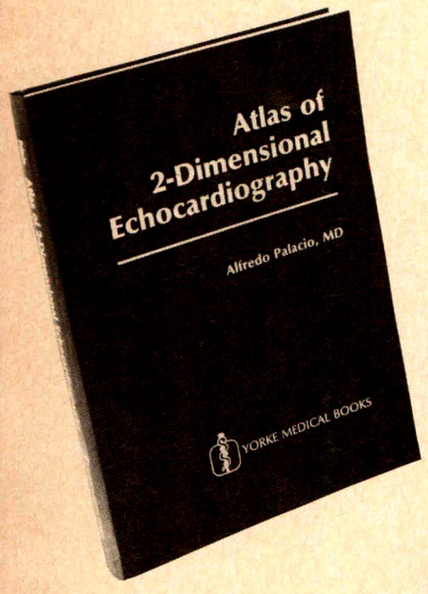
To maintain the high standards of quality care, and because some drugs work better than others on different people, it is essential to have this diversity.

America's research-based pharmaceutical companies are committed to providing a wide range of drugs of the highest quality to serve the public. Why? Because the public is made up of different people requiring different treatment—even when they suffer from the same illness.

Pharmaceutical Manufacturers Association

IF A NEW MEDICINE CAN HELP, WE'RE WORKING ON IT.

The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $69.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

Table of Contents

Foreword
Preface
Prologue
Introduction
EQUIPMENT
THE ECHOCARDIOGRAPHIC EXAMINATION
Parasternal position
  Longitudinal plane
  Transverse plane
Apical position
  Hemiaxial plane
  Axial plane
Subxiphoid position
  Transvascular plane
  Transcardiac plane
Suprasternal position
  Longitudinal plane
  Transverse plane
Final recommendations for the beginning technician
Special controls
Compendium of tomographic sections
DISEASES
Mitral stenosis
  Characteristics of the mitral stenosis in 2-dimensional echocardiography
  Longitudinal plane, long axis of the left ventricle
  Transverse plane, short axis
  Direction of future investigations
Mitral regurgitation
Tricuspid valve
Aortic valve and aortic root
Pulmonary valve
Intracardiac masses and tumors
Pericardial effusion
Ischemic heart disease
Congenital heart disease
Cardiomyopathies
Systemic arterial hypertension
MISCELLANEOUS
Valvular prostheses
Performance and volume of the left ventricle
Intracavitary cables and catheters
Bibliographic references

'ocan® SR (procainamide hydrochloride tablets)
JSTAINED RELEASE

efore prescribing, please see full prescribing information.
Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

IDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature entricular contractions, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial achycardia.

ONTRAINDICATIONS: Hypersensitivity to procainamide is an absolute contraindication. In this onnection, cross-sensitivity to procaine and related drugs must be borne in mind.

Procainamide should not be administered to patients with complete atrioventricular heart block. is also contraindicated in cases of second degree and third degree A-V nodal block unless an lectrical pacemaker is operative.

It has been suggested that procainamide be contraindicated in patients with myasthenia gravis.

ARNINGS: Granulocytopenia may follow the use of procainamide, and deaths from sepsis have ccurred. Leukocyte changes are most likely to occur during the first three months of therapy. During this time routine blood counts should be done at least every two weeks and thereafter at onger intervals throughout maintenance procainamide therapy. Complaints of malaise and aches a flu-type syndrome) are often reported in association with the granulocyte depression.

Patients should be instructed to report such symptoms promptly, as well as any soreness of nouth, throat or gums, unexplained fever, or symptoms of an upper respiratory tract infection. If hese should occur and a complete blood count indicates a granulocyte depression, procainamide herapy should be discontinued immediately and appropriate treatment instituted. Recovery of eukocyte count usually occurs within a few weeks.

The incidence of granulocytopenia appears to be higher with procainamide sustained-release ablets than with standard tablets.

RECAUTIONS: General — During administration of the drug, evidence of untoward myocardial esponses should be carefully watched for in all patients. In the presence of an abnormal nyocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, he ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization educes, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole s particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgment of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Serious hypotension can result from peripheral vasodilation and from decreases in cardiac output. At high plasma levels, procainamide may produce sinus tachycardia due to reflex sympathetic response to its hypotensive effect. Large doses may increase cardiac automaticity and can induce complete atrioventricular block, cardiac standstill, or ventricular extrasystoles that may proceed to ventricular fibrillation. These effects on the myocardium are reflected in the electrocardiogram: a widening of the QRS complex occurs most consistently; less regularly, the P-R and Q-T intervals are prolonged; and the QRS and T waves show some decrease in voltage.

Antinuclear antibodies (ANA) are often found in patients receiving long-term procainamide therapy. The induction of ANA appears to be independent of dosage. Patients with procainamide-induced increases in ANA titers may develop a syndrome resembling systemic lupus erythematosus (SLE). The mechanism of this syndrome is uncertain. Polyarthralgia, arthritic symptoms, and pleuritic pain are common symptoms; to a lesser extent fever, myalgia, skin lesions, pleural effusion, pericarditis, headache, fatigue, weakness, nausea and abdominal pain may occur. Rare cases of thrombocytopenia, Coombs' positive hemolytic anemia, increased SGOT, SGPT, and serum amylase have been reported which may be related to this SLE-like syndrome.

It is recommended that tests for systemic lupus erythematosus be carried out at regular intervals in patients receiving maintenance or prolonged procainamide therapy. The drug should be discontinued if there is a rising ANA titer or clinical symptoms of SLE appear. The SLE-like syndrome may be reversible upon discontinuation of the drug. If discontinuation does not cause remission of the symptoms, corticosteroid therapy may be effective. If the SLE-like syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, corticosteroid suppressive therapy may be used concomitantly with procainamide.

Information for Patient — Practitioners should give the following information and instructions to patients receiving Procan SR. 1. Do not crush or chew these tablets. Swallow them whole. 2. Take this medicine exactly as directed by your doctor. Do not miss any doses and do not take more medicine than ordered. Do not stop taking this medicine without first checking with your doctor. 3. If you miss a dose and remember within one hour or so, take it as soon as possible. Then go back to your regular dosing schedule. Do not take double doses. If you have any questions about this, check with your doctor. 4. Report to your doctor any flu-type symptoms, such as malaise and aches, as well as any soreness of the mouth, throat or gums, unexplained fever, skin rash, unusual bleeding or bruising, symptoms that resemble arthritis, or symptoms of an upper respiratory tract infection. 5. Do not be concerned if you occasionally notice in your stool something that looks like a tablet. In Procan SR (procainamide hydrochloride tablets), the drug is "held" in a wax core that has been specially designed to slowly release the drug for your body to absorb. When this process is completed the empty, nonabsorbable wax core, which looks nearly unchanged, is eliminated from your body. 6. Keep container tightly closed and store in a cool, dry place.

Procan® SR (procainamide hydrochloride tablets)

Laboratory Tests — Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals.

Routine blood counts are advisable during maintenance procainamide therapy. See WARNINGS for additional information.

Plasma concentrations of procainamide and NAPA should be monitored in patients with renal disease, hepatic disease, cardiac failure, or low cardiac output states.

Drug Interactions: 1. **Antiarrhythmics:** Concurrent use with procainamide may result in additive cardiac effects and/or additive toxic effects. 2. **Anticholinergics:** Procainamide enhances the anticholinergic effects. Extreme caution must be exercised with such a combination. 3. **Anticholinesterases:** Procainamide antagonizes the effect of anticholinesterases in myasthenia gravis, and paralysis returns. 4. **Antihypertensives:** Procainamide may potentiate the hypotensive effects of thiazide diuretics and other antihypertensive agents. Adjustment of dosage may be required. 5. **Histamine H_2-receptor antagonists:** It has been reported that histamine H_2-receptor antagonists such as cimetidine and ranitidine reduce renal clearance of procainamide and NAPA, resulting in higher plasma concentrations for longer durations. Caution should be exercised when administering these drugs concurrently, especially in the elderly, who have a reduced ability to clear all three. Dosage modification may be required. 6. **Neuromuscular Blocking Agents:** Procainamide potentiates the effects of skeletal muscle relaxants such as succinylcholine. It also may enhance or prolong the neuromuscular blocking activity of bacitracin, colistimethate, dihydrostreptomycin, gentamicin, gramicidin, kanamycin, neomycin, polymyxin B, streptomycin, and viomycin, producing respiratory depression.

Pregnancy — Pregnancy Category C. Animal reproduction studies have not been conducted with procainamide. It is also not known whether procainamide can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Procainamide should be given to a pregnant woman only if clearly needed.

Nursing Mothers — Procainamide and its major metabolite, NAPA, have been identified in breast milk. Caution should be exercised when procainamide is administered to a nursing woman.

ADVERSE REACTIONS: Most frequent, especially with large oral doses: 1. Anorexia; 2. Nausea; 3. Vomiting; 4. Diarrhea; 5. Urticaria; 6. Pruritus.

Less frequent: 1. Reactions in patients on long-term procainamide therapy: a. Antinuclear antibodies (ANA); b. Syndrome resembling systemic lupus erythematosus (SLE) (See PRECAUTIONS); 2. Hypersensitivity reactions: a. Angioneurotic edema; b. Maculopapular rash; c. Fever; d. Eosinophilia; e. Hypergammaglobulinemia.

Infrequent: 1. Granulocytopenia, sometimes resulting in death (See WARNINGS); 2. Convulsions; 3. Psychosis with hallucinations; 4. Confusion; 5. Mental depression; 6. Giddiness; 7. Lightheadedness; 8. Weakness; 9. Bitter taste.

Rare: 1. Hypotension; 2. A case was reported with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following a single dose of the drug.

OVERDOSAGE: Signs and Symptoms: Severe hypotension, ventricular fibrillation, widening of QRS complex, junctional tachycardia, intraventricular conduction delay, oliguria, lethargy, confusion, nausea, and vomiting.

Treatment: If ingestion is recent, emesis, activated charcoal, or gastric lavage may reduce absorption. Dopamine, phenylephrine, or levarterenol may be helpful in reversing severe hypotensive responses.

Management of overdosage includes symptomatic treatment with ECG and blood pressure monitoring. Procainamide toxicity can usually be treated, if necessary, by administering vasopressors after adequate fluid volume replacement. Intravenous infusion of 1/6 molar sodium lactate injection reportedly reduces the cardiotoxic effects of procainamide.

If procainamide toxicity causes severe hypotension and renal insufficiency, urinary elimination of procainamide and NAPA is decreased, and hemodialysis may be required. Hemodialysis significantly reduces the serum half-life of procainamide, and effectively removes procainamide and NAPA. Peritoneal dialysis is not effective.

It has been reported that one patient who ingested approximately 7 grams of procainamide hydrochloride recovered after treatment consisting of IV levarterenol, IV furosemide, attempted volume expansion with albumin, and hemodialysis. Also reported is the case of an elderly patient who recovered after ingestion of approximately 19 grams of procainamide hydrochloride. The patient was treated with IV isoproterenol and IV epinephrine. The latter report suggested that insertion of a ventricular pacing electrode is a reasonable precautionary measure in case high grade A-V block develops.

Storage Conditions: Protect from moisture. Store bottles below 30°C (86°F). Store unit-dose packages at controlled room temperature, 15°-30°C (59°-86°F).

Caution — Federal law prohibits dispensing without prescription.

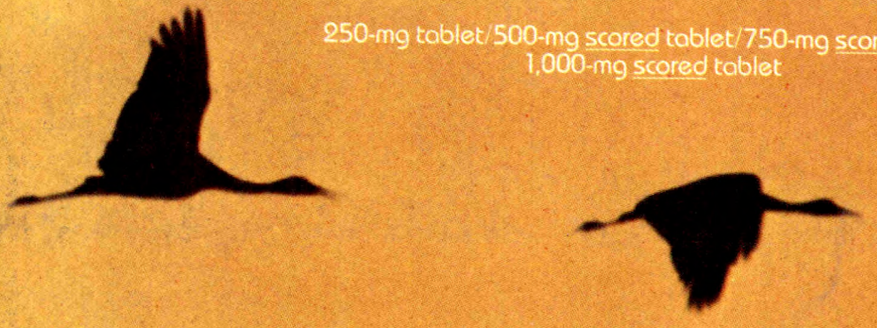
Return to a natural cardiac rhythm

SUSTAINED RELEASE Procan® SR (PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet/500-mg scored tablet/750-mg scored tablet
1,000-mg scored tablet



Now available "**UNIT OF USE**" A full month's supply (120 tablets) for each dosage strength

Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

- Administered half as often as conventional oral procainamide
- Wide versatility in cardiac conditions
- Can be used concomitantly with digoxin
- Ideal maintenance therapy

Procan SR... the original sustained-release oral procainamide

A Symposium: Silent Myocardial Ischemia and Infarction—Past, Present and Future

Introduction

DAVID P. LAULER, MD

To further our understanding of angina and silent myocardial ischemia, angina and infarction, members of the National Council on Silent Myocardial Ischemia & Infarction gathered to exchange the latest information on the prognosis and clinical management of patients with asymptomatic coronary disease. The meeting, held in Palm Beach, Florida, on September 11 to 12, 1987, was chaired and moderated by Dr. Peter F. Cohn. The presentations and discussions from this conference provide the source for this special issue of *The American Journal of Cardiology*.

The opening presentation by Dr. David Sheps focused on the abnormal pain perception documented in subsets of patients with silent myocardial ischemia. Results reported to date on endorphin/enkephalin measurements are discrepant, perhaps because different laboratory assay methods have been utilized in various types of patients.

A different perspective on silent myocardial ischemia was offered by Dr. Bimlendra Sharma from his analysis of the Hennepin County Medical Center study on out-of-hospital ventricular fibrillation. From 1974 to 1979, 1,070 patients were admitted to the emergency room of Hennepin County Hospital after an episode of out-of-hospital ventricular fibrillation. Of the 325 who were admitted to the coronary care unit, 150 survived. Among those selected for evaluation and long-term follow-up, 15 underwent preexercise and postexercise cardiac hemodynamic evaluation. There were no significant differences between patients in whom ventricular fibrillation was the initial manifestation of coronary disease and those previously known to have angina or infarction. Certain patients had a marked increase in left ventricular end-diastolic pressure without pain during exercise. Of the first 32 deaths that occurred during follow-up, 26 were sudden. Dr. Sharma's studies were interesting in that they provided objective electrocardiographic and hemodynamic evidence of exercise-induced, painless, myocardial ischemia.

Whereas these studies afforded a retrospective viewpoint of coronary artery disease, Dr. Lewis Becker gave a prospective analysis in his report of findings in asymptomatic siblings of patients with premature coronary artery disease. Because the material is being prepared for more detailed publication elsewhere, it is not included in this issue.

The significance of ST-segment depression recorded with Holter monitoring during daily activities was reported by Dr. Shlomo Stern in a study comparing patients with and without prior myocardial infarctions. These "ischemic" ST changes were associated with a higher rate of cardiac events in both groups, and reflected prognostic information, independent of stress tests, left ventricular ejection fraction or extent of coronary disease.

Dr. Stern's observation concerning the prognostic value of transient silent myocardial ischemia was reinforced during a presentation by Dr. Michael E. Assey, who, in his study of patients with documented coronary artery disease, found a significantly ($p = 0.05$) higher incidence (22%) of acute myocardial infarction in the subgroup with silent ischemia compared with that in the symptomatic group (4%). In this same study, the incidence of death was 11% in the group with

From the Yale University School of Medicine, New Haven, Connecticut.

silent myocardial ischemia compared with 0% in the group with angina.

Reports from Drs. Peter Cohn and Gary Gerstenblith addressed the prognostic significance of silent myocardial ischemia in asymptomatic patients and in those with unstable angina, respectively. A forthcoming publication elsewhere precludes their appearance in this supplement.

The rationale for the use of exercise radionuclide imaging for the detection of silent myocardial ischemia was presented by Dr. George A. Beller. His comments emphasized the greater sensitivity and specificity of this technique compared with exercise stress testing, and especially its ability to detect the onset of ischemia-induced perfusion abnormalities occurring before angina. Such perfusion abnormalities in post-MI patients identify a high-risk subset.

Dr. Mitchell Krucoff emphasized the quantitation of myocardial ischemia, using graphic projections of standard 12-lead electrocardiograms taken every 30 seconds and digital information storage. This permits viewing and analysis of data in 3 dimensions—ST levels, electrocardiographic lead and time—and also enables the calculation of a time-severity index for quantitating myocardial ischemic episodes. Dr. Krucoff and his associates noted that 78% of patients undergoing balloon angioplasty exhibited ST-segment deviations, which consisted of elevation in 67%. In the 19-hour period after angioplasty, 23% (65 patients) had ST deviation. Of this group, 38% had no symptoms, 22% had some symptoms, and 15% had a 15-minute or greater "silent" period before the onset of symptoms—a therapeutic window for aggressive intervention. Overall, 84% of patients after angioplasty had some evidence of silent myocardial ischemia.

The resurgence of interest in the entity of non-Q-wave infarction was evident during a presentation by Dr. Marcus A. DeWood, who reported that angiographically documented thrombus is found in 30 to 40% of patients with non-Q-wave infarction, and increases only slightly with time. The underlying mechanism for infarction in these patients may be platelet microaggregation or abnormal microvasomotion, or both.

Regarding therapy of patients with silent myocardial ischemia, Dr. Eliot Lazar presented Dr. William Frishman's data from a crossover trial that compared diltiazem with nifedipine in 20 patients with stable angina. Because it is to be published elsewhere, his presentation has been omitted.

This national meeting concluded with a focus on the "real-world" dilemmas of the practicing physician. Dr. John Schroeder presented selected cases from his own practice, which illustrated the role of exercise testing and ambulatory electrocardiographic evaluation in diagnosing silent myocardial ischemia in patients known or suspected to have coronary artery disease. Dr. Schroeder also included therapeutic considerations, ranging from the selective use of calcium channel blockers to consideration of coronary bypass surgery.

The bottom line for the practicing physician involves treatment of silent ischemia. Since a working definition of silent myocardial ischemia is readily grasped, i.e., ischemia in the absence of symptoms, physicians will probably be reformulating their therapeutic approach to such patients. Emphasis will be on totality of treatment, with "round-the-clock" coverage for both silent and nonsilent (angina or anginal equivalents) episodes. Because most episodes of silent myocardial ischemia occur during routine daily activities and at normal heart rates, suggesting that abnormal coronary vasomotion may be playing a role, greater use of the calcium-blocking agents can be anticipated. Which of the calcium blockers to specifically use will undoubtedly be determined by their overall adverse-effect profile, a particularly important feature when treating an asymptomatic disease.

Endorphins and Pain Perception in Silent Myocardial Ischemia

DAVID S. SHEPS, MD, ALAN HINDERLITER, MD, EDITH E. BRAGDON, MA, KIRKWOOD F. ADAMS, MD, MARGARET C. HERBST, RN, MSN, and GARY KOCH, PhD

Evidence suggests that endogenous opioids, particularly the β-endorphins and met-enkephalins, are closely involved in stress-induced analgesia and nociceptive pain control. Numerous investigations have been conducted to evaluate the role of opioids in silent vs symptomatic myocardial disease. There is good evidence to suggest that patients with asymptomatic ischemia have defective pain perception compared with those with angina; however, the precise role of the endorphin and enkephalin systems in this phenomenon remains to be elucidated. Possible sources for disparate study results include variation in patient populations, insensitive or improperly timed assay techniques, and differences in amount of ischemia.

(Am J Cardiol 1988;61:3F–6F)

The endogenous opioids are derived from larger precursor molecules. For example, pro-enkephalin A gives rise to several molecules of methionine (met)-enkephalin and 1 molecule of leucine-enkephalin. Dynorphin is created by cleavage of pro-dynorphin. Pro-opiomelanocortin is the progenitor of β-endorphin, the most potent endogenous opioid peptide yet discovered. Endogenous opioids are pharmacologically similar to, and show cross-tolerance with, morphine. Their action is reversed by naloxone.

Enkephalins, abundant throughout the central nervous system, are also found in the gut, sympathetic nervous system and adrenal medullary chromaffin cells. Dynorphin peptides are located similarly but are released from different cells; their function has not been clearly delineated. Beta-endorphins are produced in cells located in the arcuate nucleus of the hypothalamus and the pituitary. Each of these types of opioid peptides are contained in structures closely involved with nociceptive pain control.

Circulating endorphins are probably important in stress-induced analgesia. For instance, hypophysectomy or adrenomedullectomy in rats blunts opioid-dependent analgesia.[1,2] A recent study by Carr suggests that reflux of β-endorphins from blood into cerebrospinal fluid (CSF) contributes to an increase in CSF endorphin levels.[3] Endorphin levels are increased in response to exercise, in a magnitude that is directly related to the intensity of effort and degree of training. A case in point is the well-documented rise in plasma β-endorphin and met-enkephalin levels that occurs after running.

The evidence that psychological stressors influence circulating endorphin levels in humans is inconclusive. Reports have been published associating increased β-endorphin levels with the stress of an impending examination, and increased opioid activity has been observed in subjects engaged in cognitive and attentive tasks. In these studies, the amount of subjective stress experienced was closely related to opioid levels, suggesting a direct relation between endorphin response, psychophysiologic arousal and personality variables.[4]

Pain Perception in Patients with Asymptomatic Ischemia

The conflicting results of various investigations obscure the precise role of endorphins in the pathogenesis of silent myocardial ischemia.

In 1983, Droste and Roskamm[5] studied pain thresholds and tolerance in 20 patients with asymptomatic

TABLE I Summary of Studies Investigating the Effect of Naloxone on Pain Response in Patients with Myocardial Ischemia

	Droste & Roskamm 1984[5]	Ellestad & Kuan 1984[8]	Van Rijn & Rabkin 1986[7]
Subject	30 asymptomatic and 30 symptomatic on exercise testing	10 without angina; 7 = type I, 3 = type II (post–MI)	5 with exercise-induced angina
Type test	Cold pressor Electric skin stimulation Ischemic forearm tourniquet test Repeat testing after naloxone and placebo in 10 asymptomatics	2 multistage treadmill tests in 1 week, with naloxone injected before the 2nd test	3 multistage treadmill tests in 3 successive weeks: control; naloxone & placebo double-blind
Naloxone	2 mg before pain tests	2 mg before 2nd test	2 mg, 5 min before 2nd or 3rd test
Results	Threshold & tolerance levels slightly decreased after naloxone (forearm pain only)	No angina in any subject, with or without naloxone	Angina significantly earlier after naloxone, compared with placebo

MI = myocardial infarction.

ischemia and 22 patients with reproducible angina. All patients with silent myocardial ischemia had a higher threshold for electrical and forearm ischemic pain and a higher tolerance for cold pressor and forearm ischemic pain than those with some angina. The responses of the 42 subjects on the Freiberger Personality Inventory Test elicited different psychological profiles for the 2 groups, which the investigators believed might contribute to discrepant pain thresholds. In 1984, these same investigators used the same experimental measures to test pain response in 30 asymptomatic and 30 anginal patients with myocardial ischemia, and again found higher thresholds and tolerance levels for the aforementioned stressors in the asymptomatic group. To evaluate the role of endogenous opioids in this pain perception, 10 asymptomatic patients were given 2 mg of naloxone. Threshold and tolerance levels for forearm ischemic pain were significantly decreased and were no longer substantially different from those of angina patients. In fact, 2 of the 10 patients had chest pain after naloxone administration.[6] These results suggest—although they do not prove—that the lack of symptoms in patients with silent myocardial ischemia is due to a generalized hyposensitivity to pain, and that higher levels of pain tolerance might be mediated by endorphins.

Data concerning the effects of opioid antagonists on the perception of myocardial ischemia are conflicting (Table I). Van Rijn and Rabkin[7] reported that administration of 2 mg of naloxone resulted in the earlier appearance of chest pain during treadmill testing in 6 patients with exercise-induced angina. Ellestad and Kuan[8] and Cohn et al,[9] using a similar dose of naloxone, failed to precipitate angina in patients with silent ischemia during exercise testing. Furthermore, the investigators could not confirm that naloxone influenced the pain threshold in patients with reproducible effort-induced angina.

From these results, it is certainly possible that endorphins modify pain perception in patients with and without silent ischemia, and that other factors are responsible for the differences in pain sensitivity. Because the mechanism responsible for painless ischemia may be different in some patients than in others, conflicting results in studies evaluating the effects of naloxone may be due to patient selection. Also, the dose of naloxone used in these studies may not be adequate enough to block the relevant receptor sites.

In brief, there is good evidence to suggest that patients with painless myocardial ischemia have defective pain perception. In some cases, this defect is influenced by naloxone.

Beta-Endorphin Activity in Patients with Angina Versus Silent Ischemia: Study Design and Results

To test the hypothesis that endorphin secretion during exercise is related to the perception of chest pain in patients with coronary disease and angina, we measured plasma β-endorphin levels by radioimmunoassay before and after exercise in 25 patients with ischemia manifested by angina, a positive treadmill test result, and/or a positive result during exercise radionuclide study.

All patients rested at baseline for 1 to 2 hours. A supine radionuclide study was performed and blood obtained for β-endorphin analysis. Additional samples were obtained for endorphin analysis immediately after the patient performed a symptom-limited supine exercise test.

Overall results showed that the mean postexercise level of plasma β-endorphin—6.5 pmol/liter—was significantly higher than the baseline level of 4.92 pmol/liter. Fifteen patients had chest pain during exercise and 10 remained asymptomatic despite electrocardio-

TABLE II Correlation Between Plasma Endorphin Levels and Various Physiologic Parameters. Poststress Endorphin Levels Show a Positive Correlation with Time to Onset of Angina and a Negative Association with Occurrence and Duration of Angina

	Rest Endorphin	Poststress Endorphin	Difference
Angina	−0.24 (0.24)	−0.41* (0.04)	−0.24 (0.25)
Duration of angina	−0.35 (0.08)	−0.39* (0.05)	−0.15 (0.48)
Time to onset of angina	0.29 (0.16)	0.43* (0.03)	0.22 (0.28)
Maximal ST depression	−0.04 (0.86)	0.05 (0.81)	0.05 (0.81)
Time to ST depression (1 mm)	0.05 (0.81)	−0.08 (0.71)	−0.11 (0.62)
Rest ejection fraction (%)	0.29 (0.17)	0.48* (0.02)	0.28 (0.18)
Stress ejection fraction (%)	0.15 (0.48)	0.17 (0.42)	0.03 (0.88)
Peak work load (kpm/min)	−0.08 (0.69)	0.08 (0.71)	0.14 (0.50)

* $p \leq 0.05$.
Numbers in parentheses are p values.

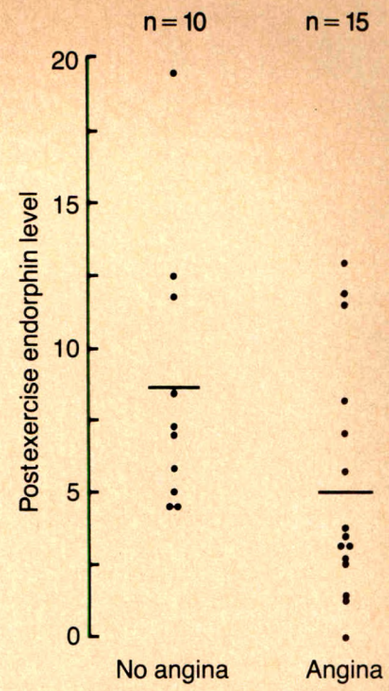

FIGURE 1. Postexercise plasma β-endorphin levels in patients who did not have angina vs those who did. The mean value in patients with angina is approximately 41% lower than it is in patients without angina despite considerable overlap.

TABLE III Summary of Studies Investigating the Plasma β-Endorphin Response in Patients with Myocardial Ischemia

	Glazier et al 1986[11]	Weidinger et al 1986[12]	Heller et al 1987[13]	Sheps et al 1987[10]
Subjects	6 asymptomatic 5 symptomatic	1 type I 4 type II 5 type III (2 post–MI) 6 normals	On exercise test: 10 anginal 12 angina-free (4 type I; 8 type II) 10 normals	25 anginal on exercise (22 in daily life; 16 post–MI)
Type test	Cold pressor Electric skin stimulation Ischemic forearm tourniquet test	2 symptom-limited upright bicycle tests, the 2nd after naxolone	Treadmill after 1 hour relaxation	Supine bicycle exercise
Blood	Baseline & at tolerance time for forearm ischemic pain	Rest, peak exercise, & 5 mins after recovery	Before, every 3 min during, & 10, 20 & 30 min after exercise	Immediately before & after exercise
Radioimmunoassay	Per Clement Jones et al and Jeffcoate et al*	New England Nuclear Kit	Immuno-nuclear Corp.	Immuno-nuclear Corp.
Results	β-endorphin levels similar during basal state & induction of forearm pain in both groups	Slight but no significant increase in β-endorphin levels postexercise in CAD pts and controls; no angina	β-endorphin levels elevated postexercise in all groups	Poststress β-endorphin levels significantly lower in anginal pts than in asymptomatic pts; positive correlation w/time to onset

CAD = coronary artery disease; MI = myocardial infarction; w/ = with.

* Clement-Jones V, Lowry PJ, Rees LH, Besser GM. Metenkephalin circulates in human plasma. Nature 1980; 283:295–297. Jeffcoate WJ, Rees LH, Lowry PH, Hope J, Besser GM. β-lipotrophin in human plasma and cerebrospinal fluid: radioimmunoassay evidence for γ-lipotrophin and β-endorphin. J Endocrinol 1978; 77:27P–28P.

graphic evidence of ischemia lasting an average of 3 minutes. A comparison of β-endorphin levels in those who had angina vs those who did not showed that β-endorphin levels were 41% lower in the angina group (Fig. 1). Postexercise β-endorphin levels were negatively correlated with occurrence and duration of angina and positively associated with time to onset of angina. No relation was found between endorphin levels and maximal heart rate × blood pressure product, work load, total work performed or ST-segment depression (Table II).[10]

Results of Other Investigations

Several other studies have measured plasma β-endorphin levels as a means of examining pain mechanisms in patients with coronary disease (Table III). Glazier et al[11] compared pain perception in patients with silent myocardial ischemia and chronic stable angina. Patients were divided into 2 groups, according to whether painless (group A) or painful ischemia (group B) was predominant. Patients in group A had episodes of ST-segment depression that were greater than 2 mm, occurring during 2 or more exercise tests; over 90% of episodes during repeat Holter monitoring were painless. Those in group B had more than 50% of episodes of ST depression occurring with pain during repeat Holter. Study participants were subjected to such stressors as cold pressor tests, ischemic forearm tourniquet tests and electrical stimulation.

Group A had a significantly higher threshold and tolerance for all stressors. The investigators compared β-endorphin, met-enkephalin, noradrenalin and adrenalin levels at basal state and during pain tolerance between both groups. There were no significant differences, and no correlation was obtained between these levels and pain characteristics. However, the investigators did not measure endorphin levels or any other hormones during spontaneous or exercise-induced ischemia.[11]

Weidinger et al[12] studied endorphin levels in 10 patients, 5 of whom were asymptomatic and 5 of whom had a mixed classification of type III chest pain. Patients performed 2 symptom-limited, submaximal bicycle exercise tests. Blood samples were obtained at rest, peak exercise and 5 minutes after recovery. Five minutes before the second test 1.2 mg of naloxone was injected. None of the study participants had angina, with or without naloxone, and patients in both groups had slightly higher β-endorphin levels during exercise.[12].

Heller et al[13] evaluated 3 groups of patients: normal control subjects, those with coronary disease and no history of angina, and those with coronary disease and exercise-induced angina. Patients exercised submaximally to the onset of angina. Blood samples were obtained immediately before exercise, every 3 minutes during exercise, and 10, 20 and 30 minutes after exercise. The groups demonstrated no differences in their β-endorphin response to exercise, all having a significant increase within 10 minutes after exercising.[13]

Conclusions

Differences in these study results could be due, in part, to discrepant or insensitive radioimmunoassay techniques, since some assays exhibit significant cross-reactivity to nonopioid peptides. Variation in patient populations—particularly in psychological profile, amount of baseline ischemia or degree of physical conditioning—is another possible source for inconsistency. The time of day that studies were performed and blood samples were obtained is also important, because β-endorphin levels are known to peak during morning hours[14]—the same time when ischemic activity is highest.[15]

It is hoped that further investigation will produce more consistent results and will clarify the role of endorphins in silent ischemia. Additional knowledge about defective pain perception in patients with asymptomatic coronary disease may hold the key to early and more effective diagnosis.

Discussion I

Dr. Cohn (*Stony Brook, New York*): That was an excellent overview, Dr. Sheps. The most striking observation is the degree of overlap in endorphin values in the various studies, and I wonder if we really are ever going to find a sharp differentiation.

Dr. Friesinger (*Nashville, Tennessee*): Dr. Sheps, can you comment further on endorphins and their measurement? Considering the large number of endorphins, in addition to their short half-life and extensive cross-reactivity, it certainly appears that evaluation could be a big problem.

Dr. Sheps (*Chapel Hill, North Carolina*): I agree. Three basic classes of endorphin peptides have been identified: β-endorphins, which are the most potent endogenous opioid peptides known; met-enkephalins; and the dynorphins. All 3 of these compounds are secreted in response to stress, both centrally and peripherally. We also know that there is a general relationship between analgesia and elevation in peripheral and central nervous system levels of β-endorphins and met-enkephalins. The role of dynorphins—including their analgesic potential—has not yet been defined. Obviously, the differences in radioimmunoassay techniques are important. The recent realization of the potential for cross-reactivity with nonopioid compounds has led to the development of assay techniques that are specific for β-endorphins and met-enkephalins. As you mentioned, half-life contributes to variable study results. The half-life of β-endorphin in the plasma is approximately 20 minutes. Improper timing of blood samples could result in erroneous measurement. One final point about endorphin studies is, very simply, are the correct substances being measured? Very few—in fact, none—of the studies have measured met-enkephalin levels during exercise or spontaneous ischemia. It may be that met-enkephalin, which is secreted by the central nervous system and the adrenal gland, is very important to pain perception. So, obviously, more work needs to be done if we are going to find an answer to these questions.

Dr. Krucoff (*Washington, D.C.*): Some of the information Dr. Sheps discussed may account for the phenomenon of walk-through and run-through angina that we are currently seeing in our health- and fitness-conscious society. Clearly, β-endorphin levels can be elevated with chronic conditioning. This may account for the ability of the marathon runner to push himself to the point of sudden death, without any ancillary warning signs or signals to slow down. The technical aspects of measuring these substances have given us conflicting information, but I think this area is an interesting and important one to pursue.

Dr. Pepine (*Gainesville, Florida*): One of the most significant correlations of Dr. Shep's study was between endorphin levels and duration of exercise to onset of angina. A key question appears to be, "What is the relationship between the onset of ischemia and the onset of anginal pain?" Are there any data examining the association between onset of ST depression and onset of angina in these individuals? In other words, do people who have ischemia marked by ST-segment shift, with a very short interval between ST-segment shift and perception of pain, have low endorphin levels compared with those who can exercise for several minutes after the onset of significant ST-segment depression before they have pain?

Dr. Sheps: That is a very good question . . . one that I have no data on. The correlations that we made with ST-segment depression were really examining time to 1 mm of ST-segment depression. In both patients with painful and painless ischemia, we found no relationship. All of our patients did have ST-segment depression for at least 2 minutes, whether or not they experienced angina. But we did not really look at endorphin levels and onset of angina—and that is obviously worthwhile doing.

Dr. Silber (*Birmingham, Alabama*): That's always a question I've had. One of the differences between the United States and Europe is that European anti-ischemic interventions are aimed at ST depression as an endpoint, whereas in the United States, therapeutic efficacy is determined by the onset of angina only. Since these endorphin studies have shown that angina is so subjective—unlike ST-segment depression—wouldn't you say that angina is a less reliable parameter for estimating anti-ischemic efficacy?

Dr. Sheps: Yes, certainly. But angina is still the only approved indication for treatment. Hopefully, that will change in the near future.

Dr. Kontos (*Richmond, Virginia*): Dr. Sheps, it seems to me that results of endorphin assay would vary according to the site involved. Isn't it possible that the really important concentration of endorphins is in the brain, and that if cerebrospinal fluid were measured, there might be a better correlation of results?

Dr. Sheps: That's obviously a good point. I would like to know what the endorphin and enkephalin levels are in the cerebrospinal fluid and also in the brain tissue itself, because even spinal fluid may not reflect what's occurring in the brain or dorsal horn of the spinal cord, where endorphin modulation appears to be centralized. Obviously, it is not practical to do this. There is a general relationship between plasma and brain levels of endorphins—at least in animals. These associations haven't been examined in man. But it certainly is possible that we are not measuring endorphin levels in the best location.

Dr. Kupersmith (*Louisville, Kentucky*): Do any of the antianginal agents we prescribe have an effect on endorphin levels?

Dr. Sheps: To my knowledge, no one has really examined that. Investigators who have studied patients on stable doses of medications have not found any correlations or differences among patient groups, according to levels of different drugs. I am not aware of any specific effect of medication on these parameters, other than nonpharmacologic agents such as caffeine, which can affect endorphin levels.

Six-Year Survival of Patients With and Without Painless Myocardial Ischemia and Out-of-Hospital Ventricular Fibrillation

BIMLENDRA SHARMA, MD, and RICHARD P. WYETH, MA

Out-of-hospital ventricular fibrillation (OHVF) is the most common cause of sudden cardiac death. Of 1,070 patients with OHVF who entered this study, 150 were discharged alive. Of this group, 120 were free of anoxic brain damage. Of these survivors, 67 (57%) had no previously demonstrated anginal symptoms. Treadmill stress testing revealed painless ST depression in 76% of these neurologically intact patients. Exercise ventriculography in a subset of 9 patients without angina before OHVF and in 6 patients with typical anginal symptoms revealed marked left ventricular dysfunction with ST depression in the absence of chest pain in all 15 patients. Sublingual nitroglycerin reversed this evidence of ischemia in the asymptomatic patients. Patients were followed for 6 years after discharge. No statistical difference in mortality could be demonstrated for patients who had previous anginal symptoms vs those who did not, nor was age a predictor of mortality. Women had the same risk of death as men at 2 years after OHVF, but a significantly higher risk by year 6. Myocardial infarction associated with OHVF did not predict lower mortality throughout the study. **(Am J Cardiol 1988;61:9F–12F)**

Sudden death, described over 2,000 years ago by Hippocrates, continues to be a major problem associated with heart disease. Out-of-hospital ventricular fibrillation (OHVF) is the most frequent cause of sudden cardiac death.[1] Whereas there is considerable controversy over the exact pathophysiologic mechanisms, myocardial ischemia appears to play a pivotal role in precipitating most episodes of OHVF.[2] Recent evidence suggests that myocardial ischemia in survivors of OHVF may be painless, whether or not these patients have preliminary angina pectoris.[3] This current study reports on survival of 1,070 patients who experienced OHVF, and compares the hemodynamics of a subset of survivors with and without previously diagnosed symptoms of coronary artery disease.

Methods

Study participants consisted of 1,070 patients who experienced out-of-hospital sudden cardiac death due to ventricular fibrillation, demonstrated on monitor strips obtained by emergency medical technicians. Concomitant occurrence of myocardial infarction (MI) with OHVF was determined independently by 3 cardiologists on the basis of creatine kinase-MB enzyme levels and serial 12-lead electrocardiographic data; in questionable cases, a technetium-99m pyrophosphate scan was also done. Patients were then classified as having definite MI, no MI, or uncertain MI associated with the admission episode of OHVF. Study participants were also grouped according to whether angina pectoris was present (symptomatic) or absent (asymptomatic) before the admission episode of OHVF.

A total of 150 patients survived hospitalization, 120 (11%) of whom avoided hypoxic brain damage (Table I). Before discharge, 108 of the 120 neurologically intact survivors underwent treadmill stress testing using standard Bruce protocol (stress testing was contraindicated in 12). A small subset of this group also underwent exercise ventriculography as an essential part of diagnosis 2 to 4 weeks after ventricular fibrillation.[3,4]

All patients were discharged on standard antiarrhythmic drug therapy. Of the 120 neurologically intact survivors, 3 were lost to follow-up. The remaining 117 were followed biannually for 6 years through personal interview or telephone inquiry to either the patient or the patient's physician, or both. Survival curve analy-

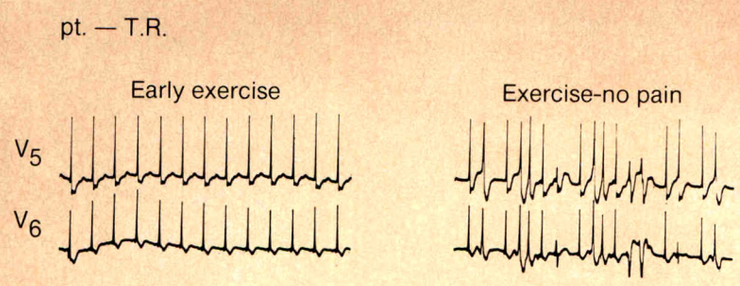

FIGURE 1. Electrocardiogram (leads V_5–V_6) from a survivor of out-of-hospital ventricular fibrillation during a treadmill stress test using the Bruce protocol. Early exercise (stage I) showed normal sinus rhythm with ST depression. At stage II (exercise, no pain), ST depression increased and ventricular ectopy developed in the patient.

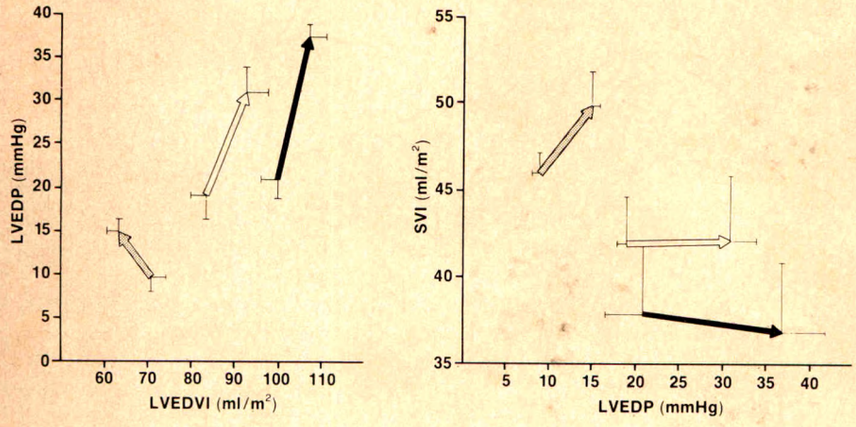

FIGURE 2. Changes in left ventricular end-diastolic pressure (LVEDP)-volume relation from rest to exercise (*left*), and changes in a modified Frank-Starling function curve (*right*). *Open arrows* show the direction of change seen with exercise in asymptomatic patients, symptomatic patients (*closed arrows*) and normal subjects (*stippled arrows*). The direction of change for both asymptomatic and symptomatic patients is markedly different from normal subjects and indicates severe diastolic and systolic dysfunction with exercise in survivors of out-of-hospital ventricular fibrillation. LVEDVI = left ventricular end-diastolic volume index; SVI = stroke volume index.

TABLE I Hospital Course of Patients with Out-of-Hospital Ventricular Fibrillation

Patient Status	Number	%
Brought to ER	1,070	100
Declared dead in ER	745	70
Transferred to CCU	325	30
Discharged alive	150	14
Neurologically intact	120	11
Anoxic brain damage	30	3

CCU = cardiac care unit; ER = emergency room.

sis used the method of Cutler and Ederer.[5] Chi-square analysis and Student *t* test were used as appropriate.

Results

Results of predischarge treadmill stress testing showed ST-segment depression without angina in 91 patients (76%); in 10% of patients, angina accompanied ST-segment depression. In 17 patients (14%) there was no ST depression. Of these 91 patients, 36 (40%) had, with further exercise, evidence of ventricular ectopy associated with painless myocardial ischemia. No patient had dysrhythmia without evidence of myocardial ischemia (Fig. 1).

In 15 of the neurologically intact survivors (9 asymptomatic, 6 symptomatic), exercise ventriculography was performed. A decrease in both diastolic and systolic left ventricular function was observed during submaximal exercise in both groups (Fig. 2). This exercise was painless in all 15 patients, despite a significant increase in ST depression in asymptomatic patients. When sublingual nitroglycerin was given to 6 of these asymptomatic patients and a second but identical exercise test completed, there was a reduction in left ventricular end-diastolic volume, from 102 ± 24 ml/m^2 to 81 ± 19 ml/m^2 (difference not significant). End-systolic volume also decreased, from 57 ± 15 ml/m^2 to 36 ± 16 ml/m^2 ($p < 0.008$). This improvement in left ventricular function was accompanied by a significant reduction in ST depression, from 0.24 ± 0.16 mV to 0.07 ± 0.14 mV ($p < 0.01$) and was reflected in the improvement of stroke volume, from 43 ± 9 ml/m^2 to 50 ± 7 ml/m^2 ($p < 0.01$). Thus, these asymptomatic patients showed hemodynamic and electrocardiographic improvement with nitroglycerin, despite the lack of typical angina pectoris (Fig. 3).

Two years after discharge, 85 of the 117 patients (73%) were alive. Of the 32 patients who died, 26 (81%) subsequently succumbed to sudden cardiac death, 4 had congestive heart failure and 2 died from noncardiac causes (Fig. 4). By year 6, an additional 34 survivors of OHVF had died. Of these 34 deaths, 8 (24%) were sudden cardiac death. Thus, overall survival for these patients was 44% at 6 years. Of the 56% mortality rate observed at 6 years, 30% of all deaths could be attributed to another episode of OHVF. MI associated with the admission episode of OHVF did not influence long-term survival and was not protective (Fig. 5).

Survival for symptomatic and asymptomatic patients at 2 and 6 years was similar. There was no difference in the percentage of female vs male survivors at 2

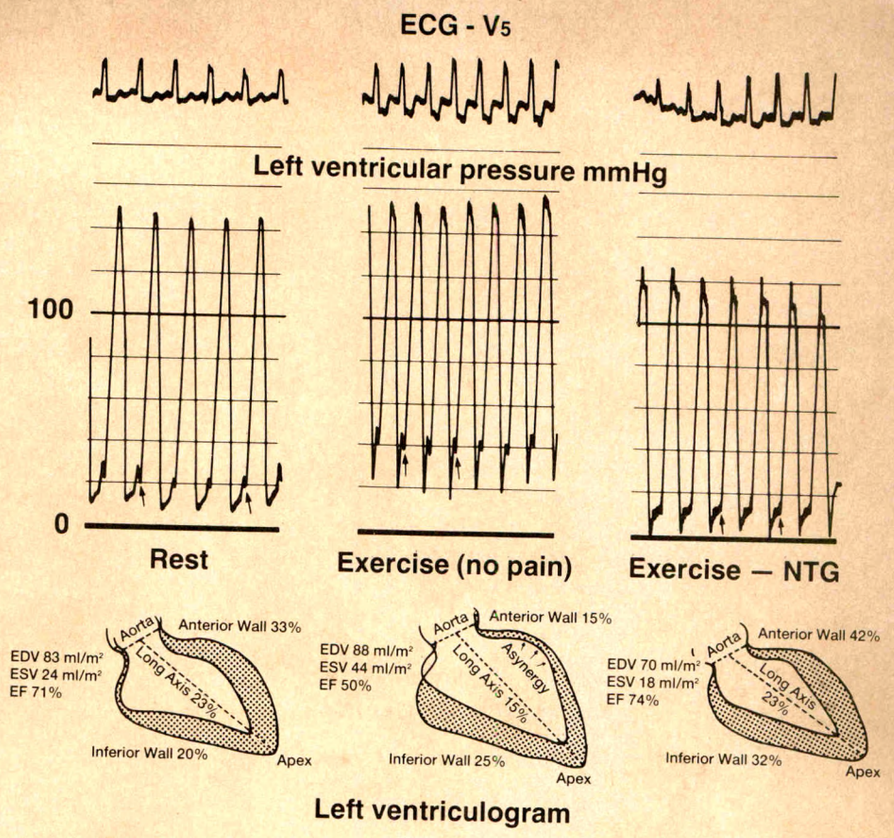

FIGURE 3. Simultaneous recording of chest lead V_5, left ventricular pressure, and ventriculogram from an asymptomatic patient during supine bicycle exercise indicating electrocardiographic, hemodynamic and left ventriculographic evidence of painless myocardial ischemia. Note the development of ST depression, increased end-diastolic pressure (*arrows*), decreased ejection fraction, and development of anterolateral asynergy with exercise. A reversal of this global and regional left ventricular dysfunction was seen at exercise after 150 μg of sublingual nitroglycerin (NTG). ECG = electrocardiogram; EDV = end-diastolic volume; EF = ejection fraction; ESV = end-systolic volume.

years, but by year 6, there was a marked increase in deaths among women. Age was nondiscriminatory at both 2 and 6 years (Table II).

Discussion

This study shows that sudden cardiac death associated with OHVF is profoundly morbid, with only 30% of patients surviving the initial event. About half of those who initially survived OHVF in our study died in the hospital. This is similar to earlier reports.[6]

The current results indicate that MI occurs in at least half of the patients who survive OHVF. Data from studies done in survivors may be more reliable than than those obtained by trying to determine the occurrence of myocardial ischemia in those who die from OHVF.[2] Our findings further suggest that the concomitant occurrence of MI with an episode of OHVF does not alter the prognosis for 6-year survival. This differs from the classic works of Baum et al[7] and Schaffer and Cobb.[8] This contrast may be due to the difference in enzymatic criteria for MI, which, in 1974, used lactate dehydrogenase and serum glutamate-oxaloacetate transaminase instead of the more definitive creatine kinase-MB currently used.

Our results from survivors of sudden death suggest that while women who experience OHVF are at the same risk for cardiac death 2 years after the event, they are at significantly higher risk than their male counterparts by the sixth year. It is well documented that men are at a much higher (approximately 4-fold) risk for sudden death than women.[9] The women in our study

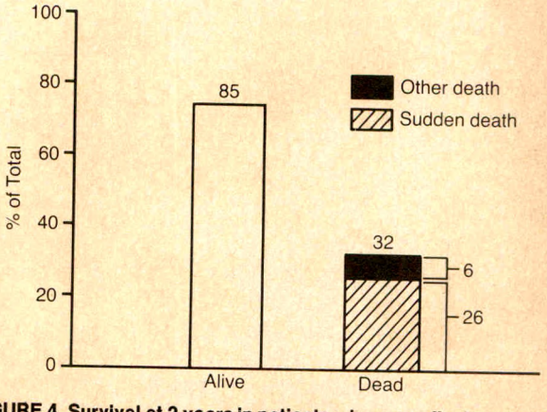

FIGURE 4. Survival at 2 years in patients who were discharged after an episode of sudden cardiac death associated with out-of-hospital ventricular fibrillation. The numbers *above* and to the *right* of the bar graphs are numeric totals.

may also represent an atypical cohort by virtue of their entry into the study. It is also possible that the small number of women in this study has produced a statistical artifact due to small sample size. The results of the current study do indicate that once an episode of OHVF has occurred, there is no statistical difference in survival, from the time of hospital discharge to the sixth year, in patients with either typical symptoms of angina or painless myocardial ischemia.

The induction of dysrhythmia with treadmill exercise as seen in this study was invariably associated

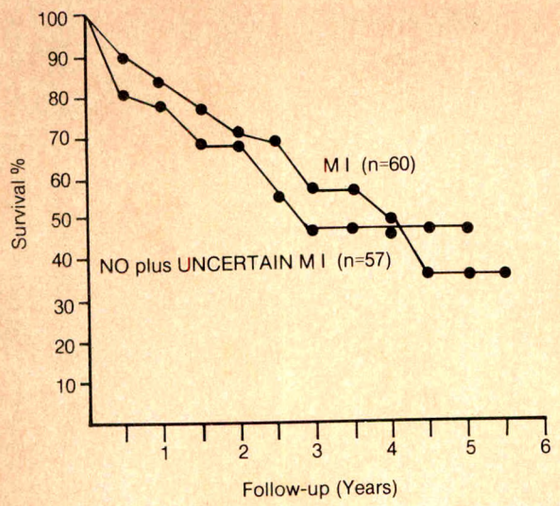

FIGURE 5. Long-term survival curve of patients with concurrent myocardial infarction (MI) and out-of-hospital ventricular fibrillation. Regardless of status, there was no statistical difference in survival throughout the follow-up period.

TABLE II Six-Year Prognosis by Group in Survivors of Out-of-Hospital Ventricular Fibrillation

Group	Number (% of Total Survivors at Discharge)	Number (% Survival of Group)	
		Year 2	Year 6
Total	117 (100)	73 (85)	44 (51)
Men	102 (87)	73 (74)	48 (49)
Women	15 (13)	11 (73)	2 (13)*
Asymptomatic	67 (57)	67 (45)	39 (26)
Symptomatic	50 (43)	80 (40)	50 (25)
<49 years	11 (9)	11 (100)	9 (82)
≥49 years	106 (91)	70 (74)	40 (42)

* $p < 0.01$.

with electrocardiographic evidence of painless myocardial ischemia. Experimental evidence has demonstrated that acute ischemia and submaximal exercise may induce ventricular fibrillation.[10] There is also recent clinical demonstration of ventricular fibrillation induced by painless myocardial ischemia during exercise testing.[11] Evidence shows that myocardial ischemia may be painless, yet produce marked left ventricular dysfunction in patients with and without documented coronary artery disease.[3]

Severe coronary artery disease is found in most patients after OHVF, both in those who survive and those who do not.[2,12] Sudden cardiac death may result from coronary artery disease that induces platelet aggregation, which in turn causes vasospasm and thrombus formation.[13–15] In fact, it has been possible to prevent ventricular fibrillation in a canine model of sudden cardiac death by preventing coronary thrombosis with prostacyclin.[16] The duration of such vasospasm or thrombic coronary occlusion, or both, may thus determine if MI is associated with sudden cardiac death.

From their survey of trials on the use of platelet-suppressive drugs after MI, Gelman and Mehta[14] suggest that the use of antiplatelet therapy in post-MI patients at high risk for sudden death may be beneficial. Based on current data, it may be advantageous to offer all survivors of OHVF a therapeutic regimen that includes antiplatelet agents and vasodilators.

Discussion II

Dr. Kennedy (*St. Louis, Missouri*): Dr. Sharma, I was looking at the defibrillation data. One of the things that immediately comes to mind is the Medic I study in Seattle.[1] Schaffer and Cobb reported a mortality of 25% to 35% in the first year for patients with primary ventricular fibrillation—not associated with myocardial (MI) or secondary ventricular fibrillation—who had no associated infarction. The group that sustained necrotic damage had a much lower mortality. Did you have a reason why?

Dr. Sharma (*Little Rock, Arkansas*): Schaffer and Cobb, as well as Baum, collected their data in 1974.[1,2] At that time, the diagnosis of MI was not as accurate as it is currently. The data I presented specifically addressed the lack of difference in mortality rates between patients with and without MI. Our diagnosis of MI was based on the independent observations of 3 cardiologists, unaware of the others' interpretations. Serial electrocardiogram (ECG) and creatinine kinase MB (CK-MB) enzyme determinations were analyzed. If the diagnosis was not unanimous, technetium-99 pyrophosphate scintigraphy was done. Even then, we were not able to determine if MI had occurred in 14 of the 117 patients we followed. That is, in 12% of our patients, we could not be certain if enzyme increases were due to resuscitation, with minimal or no ECG changes.[3] Our data seem to indicate that MI affords no protection. The incidence of sudden death through the sixth year of this study was no different for patients who had concomitant MI vs those who did not.

Dr. Kennedy: So your findings are consistent when you divide the 2 subpopulations?

Dr. Sharma: Yes, I am not sure that the 1974 diagnosis of certain infarction or no infarction, based on serum glutamic-oxaloacetate transaminase/lactate dehydrogenase, was as reliable as it is currently, using CK-MB. This may account for the difference in mortality in our vs Schaffer and Cobb's data.

Dr. Kennedy: During exercise, did the presence or absence of ST-segment changes in any subpopulation influence outcome?

Dr. Sharma: We had ST-segment changes in 76% of patients during submaximal exercise.[3] Had we exercised patients maximally—which we didn't do because we wanted to approximate a real-life situation—we might have seen more ST-segment changes.

Dr. Sheps (*Chapel Hill, North Carolina*): How do you relate finding evidence of silent ischemia in the majority of the survivors of sudden death to the relatively rare occurrence of serious arrhythmia in patients with a lot of silent ischemia before sudden death? If frequent episodes of silent ischemia are a risk factor for arrhythmic sudden death, why aren't we seeing more arrhythmias in patients with a lot of silent ischemia?

Dr. Sharma: I don't have an answer to that. But over 6 years of follow-up, we have seen cardiac arrest recur in many of these patients (27%). There is a matter of timing—ischemia during exercise and arrhythmia have to be timed in a certain manner for sudden death to occur.

Dr. Cohn (*Stony Brook, New York*): I would also like to answer that question, because it comes up repeatedly. In other words, if silent ischemia is so bad, why don't we see more ventricular tachycardia with it? We have to look at the other side of the coin. How often does ventricular tachycardia occur with angina? Not often, yet it is the patient with angina and coronary atherosclerosis who is going to develop ventricular fibrillation or some other manifestation of electric instability. To find a link in a given situation is unusual, however. Dr. Sharma obviously was looking from the retrospective side—his patients had "died." How to recognize which patients are going to progress to sudden death is, of course, the $64,000 question. Dr. Sharma was able to show a sudden death population that had no history of heart disease, but definitely had silent ischemia. We don't know whether his patients had silent ischemia before sudden death, but autopsy data in other studies have shown not only extensive atherosclerosis, but also scars of small infarctions that went unrecognized. We need a combination of prospective and retrospective data to make the case as convincing as possible. I should add, too, that other investigators have data similar to yours, Dr. Sharma, but they have not yet reported them.

Dr. Beller (*Charlottesville, Virginia*): In a study undertaken at the University of Virginia, we looked at a group of 38 patients with recurrent sustained ventricular tachycardia. Symptom-limited stress thallium-201 testing confirmed that very few had exercise ischemia. Also, in this study, there was no difference in the prevalence of thallium-201 redistribution in those who did or did not have exercise-induced ventricular tachycardia.[4] In contrast, patients who had out-of-hospital cardiac arrest or who developed exercise-induced ventricular fibrillation on treadmill testing had a higher prevalence of ischemia compared with those with inducible sustained ventricular tachycardia. Patients with sustained ventricular tachycardia who are inducible during exercise testing usually have marked myocardial damage, characterized by a significantly decreased ejection fraction, multiple persistent thallium-201 defects consistent with myocardial scar, and very little thallium-201 redistribution.

Dr. Stern (*Jerusalem, Israel*): It is very important that the possible association between ischemia and arrhythmia came

up during this meeting. For the past 15 years I have been searching for such a link, to no avail. In this audience, we have personal experience of tens of thousands of ischemic episodes, and anyone who has seen an ischemic episode that continues with arrhythmia should raise his hand. I can't raise mine. This relationship between arrhythmias and ischemia came up recently during a Holter monitoring workshop at an internationally attended arrhythmia meeting. Those present also confirmed that they rarely, if ever, see an association between ischemia and arrhythmia. So I think that we have to relinquish the concept that arrhythmia induces ischemia or vice versa.

Dr. Deanfield (*London, England*): I would agree with Dr. Stern that the association between transient ST-segment depression and malignant ventricular arrhythmias—if present at all—is very loose and not strongly related to the cause of death in these patients. We have to try to differentiate between a frequent phenomenon in patients with coronary artery disease and the end-stage event, which can only happen once. There is a very poor association between transient ST-segment depression and the end event. That doesn't tell us that the final event in these patients is not associated with a very severe ischemic insult, and long-term follow-up sometimes reveals evidence of transmural myocardial ischemia and ST-segment elevation. Those patients have a very poor prognosis; in their situation, the association between ST elevation and ventricular tachycardia is much tighter than it is with frequent episodes of transient ST-segment depression. So the lack of good correlation between ST depression and malignant ventricular arrhythmias doesn't say anything about what is happening as the terminal event in those patients. It may still be related to severe transmural myocardial ischemia as an end event.

Dr. Cohn: The problem of sudden death in the general population is a real one. We've estimated in this country, for example, that at least 50,000 people a year die suddenly who have no previous history of cardiac disease, and yet at autopsy have extensive disease. There's a distinct population at risk, and even though there are technological, ethical and practical problems about identifying these patients before they present with infarction or death, it is not acceptable for us to simply to throw up our hands and say, "Well, the problems are insurmountable, so let's look at something else."

Dr. Sharma: The same thing has bothered me for a long time. During angioplasty, we find that while the chest ECG may not show evidence of ischemia, other epicardial leads show tremendous ST elevation/ST depression.[5,6] It is possible that surface ECGs do not always show evidence of myocardial ischemia.

Dr. Deanfield: That isn't actually the issue here, because you are detecting it, but are failing to show an association. All I'm saying is that the lack of close relationship between transient ST-segment depression and ventricular arrhythmias during everyday activities should not detract us from the concept that the terminal event may be related to transient ischemia. Those are not mutually exclusive observations.

Dr. Silber (*Birmingham, Alabama*): Yes, but whether the terminal event might still be related to ischemia is hypothetical. I agree with Dr. Stern's belief that ischemia is not related to arrhythmias. The same is true of exercise-induced ischemia. My colleagues and I have studied over 300 patients with proven coronary artery disease and significant ST-segment depression during exercise after withdrawal of all anti-ischemic medication, and only 1 of these had ventricular fibrillation during exercise testing.

Dr. Krucoff (*Washington, D.C.*): I think we have to consider 2 other terms: the very significant majority vs a potentially significant minority. I agree with Dr. Stern that no one would claim to have frequently seen an association between ST changes and arrhythmias. On the other hand, we certainly see plenty of association between reperfusion phenomena and arrhythmias. This is closer to what Dr. Deanfield was mentioning, namely, that transient, very severe, transmural myocardial ischemia, when suddenly relieved (which clearly happens endogenously through spasm or platelet-mediated thrombosis and sudden reperfusion), can result in very profound primary ventricular fibrillation and other arrhythmias. That's clearly not the majority of people in whom we document ischemic episodes, but it is at least a significant minority of persons in whom some sort of intervention is very important.

Dr. Friesinger (*Nashville, Tennessee*): The exercise test is, by any criteria, a relatively poor diagnostic test for ischemia. However, at least in stable subsets, it's a relatively powerful prognostic tool, in terms of what we can learn from the exercise load and duration.

Dr. Cohn: There is a definite incidence of coronary disease and fatal events in people who have negative exercise tests. The risk ratio is obviously much higher in those with the positive test, but those with negative tests also are having events, and they outnumber the positive responders in sheer volume. The question is whether the exercise test is missing the diagnosis, which is certainly possible. My point is that, if we recommend cardiac catheterization for asymptomatic patients, we should have very strong noninvasive evidence of disease before subjecting people to the risks of the procedure. I don't have any answer yet on how to approach the patient we suspect of being at risk but who has negative, noninvasive indices. Yes, some of those people will go on to disease, but I'm much more concerned with the patient who has a positive noninvasive test. Someone once said to me, "Well, sudden death is fine. I mean, it's a quick, painless end, so therefore we shouldn't be that concerned with it." And it's true that it's not a bad way to die when you are 75 or 80, but not when you're 40 or 45. That's why I feel we're obligated to continue to investigate, even though it's fraught with problems. Dr. Becker, did you have any comments?

Dr. Becker (*Baltimore, Maryland*): I would agree with that idea. The more we know, the easier it will be to finally make these decisions. In terms of the clinical care of a patient, I agree that it would not be desirable to catheterize everybody who, by virtue of age or risk factors, is in a high-risk group. We'd like noninvasive tests to specifically indicate that the patient has an increased likelihood of having cardiac disease. We obviously need to continue our efforts at technological improvements to facilitate detection. Hopefully, tomographic thallium is one approach to this problem, but it has problems as well.

Dr. Pepine (*Gainesville, Florida*): One of the topics that's come up repeatedly, relative to both silent and painful ische-

mia, is what the signal is for pain, and whether or not the heart is sending out a signal. My understanding of nociceptive receptors is that they respond to either metabolic stimuli or changes in mechanics. Long ago, metabolic stimuli for pain perception were ruled out, relative to the heart, leaving the possibility of a mechanical stimulus. Could a change in left-ventricular diastolic properties, reflected in end-diastolic pressure or left atrial pressure, be the mechanical stimulus for pain perception? Your data show very clearly that these people have a tremendous rise in left-ventricular end-diastolic pressure during exercise without reporting pain, so it's probably not the absolute pressure, but could some characteristic of the pressure change or the end-diastolic volume change account for pain perception?

Dr. Sharma: I don't have these data, but I do have a group of patients who were first exercised submaximally with no ischemia, and showed a rise in left-ventricular diastolic pressure that was almost abnormal. They continued to exercise, had another left ventriculogram run, and had angina. But, the hemodynamics, volumes, and pressures were higher in that group. The same asymptomatic submaximal exercise test in coronary artery disease can become symptomatic during continued exercise.

Dr. Amsterdam (*Davis, California*): I would like to refer back to the ischemia-arrhythmia issue. The relative lack of ventricular ectopic activity with exercise-induced ischemia doesn't eliminate ischemia, *per se*, as a cause of arrhythmias. Exercise is a complex function with inhibitory (ie, tachycardia) and provocative (ie, ischemia, sympathetic activation) effects on ventricular ectopic activity, and the occurrence of arrhythmias is a function of the interplay between these factors. There are examples in the literature of the association between ischemia and lethal arrhythmias during ambulatory ECG monitoring.[7] The relationship is unclear, but appears to be definite in some instances. Also, as Dr. Cohn says, absence of arrhythmias during ST-segment alteration on ambulatory ECG does not preclude an association between these factors in the final clinical event. It may depend on the presence of the proper constellation of factors at a given time. Dr. Sharma's data relate to this issue. It is not surprising that patients with coronary artery disease who have survived cardiac arrest have silent ischemia. The latter is prevalent in a majority of the coronary population as a whole, and therefore, in itself, does not identify risk of sudden death. So, as has already been stated here, we are currently unable to identify the patient with silent myocardial ischemia who is at increased risk for sudden death.

Dr. Sharma: I agree. What I have shown today is the association of ischemia in patients with sudden death from ventricular fibrillation. But, during our treadmill testing, I also showed that stage I patients have ischemia, and stage II have multiple bizarre arrhythmias, but it doesn't happen in every patient we exercise. As you said, timing and situation have to be there, and the considerations are multifactorial.

Clinical Outcome of Silent Myocardial Ischemia

SHLOMO STERN, MD, ALEX GAVISH, MD, DAN ZIN, MD, and DAN TZIVONI, MD

Asymptomatic coronary artery disease can be detected by an abnormal electrocardiogram at rest, by a positive exercise test result unaccompanied by pain, or by the demonstration of silent ischemic episodes during daily activities. However, the clinical outcome of patients with silent myocardial ischemia has not yet been clearly defined. In a study of 356 patients with documented coronary disease—211 of whom had previous myocardial infarction—the prognostic information of spontaneous ST-segment depression was found to be independent of that associated with a positive exercise test result, ejection fraction, and extent of arteriographically documented coronary artery disease. Patients with asymptomatic ischemia had a higher coronary event rate than those without ischemia. Cardiac event rates followed a similar pattern for patients with silent, symptomatic and mixed ischemia—whether or not there was previous myocardial infarction.

(Am J Cardiol 1988;61:16F–18F)

Asymptomatic coronary artery disease can be detected by an abnormal resting electrocardiogram (ECG), by a positive exercise test result unaccompanied by pain, or by the demonstration of silent ischemic episodes during daily activities. However, the clinical outcome of patients with silent myocardial ischemia has not yet been clearly defined. The ECG at rest enabled Froelicher et al[1] to diagnose silent ischemic heart disease in asymptomatic airmen. Subsequent study showed that many of these 78 airmen had significant occlusions in their coronary arteries, and that during an average follow-up period of 17 months, 22 had overt signs of ischemic heart disease, 4 had myocardial infarction (MI) and 2 died suddenly.[2]

Silent myocardial ischemia is frequently observed during exercise testing. ST depression, without accompanying pain, was detected in 50% of 540 patients who had a positive result during the Bruce protocol treadmill test.[3] In most of the patients who had chest pain ischemia preceded the pain. Weiner et al[4] analyzed the data of 2,982 patients from the Coronary Artery Surgical Study. They demonstrated that in patients with silent myocardial ischemia during exercise testing, the extent of coronary artery disease and the 7-year survival rate were similar to that of patients with symptomatic ischemia during exercise testing. The prognosis was determined primarily by the extent of coronary disease, and not by the presence or absence of pain during a positive treadmill test.

In a study from the National Institutes of Health involving 147 asymptomatic or mildly symptomatic patients, Kent et al[5] found a relatively low (3%) annual mortality rate. However, among asymptomatic patients with 3-vessel disease and poor exercise capacity, 20% died and another 20% had symptoms requiring coronary surgery during a mean follow-up period of 25 months. The investigators recommended that such patients undergo early coronary bypass surgery, even though they lacked symptoms. An updated follow-up study in this group showed that the prognosis of patients with silent or symptomatic ischemia during exercise testing was similar.[6]

Thallium-201 imaging was combined with treadmill testing by Walters et al.[7] Twenty-eight of their patients had silent ischemia and had the same hypoperfusion during stress as the 27 patients who had symptomatic ischemia. The silent group had an even higher incidence of MI and death than the symptomatic patients during 1-year follow-up. In 241 postinfarction patients, Gibson et al[8] studied the prevalence and prognostic significance of silent ischemia by thallium-201 exercise testing. The prevalence of silent myocardial ischemia in this study was 41% at 2 weeks after an uncomplicated infarction. Contrary to the results of other workers, these investigators found that asymptomatic ischemia correlated with smaller ischemic territories and less extensive coronary artery disease. During a follow-up period of 27 months, the frequency of cardiac events was lower in patients with silent

ischemia than in symptomatic patients. Kouz et al[9] found that silent ST depression during treadmill testing in 103 postinfarction patients was associated with the same extent of coronary disease, the same left ventricular function, and the same exercise duration as in 97 other patients with painful ST depression. These findings may provide the explanation for the similar prognosis of patients with and without pain.

An association between exercise-induced painless myocardial ischemia and out-of-hospital ventricular fibrillation was suggested by Sharma et al.[10] Of the 15 patients studied who had ventricular fibrillation, 12 had a positive treadmill test result, although none had chest pain. The ischemic changes were associated with an increase in left ventricular pressure and volume. These investigators suggested that the prognosis of patients with silent myocardial ischemia may be worse than that of patients with overt angina pectoris, because painless ischemia may remain unrecognized until a life-threatening cardiac event, such as MI or ventricular fibrillation, occurs.

Silent Ischemia During Daily Activities

My colleagues and I described ischemic changes during everyday activities without accompanying pain in 1973 and 1974.[11–13] In most of the patients, these changes were unprovoked by physical or mental stress and were documented to occur during both day and night. In a subsequent study, many of these patients were found to have severe coronary artery disease on coronary angiography.[14] Silent ischemic episodes during everyday activities were subsequently demonstrated by Shang and Pepine,[15] as well as other workers.[16,17]

The ischemic nature of such episodes of ST depression was provided by Maseri[18] (Italy) and Deanfield et al[19] (England). These groups have shown that silent and symptomatic ischemic episodes are associated with similar hemodynamic alterations and a similar extent of transient myocardial perfusion defects on radionuclide testing. Most investigators agree that about two-thirds of patients with an ischemic response to stress testing have transient ischemic changes during daily activity as well.[20] Approximately 70 to 80% of these episodes are silent.[16,21]

Outcome of Patients with Silent Ischemia in Unstable Angina

The prognostic significance of silent ischemic episodes was evaluated in 70 high-risk patients with unstable angina. Gottlieb et al[22] found that patients who had at least 60 minutes of silent ischemia during 24 hours had a worse prognosis after a 1-month follow-up than those who did not. In these patients, silent ischemia was the best predictor of poor outcome among 15 different variables. A more recent follow-up study of these patients confirmed that the poorer prognosis of the patients with silent ischemia persisted throughout a 2-year period, and infarction and cardiac death were more frequent in the 37 patients than in the 33 patients without silent ischemia.[23] Nademanee et al[24] obtained similar results concerning the prognostic significance of silent ischemia in patients with unstable angina.

TABLE I Cardiac Events During an Average of 24 Months of Follow-Up

	Pts (n)	Events			
		Death	MI	PTCA/CABG	Total
Previous MI with ischemic episodes	76	5	5	13	23
Previous MI, no ischemic episodes	135	5	5	5	15
No previous MI with ischemic episodes	86	3	6	17	26
No previous MI, no ischemic episodes	59	4	2	2	8
Total	356	17	18	37	72

CABG = coronary artery bypass surgery; MI = myocardial infarction; PTCA = percutaneous transluminal coronary angioplasty.

Prognostic Significance of Ischemic Episodes During Everyday Activities

In our early study of patients with chronic stable ischemic heart disease, 6- to 12-month follow-up revealed that of the 37 patients who had ischemic episodes during daily activities, 16 had worsening of their anginal state and 7 had pathologic ST-T changes in their ECG at rest. Of the 43 patients without ischemic episodes, deterioration occurred in only 3, and none had electrocardiographic abnormalities at rest.[13]

Recently, we analyzed the data of 356 patients (211 of whom had MI at least 3 months earlier) who had ischemic episodes during activities on Holter monitoring.[25] We included only patients who were active during the day of monitoring and excluded patients with congestive heart failure, those with unstable angina during the previous 3 months of Holter monitoring, or those who had an abnormal ST-T segment at rest. In 76 of the 211 postinfarction patients, we recorded 162 ischemic episodes, 126 (78%) of which were silent. In 59 of the 145 noninfarction patients, we recorded 171 ischemic episodes, 93 (57%) of which were silent.

During a 2-year follow-up period, the patients were examined at least every 6 months. Cardiac death, MI, coronary bypass surgery and balloon angioplasty constituted cardiac events in this study. The Holter monitoring results were not taken into consideration for the decision to submit a patient to 1 of these interventions. Of the 211 patients with previous MI, 76 had ischemic episodes. In this group, 30% had cardiac events compared with only a 9% event rate in those who did not ($p < 0.01$) (Table I). Of the 145 patients without previous infarction, 86 had ischemic episodes; 30% of them had cardiac events compared with 13% in those who did not ($p < 0.025$).

The cardiac event rate in the patients with or without previous infarction was similar in both subgroups; i.e., those with and without ischemic episodes during daily activities. Because high-risk patients (those with signs of heart failure or unstable angina) were exclud-

ed from the study, the expected incidence of mortality and of MI was a priori low. Therefore, it is not surprising that progression of coronary disease during the follow-up period manifested itself mainly by a deterioration in clinical status of patients requiring bypass surgery or balloon angioplasty. These results indicate that patients with coronary artery disease and ischemic episodes, silent or symptomatic, have a worse prognosis than patients without such episodes.

Our results are similar to those reported by DeWood and Rozanski,[26] who reported a worse outcome among the 26 patients with ischemic episodes during Holter monitoring than in 32 patients without. Rocco et al[27] investigated 86 patients with coronary artery disease and found a higher event rate (death, MI, unstable angina, bypass surgery and angioplasty) in patients with ischemic changes during daily activities than in patients without such changes.

Conclusions

Data from published reports indicate that the presence of myocardial ischemia during exercise testing or everyday activities is associated with a higher frequency of subsequent cardiac events, even if not accompanied by pain. Therefore, the management of patients should not only be based on the presence or absence of angina, but also should take into consideration all forms of ischemia—provoked or spontaneous, silent or symptomatic.

Prognosis in Stable Angina Pectoris and Silent Myocardial Ischemia

MICHAEL E. ASSEY, MD

The results of current investigation suggest that a former clinical standby, namely, the presence or absence of angina, is no longer the principal prognostic factor for determining a patient's risk of cardiac events, including myocardial infarction. In a retrospective analysis, patients with chronic stable angina were compared on the basis of presence or absence of angina during ischemia detected by thallium imaging. Patients were similar in terms of risk factors, clinical characteristics and catheterization data. At 30 months of follow-up, the myocardial infarction rate was 22% in the silent group compared with 4% in the group with angina. Transient asymptomatic ischemia has prognostic value independent of other variables such as exercise stress testing or cardiac catheterization data. Future prognostic studies should be careful to include patient populations with similar characteristics; they also will need to provide protracted follow-up and utilize sensitive and reproducible diagnostic techniques.

(Am J Cardiol 1988;61:19F–21F)

In this era of silent myocardial ischemia, chronic stable angina pectoris is increasingly difficult to define. For the purposes of this review, the syndrome includes patients who are out of the hospital, ambulatory, and stable enough to undergo exercise stress testing.

Current Data

Rabaeus[1] evaluated 150 patients with effort angina who were asymptomatic during a positive exercise treadmill test. All had previous infarction or angiographically documented coronary artery disease. In 45 months of follow-up, 76 of these patients (51%) had a coronary event: 2.5% had unstable angina, 8% had myocardial infarction (MI), 7.5% died suddenly and 33% had to undergo coronary artery bypass grafting.

During a 4-year follow-up, there were 11 sudden cardiac deaths plus 8 other cardiac deaths. Three of these "other" deaths occurred after infarction, 3 occurred after surgery and 2 resulted from late ischemic cardiomyopathy. Thus, the mortality rate totaled 13%, or 3.5%/year in this uncontrolled study.[1]

In the Coronary Artery Surgical Study (CASS), patients exercised and were classified into 4 groups according to the presence or absence of pain and the presence or absence of ST-segment depression. Patients with silent myocardial ischemia had a 1-year survival rate of 76%, which was equivalent to that of patients with angina—whether or not they had ST-segment depression. Seven-year survival rates of patients with silent myocardial ischemia were 86% for those with 1-vessel disease, 73% for those with 2-vessel disease and 57% for those with 3-vessel involvement.[2] Thus, the extent of ischemia—in this case judged angiographically—determined prognosis, independent of angina.

This, of course, had been suggested years before by Cohn et al.[3] In this study, the prognosis for patients with 3-vessel disease and silent ischemia was no better than that of patients with angina and similar coronary anatomy.

Although the study of Amsterdam et al[4] did not specifically look at mortality, it is well documented that in patients with chronic stable angina, the extent of coronary artery disease and left ventricular ejection fraction are valid determinants of prognosis. These determinants were found to be the same in patients with ST-segment depression that occurred without angina or a minute before angina, and in those who had angina without ST-segment depression, or those who had simultaneous ST-segment depression and angina. It is likely that patients with chronic stable angina have a silent element even to their symptomatic ischemic episodes.

TABLE I Exercise Stress Test Variables*

Variable	Group I—Silent (n = 27)	Group II—Symptomatic (n = 28)	p Value
Exercise duration (sec)	450	345	<0.05
Patients with ≥1 mm ST-segment depression over baseline	11 (41%)	14 (50%)	NS
Maximal heart rate (beats/min)	129	121	NS
Peak systolic blood pressure (mm Hg)	166	152	NS
Peak double product (heart rate × systolic BP)	21,414	18,392	<0.05

* Exercise stress test variables in patients with silent vs symptomatic myocardial infarction. Only 41% of the asymptomatic patients and 50% of the patients with angina had ST-segment depression on electrocardiography; therefore, stress testing that used ST-segment shifts only would have missed the diagnosis in as many as half the patients that were diagnosed as having ischemia based on thallium imaging. (Reprinted with permission by Am J Cardiol 1987;59:498.)

BP = blood pressure; NS = not statistically significantly different.

TABLE II Medical Therapy*

Drug	Group I—Silent (n = 27)	Group II—Symptomatic (n = 28)	p Value
β blockers	18 (67%)	18 (64%)	NS
Calcium channel blockers	11 (41%)	17 (61%)	NS
Nitrates	11 (41%)	22 (82%)	0.01
Aspirin	7 (26%)	11 (39%)	NS
Digoxin	9 (33%)	10 (36%)	NS
Antiarrhythmic therapy	2 (7%)	1 (4%)	NS

* Medical treatment in the 2 groups ranged from β blockade to antiarrhythmic therapy. The only significant difference was in the use of nitrates, which was almost twice as frequent in the symptomatic than in the silent group.

NS = not statistically significantly different.

Falcone et al[5] reported equal survival in 269 symptomatic and 204 asymptomatic patients with similar coronary anatomy and left ventricular ejection fractions. However, patients with silent ischemia were characterized by the following: a longer exercise duration, higher peak double product, more ST-segment depression at peak exercise and exercise-induced ventricular ectopy—a fertile substratum for sudden death in this otherwise chronic stable angina group.

Radionuclide Imaging in Patients with Stable Angina and Silent Myocardial Ischemia

Radionuclide imaging studies have given additional insight into characteristics of patients with silent myocardial ischemia and can enhance detection of those at increased risk for cardiac events.

Reisman et al[6] performed thallium imaging studies in over 1,000 patients who had no previous history of MI or coronary bypass surgery. About 10% of them (160 patients) had hypoperfusion during stress that reached normal levels at rest. Of this group, 83 were asymptomatic and 77 had angina. The cardiac event rate at 1 year was low. However, patients with chronic stable angina may have to be followed longer than 1 year to define the true endpoint, unlike unstable patients who may have a definable endpoint as early as 30 to 60 days. A cardiac event (death, MI, bypass) occurred in 7 (8%) of the asymptomatic and in 14 (18%) of the symptomatic patients. When the events were evaluated in terms of whether these patients had achieved 85% of predicted heart rate, something very important appeared: When unable to reach maximal predicted heart rate, the asymptomatic patients had an event rate similar to that of the symptomatic patients, and the amount of perfusion defect, as judged by number and size of thallium defects, was similar. Therefore, thallium testing identified a high-risk group in an otherwise asymptomatic cohort of patients.

Radionuclear angiography can also be useful when risk-stratifying patients with chronic stable angina. In 131 patients at the National Institutes of Health who underwent cardiac catheterization and exercise testing, there was a very high prevalence of silent ischemia. Patients in this study most likely to have angina were those with left main and 3-vessel disease or a low ejection fraction. All of the deaths occurred in patients who had both an exercise-induced decrease in ejection fraction and ST-segment depression. Dividing these patients into subsets of those with angina and silent myocardial ischemia, the risk of dying with left main disease or with left main and 3-vessel disease was independent of the presence or absence of angina during the test.

TABLE III Cardiac Catheterization Data*

Variable	Group I—Silent (n = 27)	Group II—Symptomatic (n = 28)	p Value
Below normal ejection fraction (<50%)	3 (11%)	4 (14%)	NS
Elevated left ventricular end-diastolic pressure (>12 mm Hg)	12 (44%)	13 (46%)	NS
Left main CAD	1 (4%)	2 (7%)	NS
3-vessel CAD	10 (37%)	12 (43%)	NS
2-vessel CAD	8 (30%)	11 (39%)	NS

* Cardiac catheterization data were not significantly different in the 2 groups. An approximately equal distribution was seen in occurrence of 1-, 2- and 3-vessel disease in the asymptomatic and symptomatic groups. (Reprinted with permission by Am J Cardiol 1987;59:498.)

CAD = coronary artery disease; NS = not statistically significantly different.

Retrospective Findings in Patients with Chronic Stable Angina and Silent Myocardial Ischemia

My colleagues and I performed a retrospective study of 55 patients with angiographically documented coronary artery disease. Group I comprised 27 patients who had transient ischemia without angina during thallium testing; group II comprised 28 patients who had ischemia with angina during the procedure. All of the patients had undergone cardiac catheterization within 6 months of the study; 90% had undergone catheterization within 6 weeks. Patients were followed

for at least 2.5 years to determine the significance of a reversible thallium defect detected during exercise testing that was unrecognized by the patient. Study endpoints were hospitalization for unstable angina, MI and sudden cardiac death.

In the silent group, 41% of patients had ST-segment depression compared with 50% of the symptomatic patients. Thus, if we had just looked at electrocardiographic changes, ischemia would have been detected in only half of our patients. The absence of angina in group I was not due to a submaximal exercise load; all patients were pushed to exhaustion, and the double product was higher in the silent group than in the symptomatic group (Table I).

The clinical characteristics of the 2 groups were similar in terms of known risk factors for coronary atherosclerosis. Drug therapy could not be controlled in this study. However, there was only 1 difference in treatment between the groups: Patients who were symptomatic on the treadmill were taking nitrates more frequently, usually in the form of supplemental sublingual nitroglycerin (Table II). Cardiac catheterization data were also similar in both groups (Table III).

Considering their hemodynamics, these patients should have had a very low complication rate. But at 30 months of follow-up, acute MI had occurred in 6 asymptomatic patients (22%) and in 1 symptomatic patient (4%). There were no unusual findings in the 6 patients who had the infarcts. One of the patients had 1-vessel, 2 had 2-vessel and 3 had 3-vessel disease. In 3 of the asymptomatic patients, infarction terminated in death, for a mortality rate of 11%. None of the patients with angina died. The incidence of hospitalization for unstable angina was 48% in the silent group vs 57% in the group with angina.[8]

We concluded that transient ischemia, identified in this manner, has prognostic value independent of other variables such as standard exercise testing and cardiac catheterization data. The demonstration of exercise-induced silent ischemia may predispose the patient to a higher infarct rate. Certainly, the absence of angina did not impart a better prognosis to these patients.

Considerations for Future Prognostic Studies

In planning future prospective studies on the prognosis of stable angina patients with silent myocardial ischemia, investigators should be careful to select subjects who are free of prognosis-altering medications or interventions, particularly bypass surgery. Our study contained an element of bias because participants were receiving medical treatment. Although we tried to minimize the impact of this by demonstrating equal therapy between groups, a given therapy may not have the same effect in one patient as in another. The study populations should be well defined and homogeneous, with no recent history of MI, and follow-up will have to be prolonged if we are to determine true prognosis. Finally, techniques for detecting silent myocardial ischemia will need to be sensitive and highly reproducible.

Myocardial Perfusion Imaging for Detection of Silent Myocardial Ischemia

GEORGE A. BELLER, MD

Despite the widespread use of the exercise stress test in diagnosing asymptomatic myocardial ischemia, exercise radionuclide imaging remains useful for detecting silent ischemia in numerous patient populations, including those who are totally asymptomatic, those who have chronic stable angina, those who have recovered from an episode of unstable angina or an uncomplicated myocardial infarction, and those who have undergone angioplasty or received thrombolytic therapy. Studies show that thallium scintigraphy is more sensitive than exercise electrocardiography in detecting ischemia, i.e., in part, because perfusion defects occur more frequently than ST depression and before angina in the ischemic cascade. Thallium-201 scintigraphy can be performed to differentiate a true- from a false-positive exercise electrocardiographic test in patients with exercise-induced ST depression and no angina. The development of technetium-labeled isonitriles may improve the accuracy of myocardial perfusion imaging.

(Am J Cardiol 1988;61:22F–26F)

Exercise radionuclide imaging can help detect silent ischemia in numerous patient populations, including those who are totally asymptomatic, those who have chronic stable angina, and those who have recovered from an episode of unstable angina or an uncomplicated myocardial infarction (MI). Exercise radionuclide imaging is also useful as a follow-up to coronary angioplasty and thrombolytic therapy.

Radionuclide Imaging Versus Exercise Electrocardiography for Detecting Silent Myocardial Ischemia

The rationale for using exercise radionuclide imaging to detect myocardial ischemia is based on the following: (1) perfusion imaging is more sensitive and specific than exercise ST-segment depression in identifying patients with ischemia; (2) patients with high-risk coronary artery disease can be identified by the combination of imaging and exercise electrocardiographic (ECG) stress test variables; and (3) ischemia-induced perfusion abnormalities tend to occur before the onset of angina in patients who are undergoing treadmill testing.

The relative sensitivity and specificity of tests for detecting ischemia in patients with 1-vessel disease and no previous history of MI was undertaken by Port et al.[1] A comparison of exercise electrocardiography, planar and tomographic thallium-201 (Tl-201) and exercise radionuclide angiography demonstrated a sensitivity and specificity of 52% and 72%, respectively, for exercise electrocardiography. The figures were 91% and 83% for planar thallium, 89% and 89% for tomographic thallium, and 65% and 72% for exercise radionuclide angiography. Thus, the exercise radionuclide tests were more sensitive than exercise electrocardiography in detecting ischemia. The perfusion approach in this study demonstrated the optimal balance between sensitivity and specificity for identifying 1-vessel disease.

Another study by Kaul et al[2] similarly found that the prevalence of a Tl-201 defect was approximately 25% more sensitive as an indicator of ischemia than ST-segment depression in patients with 1-vessel disease involving either the left anterior descending, circumflex or right coronary artery.

Canhasi et al[3] compared the accuracy of a markedly positive stress electrocardiogram with that of a high-risk Tl-201 scan in 40 patients with proximal 3-vessel and left main disease. Using the marked positive ECG criteria of ST-segment depression of more than 2 mm, occurring within 6 minutes of the onset of exercise, 15 of these 40 patients were identified as high-risk, a sensitivity of 38%. A high-risk thallium scan, defined as

multiple thallium defects in more than 1 vascular region, increased lung uptake of thallium, or decreased basal uptake or exercise-induced left ventricular dilatation, identified 38 of these 40 patients, yielding a sensitivity of 95%.

One explanation for the enhanced sensitivity of Tl-201 imaging in identifying ischemic and high-risk patients is that it can detect more perfusion defects at a lower rate-pressure product and exercise load compared with prevalence of ST depression with stress testing (Fig. 1). It may take a greater imbalance between oxygen supply and demand, and perhaps more metabolic changes in the heart, before ischemic changes can be detected by the stress electrocardiogram. Coplan et al[4] examined exercise ECG changes in 37 patients with coronary artery disease and Tl-201 redistribution. In the 13 patients who had thallium redistribution and no exercise ST depression, the maximal exercise heart rate was 117 beats/min. In patients who had both ST depression and Tl-201 redistribution, the peak heart rate averaged 132 beats/min.

In another study by Upton et al,[5] a group of 25 patients exercised to an endpoint of either ST depression or angina. These patients all had an abnormal exercise ejection fraction. The stress test was repeated at a lower work level in the same patients. None of the patients had ST expression or angina, but in 18 of the 25 (72%), the ejection fraction was still abnormal or failed to increase by more than 5%, which means that the functional abnormality must have occurred very early during the exercise. The ejection fraction became abnormal in 7 more patients later on. None of the patients had ST depression or angina when the functional disturbance appeared, which correlates very well with the perfusion abnormalities seen in other studies that occurred at an early point during the exercise work load.

Another interesting aspect of the discrepancy between perfusion abnormalities, functional abnormalities, and the exercise electrocardiogram or angina is its possible association with the extent or severity of disease, and not only with the heart rate and work load achieved. Painful episodes of ischemia may be associated with a greater amount of myocardium rendered ischemic than painless episodes.

Thallium-201 Exercise Imaging in the Totally Asymptomatic Patient

In the totally asymptomatic patient, tomographic or planar Tl-201 imaging seems to identify more patients with asymptomatic ischemia than the exercise ECG test alone.[6] This is probably because perfusion imaging is more sensitive than exercise ST depression, particularly at peak exercise heart rates less than 85% of maximal predicted heart rate.

An interesting study involved 130 asymptomatic Air Force pilots who had been referred for catheterization because of coronary risk factors or a positive stress electrocardiogram.[7] Of the 22 who had significant coronary disease, that is, more than 50% stenosis, all had an abnormal Tl-201 scan. Of the 130 patients, 12 were deemed by angiography to have nonsignificant disease, i.e., lesions between 25% and 50%, and of these 12, 8 had abnormal Tl-201 scans. These data suggest that exercise Tl-201 imaging can be the first test performed to identify or confirm presence of silent ischemia in a patient who demonstrates painless ST depression on the exercise electrocardiogram, or who has multiple risk factors and a strong family history of coronary artery disease but a normal exercise electrocardiogram at a suboptimal heart rate response.

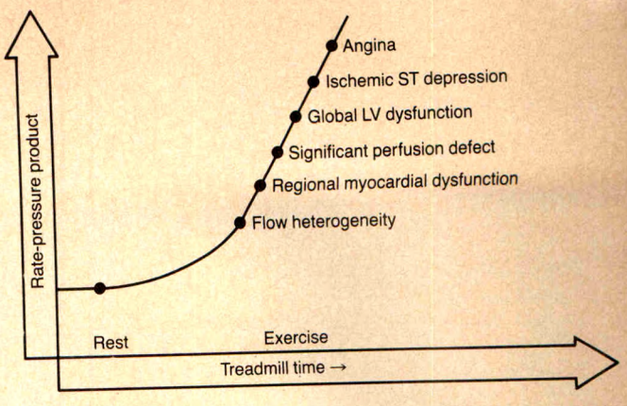

FIGURE 1. A 10% decrease in blood flow is sufficient to cause regional myocardial dysfunction during exercise. This is too small to be detected at low levels of exercise. However, as exercise continues and the rate-pressure product increases, a perfusion defect becomes identifiable by thallium imaging, given significant coronary disease. Perhaps in order for angina to become apparent, the rate-pressure product must get even higher and exercise duration must be longer. LV = left ventricular.

There are asymptomatic patients who have what appears to be a strongly positive exercise electrocardiogram, but no significant abnormalities on thallium scan. Some of these patients may have baseline ECG abnormalities, hypertension, mitral valve prolapse, Wolff-Parkinson-White syndrome, or are receiving digitalis. A Tl-201 scan would help resolve the specificity problems associated with reliance on a single test that has a high false-positive rate in populations with a low pretest likelihood of coronary artery disease. Figure 2 depicts quantitative anterior and 45° left anterior oblique Tl-201 scintigrams in a patient with Wolff-Parkinson-White syndrome and a suspected false-positive ST response to exercise. The scan was entirely normal at a high level of exercise.

Guiney et al[8] studied 35 patients who had ST depression and no angina during exercise stress testing. Patients underwent a Tl-201 stress test before angiography, which identified defects in a group of 11 patients. Subsequent angiography in this group identified 8 patients with significant coronary artery disease and 2 patients with subcritical (<50%) stenoses. Therefore, approximately one-third of the patients actually had silent ischemia, with good correlation between the Tl-201 perfusion scan and the coronary angiogram, and two-thirds (24) of the patients had no defects. In this group, coronary angiography revealed normal coronary arteries in 23 patients and identified

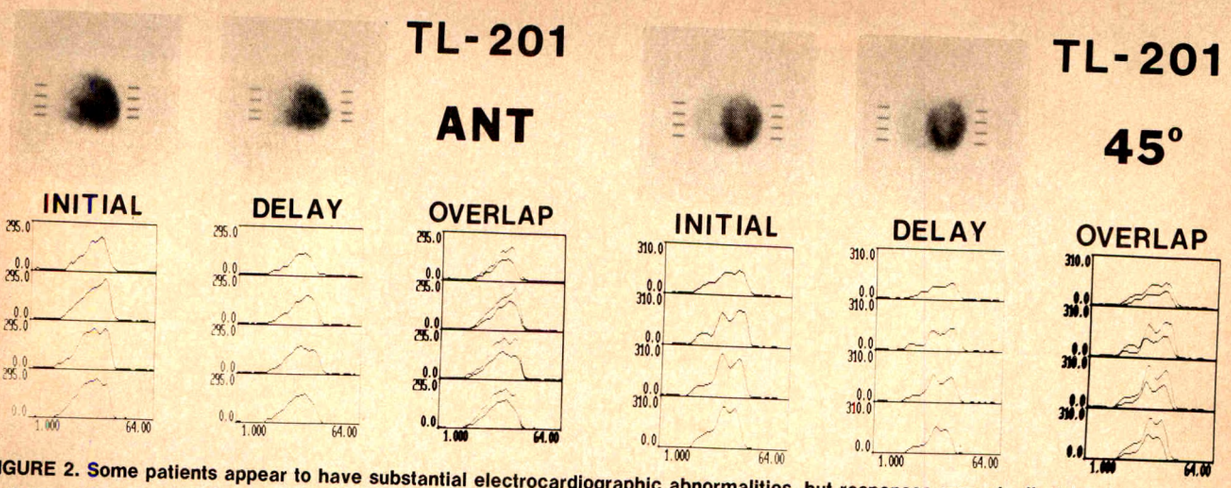

FIGURE 2. Some patients appear to have substantial electrocardiographic abnormalities, but responses are actually false-positive. For instance, this patient had Wolff-Parkinson-White syndrome and a suspected false-positive ST response during exercise testing. The patient's thallium (Tl-201) scan really showed no significant abnormalities by quantitative criteria, and he had false-positive electrocardiographic stress test results. *Left*, anterior (ANT) view scintigram. *Right*, 45° left anterior oblique scintigram. Quantitative count profiles are shown beneath each image and demonstrate uniform thallium-201 uptake and washout from all myocardial segments.

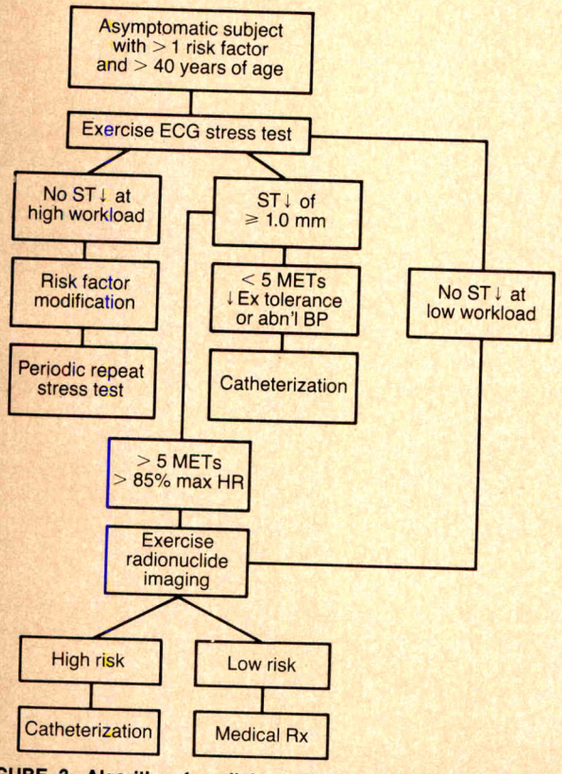

FIGURE 3. Algorithm for clinical management of asymptomatic patients who are older than age 40 years and have more than 1 cardiac risk factor. Patients without ST-segment depression at a high work load are candidates for risk factor reduction and periodic checkup. ST depression that occurs at a low work load calls for cardiac catheterization; when it occurs at a high work load, exercise radionuclide imaging is appropriate. abn'l = abnormal; BP = blood pressure; ECG = electrocardiogram; Ex = exercise; HR = heart rate.

significant 1-vessel disease in 1 patient. These data again illustrate the usefulness of Tl-201 scintigraphy in identifying patients with silent ischemia among those with painless ST-segment depression on a standard exercise ECG stress test.

Approach to Testing the Asymptomatic Patient

Some basic guidelines, derived from clinical experience, can improve the efficiency and accuracy of diagnosing silent myocardial ischemia in the asymptomatic patient (Fig. 3).

In the totally asymptomatic patient who has stress testing for a variety of reasons, such as a strong family history, multiple risk factors, or consideration for a high life-insurance premium, the exercise ECG stress test is cost-effective as the first test to be performed. If the exercise electrocardiogram shows no ST depression or no angina at a very high work load (≥85% or more of maximal heart rate), then risk-factor modification, without repeat testing with Tl-201, would be appropriate because the patient has a low probability of having functionally significant coronary artery disease. A positive ST-segment shift of 1 mm or more that occurs at <5 METs and is associated with either decreased exercise tolerance or an abnormal blood pressure response is probably a true-positive response, since the work load is so low. This test result suggests a high possibility of silent ischemia, and moving directly to cardiac catheterization would be a worthwhile consideration. If there is no ST-segment depression at a low work load, the patient may be demonstrating a false-negative response and therefore is likely to benefit from repeat exercise testing with radionuclide imaging. If the Tl-201 scan suggests high risk, catheterization is appropriate. If the scan indicates low risk, perhaps consistent with 1-vessel right coronary artery disease, medical therapy is a good alternative of

choice. Some patients have ST-segment depression at a very high work load, without accompanying chest pain. This often proves to be a false-positive response; exercise radionuclide imaging can determine whether the patient does, in fact, have ischemia.

Thallium-201 Exercise Imaging After Uncomplicated Myocardial Infarction

Gibson et al[9] evaluated the asymptomatic response in the post-MI setting. Study participants—190 patients who had sustained MI within the past 8 to 10 days—underwent predischarge, submaximal exercise testing to a heart rate of 120 to 130 beats/min, or to 5 METs or less. During testing, 100 patients remained free of angina or ST depression. About half of the patients had Tl-201 redistribution as determined by quantitative scan analysis. In this group, the rate of death or recurrent infarction at about 27 months' follow-up was 24%, compared with 2% in the patients with no ST depression, angina or redistribution (Fig. 4). Therefore, it can be concluded that many of these patients probably did have silent ischemia, evidenced only by Tl-201 redistribution. There was another group of 43 patients who had asymptomatic ST depression on predischarge exercise Tl-201 imaging. In those who also had thallium redistribution, the incidence of recurrent infarction or death (20%) was not substantially different than it was in the group who had no ST depression and Tl-201 redistribution (n = 20). The event rate was higher than observed in patients with ST depression and no associated Tl-201 redistribution (20% vs 9%). Because of this small number of patients, this difference was not statistically significant.

A third group of 47 patients in this post-MI study had angina as an endpoint in the stress test with or without ST depression. Those who also had Tl-201 redistribution (n = 37) had about the same event rate as those without angina and Tl-201 redistribution, irrespective of the presence of ST depression (Fig. 4). Patients with angina and no Tl-201 redistribution had about a 50% lower event rate (10%) than patients with angina and Tl-201 redistribution (24%). Again, because of the relatively low number of patients, this difference was not statistically significant. When development of class III or IV angina in the follow-up period was also considered an event, the difference in event rate in patients with Tl-201 redistribution compared with those without redistribution was statistically significant in all subgroups shown in Figure 4.

Gibson et al[9] made an interesting observation regarding the specificity of the ST response in certain subgroups of post-MI patients. Some patients with circumflex or right coronary infarct-related vessels had significant precordial ST-segment depression in leads V_2 and V_3 on the predischarge exercise test, but no evidence of left anterior descending disease on angiography or Tl-201 redistribution in anterior wall or septal segments. Some had increasing ST-segment elevation in inferoposterior leads in response to exercise, and the precordial ST depression might have represented "reciprocal" changes rather than ischemia. This may account for the group of patients who had silent ST depression without Tl-201 redistribution who had a fairly good prognosis, because they did not manifest ischemia.

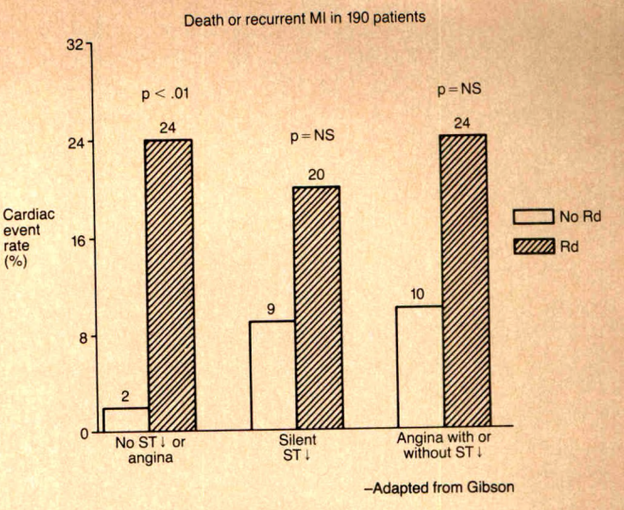

FIGURE 4. Correlation between the cardiac event rate (%) and thallium-perfusion findings in postinfarction patients with no ST depression (↓) or angina (n = 100), silent ST depression (n = 43), or exercise angina with or without ST depression or predischarge exercise testing (n = 47). MI = myocardial infarction; NS = not significant; Rd = thallium-201 redistribution. (Adapted from Gibson et al.[9])

The results of this study suggest that silent ischemia occurs often after uncomplicated MI and identifies a subset of patients at a higher risk for recurrent infarction and death. Tl-201 scintigraphy improves both sensitivity and specificity for identifying these high-risk patients.

Limitations of Thallium Imaging

As with so many diagnostic tools, Tl-201 imaging does have some limitations. Because of its low-energy emission, there are many attenuation artifacts that increase the false-positive rate. The false-positive rate is also high in patients with left bundle branch block and patients who have exaggerated apical thinning. Left circumflex and milder stenoses are not as easily detected as left anterior descending and right coronary lesions, or lesions of >80% narrowing. Tl-201 has a long half-life, is expensive, and requires quantitation of uptake and washout for optimal use.

Future Advances in Imaging Technology

A new agent—a technetium-labeled isonitrile, 2-methoxyisobutyl isonitrile (MIBI)—also is taken up by the myocardium in proportion to blood flow. The scintigraphic images it provides in animals and humans is comparable to that achieved with Tl-201. It may give better resolution of the posterior wall, particularly in a 70° projection, and in preliminary studies there ap-

pears to be a good correlation between abnormal perfusion and abnormal wall motion. Because this is a technetium-labeled perfusion agent, images can be easily gated. Furthermore, MIBI does not redistribute, which means that images can be obtained as they would appear immediately after exercise—even after a delay. This is because the isonitrile enters the myocardium passively through the sarcolemmal membrane, and has a subsequent very slow washout.

In a preliminary study comparing the Tl-201 scan with the technetium-99m MIBI scan in the same patient, there was good correlation with segments interpreted as normal, showing ischemia or scarring with some discordance on either side.[10] Early studies, suggesting that MIBI imaging is as good as Tl-201 scintigraphy in detecting coronary artery disease, are encouraging.[11]

Positron emission computed tomography also holds promise for imaging regional myocardial blood flow using rubidium-82 as the perfusion agent. Preliminary clinical studies suggest a high sensitivity and specificity for coronary artery disease detection.

In summary, myocardial perfusion imaging is a useful technique, particularly for identifying patients with silent ischemia. Patients who have Tl-201 redistribution without pain appear to have a worse prognosis than patients with no scintigraphic evidence of ischemia. In post-MI patients, Tl-201 redistribution is also more specific than ST depression for identifying those with residual ischemia. Newer technetium-99m-labeled perfusion agents and positron imaging with $^{82}Rb^{+}$ appear promising for enhancing the diagnostic and prognostic capabilities of exercise radionuclide imaging.

Discussion III

Dr. Assey (*Charleston, South Carolina*): I have 2 questions concerning Dr. Stern's prognostic update in patients with silent myocardial ischemia. Were study participants on routine medical therapy, and if so, was that controlled for in the overall end results? Secondly, was the decision to proceed to angioplasty based on Holter monitoring data?

Dr. Stern (*Jerusalem, Israel*): To answer your first question, the patients were on routine medical therapy. We could not find any significant difference between therapy in patients who had ischemic episodes vs those who did not. The second question is very relative. The results of Holter monitoring were not taken into consideration when deciding whether to send the patient for angioplasty or surgery.

Dr. Horwitz (*Denver, Colorado*): I would like to comment on the use of exercise testing compared with Holter monitoring for determining prognosis. Overwhelmingly, the most reliable prognostic evidence from an exercise test is exercise capacity. The detection of ischemia, whether by thallium or electrocardiogram, is much less certain. I think most of us use exercise testing not just to see whether it is positive. Rather, if a test is positive at a high exercise load, it concerns us a lot less if the exercise test is positive by ST-segment shift or radionuclide angiography at a low level of exercise. A positive Holter monitor during everyday activities is, in a sense, detecting ischemia at a low exercise load. When comparing this with whether there is a positive exercise test, you are comparing these people with some who may only get ischemia at an extraordinarily high load. In terms of prognosis, it is more valuable to divide positive exercise tests between those who are positive at a high load only and those who are positive at a relatively low load. Those people seem to have a very bad prognosis, whether or not they have angina, either because they have a large area of ischemia, which suddenly impairs performance, or because there is a lot of underlying fixed disease. I don't think it is nearly as valuable to compare monitoring data with a positive test, without regard to the work level at which the positive response occurs.

Dr. Cohn (*Stony Brook, New York*): Dr. Stern, do you want to respond in terms of the breakdown of your patients who had a positive exercise test?

Dr. Stern: I fully agree that so far, with Holter monitoring, we are speaking about a "yes" or "no" situation. Is the patient having ischemic episodes or not? The situation with exercise testing is currently very similar. Most of the exercise tests are classified as either positive or negative. But I agree that the low-load positive exercise test may have a completely different prognostic significance than a high-load positive exercise test. We really should consider our results according to the degree of work during the exercise test.

Dr. Friesinger (*Nashville, Tennessee*): To extend that, the increase in myocardial oxygen demand is much less during Holter monitoring than during exercise testing, suggesting a different pathophysiologic mechanism for ischemia, namely, that the vascular reactivity of the bed differs from that during exercise. One way this has been evaluated is by examining the duration of ST-segment depression during a 24-hour period. I was wondering if anyone has examined the duration of ischemia during a 24-hour period, to check the possibility that the bed is more reactive, that coronary tone has changed, and that these patients are in a less stable phase of their ischemic disease.

Dr. Stern: I agree that we should find out which is the most significant determinant of ischemia on Holter monitoring. Is it the duration of this ischemic period? Is it the heart rate at which ischemia appears? Is it the degree of ST depression (1 mm vs 2 mm or 3 mm)? I have to agree that we do not have an answer for that yet. We are trying to look into it now.

Dr. Assey: In our study of stable angina, we didn't simultaneously look at ambulatory electrocardiographic monitoring in patients who were exercised. So, I cannot answer the question. Although the potential for different ischemic mechanisms is undeniable, the role of sympathetically mediated changes in vasomotor tone during exercise is also a complicating factor.

Dr. Amsterdam (*Davis, California*): We also have to consider that ischemia during relatively low heart rates associated with everyday activities may still relate to increased oxygen demand, because blood pressure is not usually measured out of hospital. While there can be increases in coronary tone, it is still possible that demand is a component, i.e., blood pressure may be high. Those are difficult data to get, even with an ambulatory blood pressure monitor, because there is a limit to how frequently pressure measurements can be obtained.

Dr. Deanfield (*London, England*): Investigators at Hammersmith have examined amulatory blood pressure with a continuous intra-arterial recording (ST-segment depression on frequency-modulated boxes). Unlike the heart rate, blood pressure does not rise before the onset of ST-segment depression during daily life. Still, that does not negate the potential relevancy of changes in myocardial oxygen consumption to the genesis of ischemia out of hospital.

Dr. Hollenberg (*San Francisco, California*): I could add that during intraoperative monitoring, which gives continuous blood pressure and transesophageal echocardiographic recordings, most of the ischemic episodes that we see are not associated with changes in heart rate/blood pressure. Al-

most inevitably they are associated with significant changes in regional wall or global dysfunction, as seen on transesophageal echo. We have also seen marked deterioration of left ventricular function, as evidenced by a significantly decreased ejection fraction, associated with an obviously ischemic episode—that was not associated with ST-segment changes on 12-lead monitor during the operation, but with a substantial increase in R-wave height. Now, we probably could discuss for an hour what changes in R-wave values mean electrocardiographically. There is no question that, in the operating room, there is a correlation between changes in left ventricular function and R-wave changes not associated with significant ST-segment changes. There may be other markers of the ischemic event than pure ST-segment changes alone. I would like to make one other comment, and I am glad that the exercise tests were so amply defended by Dr. Horwitz. I think we are now comparing qualitative changes in the electrocardiogram with qualitative changes by thallium imaging. What we have to progress to is quantitation of the exercise test both electrocardiographically and by thallium. Presently, when we talk about a thallium defect, we make very little discrimination whether this defect is provoked after 3 or after 15 minutes of exercise. We talk about a reversible defect, or a nonreversible defect, and we almost never mention what level of exercise is necessary to induce it, or what are the hemodynamic parameters that are necessary to elicit such nonhomogeneous perfusion. I would make a plea to start looking at it in a more sophisticated fashion. We classify high-risk patients as those needing more than 2 mm ST depression, and yet we totally ignore the QRS amplitude in the monitored lead. Is the R wave at rest 8 mm or 30 mm tall? We have shown that you have to relate the ST-segment depression to the R wave that is monitored.[1] A 0.7 mm depression is a small QRS complex that occurs at 3 minutes of exercise may be highly significant and may represent a strong positive response, whereas a 3 mm depression that is elicited at 13 or 14 minutes of exercise may be normal. So, I think we are being very simplistic in the kind of qualitative comparison we are making between the exercise thallium and the exercise electrocardiogram as diagnostic tools. We are presently able to quantify electrocardiographic responses by more sophisticated methods. Further, we have attempted to quantify thallium defects and relate them to the work load necessary to elicit a certain volume of myocardium that exhibits nonhomogeneous flow. I would like to see more discussion of these quantitative aspects, and not whether thallium is better than the electrocardiographic interpretation that has been used for 40 years and that we really have not improved upon.

Dr. Silber (*Birmingham, Alabama*): Our discussion should not go in the direction of comparing exercise radionuclide studies with exercise electrocardiographic studies. There is so much information showing that exercise radionuclide studies are more sensitive and specific than exercise electrocardiography. The point in comparing radionuclide techniques with electrocardiograms is that the ST segment has 1 major advantage: the possibility of ambulatory monitoring. The key question is, what is the difference between ambulatory ST-segment monitoring and the exercise test? If we have a middle-aged asymptomatic patient with more than 1 risk factor, where is the place for exercise testing and for Holter monitoring? Should we do both, or can we just rely on one of these tests? I think we need more data to determine if we are measuring 2 different things.

Identification of High-Risk Patients with Silent Myocardial Ischemia After Percutaneous Transluminal Coronary Angioplasty by Multilead Monitoring

MITCHELL KRUCOFF, MD

Quantification of total ischemic burden can be improved by use of microprocessor-driven, multichannel, digital, ST-monitoring devices. ST deviation recorded during angioplasty provides a patient-specific template for identification of patients at increased risk for coronary events after angiographically successful dilation. In patients with ST-segment elevation, evidence of these ST "fingerprint" patterns are associated with elevated risk for coronary events in the postangioplasty period. Such risk is not seen in patients with ST-segment depression or with no ST changes. The increased monitoring capability afforded with digitized 3- or 12-lead monitoring creates new criteria for what constitutes accurate determination of total ischemic burden.

(Am J Cardiol 1988;61:29F-34F)

In the quantitation of ischemic burden, there is no more rapidly emerging technology than the addition of microprocessor capability to electrocardiography/ST-segment monitoring. This certainly heralds a new era of diagnostic capability that may improve our ability to monitor disease activity and identify high-risk patients.

Early ST-Segment Monitoring: More Leads to More Definition

In its early stages, ST monitoring was impeded by a high rate of false-positive diagnoses resulting from patient selection and the equipment used. In the 1970s, Wolf et al,[1] using a single-channel Holter recorder with improved frequency response, were able to gather accurate information, validated against simultaneous exercise recordings. They later applied a dual-channel recorder that increased the sensitivity of ischemia detection.[2] Simultaneously, in the 1970s, Selwyn et al[3] were placing multiple leads over the precordium during exercise and mapping out precordial zones of ST activity, which, in an exercise context, was consolidated to 2 zones in a V_2–V_3 area and an inferolateral V_5-like area. Most of the currently reported Holter data from patients with silent ischemia use lead placements extrapolated from their technique and results.

There has been, however, another use of multiple-lead acquisitions in earlier studies, not on exercise tests or Holter monitors, but from 12-lead electrocardiograms in patients with coronary occlusion and myocardial infarction. For several decades, anterior, posterior, inferior and lateral myocardial infarction has been described on the basis of 12-lead electrocardiographic patterns. Unlike the poor correlation found between coronary anatomy and the precordial zones during exercise on a treadmill, precordial patterns of ST elevation or injury current usually correspond well with coronary anatomy, identifying the epicardial vessel involved. This has been emphasized by work like Maroko et al[4], using multilead ST maps to define not only the location of myocardial injury but also a zone of risk that is proportional to the jeopardized myocardium in the setting of coronary occlusion. In addition, there is a considerable number of studies in the literature, evaluating not only areas of injury but also areas of reciprocal ST changes. In the setting of myocardial infarction, reciprocal changes seem to define a patient population with a poorer clinical prognosis.[5]

Thus, multilead recordings provide important anatomic and prognostic information, as well as improved episode detection when used for evaluation of total ischemic burden. Microprocessor technology makes

analysis of multilead data a reality in current commercially available devices.

Quantitating Total Ischemic Burden

Many approaches to ST monitoring for quantitating total ischemic burden involve examining arbitrary parameters, such as the number of episodes during a recording period, the duration of each episode (individually and together with all episodes), the severity or actual ST deviation of each episode, or the peak ST deviation over a recording period. There is also a range of technical considerations, such as selecting patients who have known coronary disease to try to eliminate false-positive diagnoses, record/playback electronics, low-frequency response, phase-shift, the duration of recording, the placement of leads, and the number of leads needed to accurately quantitate ischemic activity.

Much of the mapping work that has been done has focused on identifying a precordial central zone of ischemia, i.e., the area of peak severity that would then be an ideal place for an electrode to record all of the episodes as well as the maximal ST deviation. This is assumed by most investigators to also be the position that will show the longest duration of abnormal activity. Numerous factors may modify the precordial zone of activity, including the development of collaterals to the vessel, changes in medications, or the presence of multiple vessels with stenoses.

Computerized Ischemia Monitoring: Method

Two monitoring devices are used in our laboratory (Georgetown Ischemia Monitoring Laboratory): a 3-channel Holter (Scole Alta II), analyzed on a fully digitizing playback computer (Marquette 8000) and a 12-lead real-time portable programmable ST monitor (Mortara EL-I).

Holter recordings are continuous in 3 standard bipolar vectors: leads V_2, V_5 and aVF. Digital playback analysis is performed only on normally conducted beats, with a mean ST level generated every 10 seconds. This high-resolution analysis allows detection and quantitation of even very brief ischemic episodes, such as balloon occlusions during percutaneous transluminal coronary angioplasty (PTCA) (Fig. 1). Low-frequency response and phase shift of this system have been previously validated with a programmable electrocardiographic/ST calibration signal throughout.[6]

The 12-lead ST monitor acquires standard electrocardiograms every 30 seconds. ST level at J + 60 ms in every lead is instantly compared with a baseline electrocardiographic template. The device can be programmed to alarm if ST deviation is detected on 2 electrocardiograms in a row over a 60-second period.

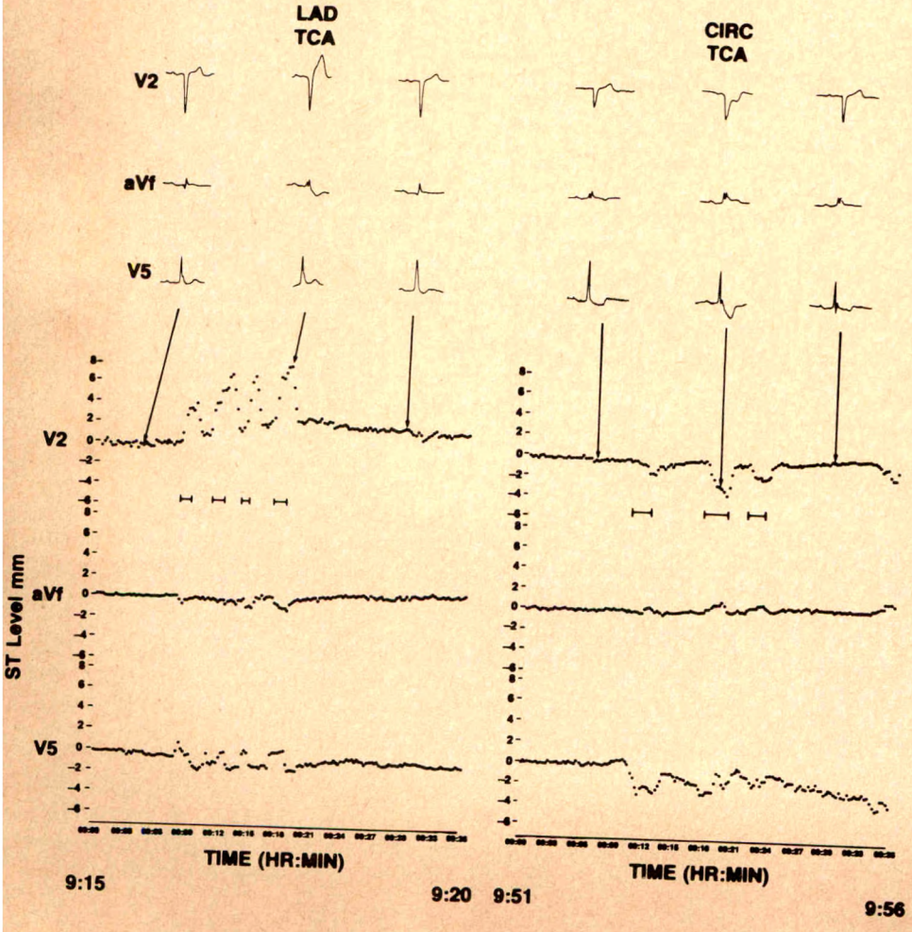

FIGURE 1. High-resolution 3-channel ST-segment trend during percutaneous transluminal coronary angioplasty (TCA) of the left anterior descending artery (LAD) and circumflex (CIRC) arteries in the same patient. *Horizontal bars* show balloon inflations in each artery. Discrete reproducible patterns of anterolateral ST elevation with some reciprocal inferior ST depression are seen during occlusion of left anterior descending artery, compared with inferior ST elevation with anterolateral ST depression during circumflex occlusion in the same patient.

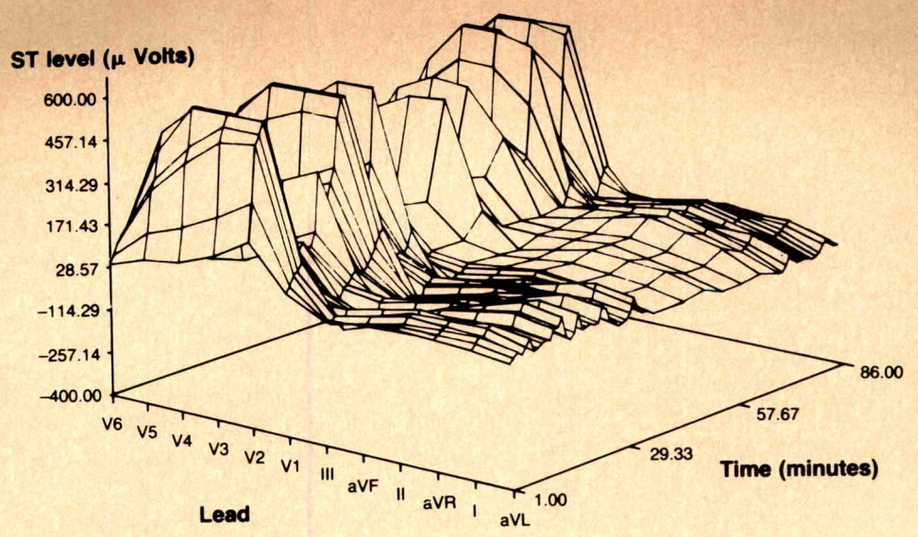

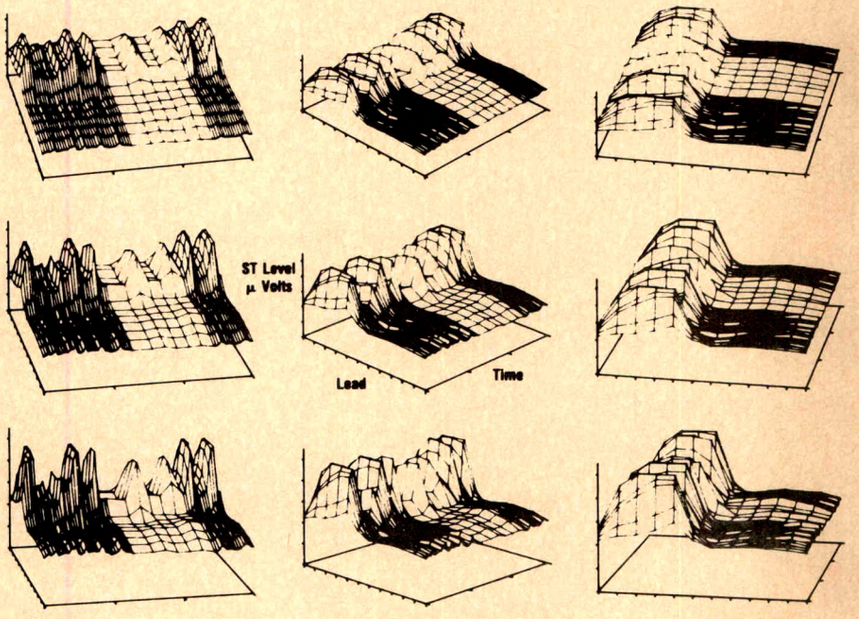

FIGURE 2. High-resolution 12-lead acquisition during percutaneous transluminal coronary angioplasty of a left anterior descending/diagonal branch bifurcation lesion, showing full precordial extent of anterolateral ST elevation, as well as reciprocal inferior ST depression (*top*). Spatial rotations of recording (*top*) show duration of each of 9 dilatations (*left*) as well as reproducibility of ST fingerprint for occlusion at that site (*middle*). Coronary care unit recording from the same patient, showing recurrence of the same ST fingerprint during spontaneous episodes of ischemia (*bottom*).

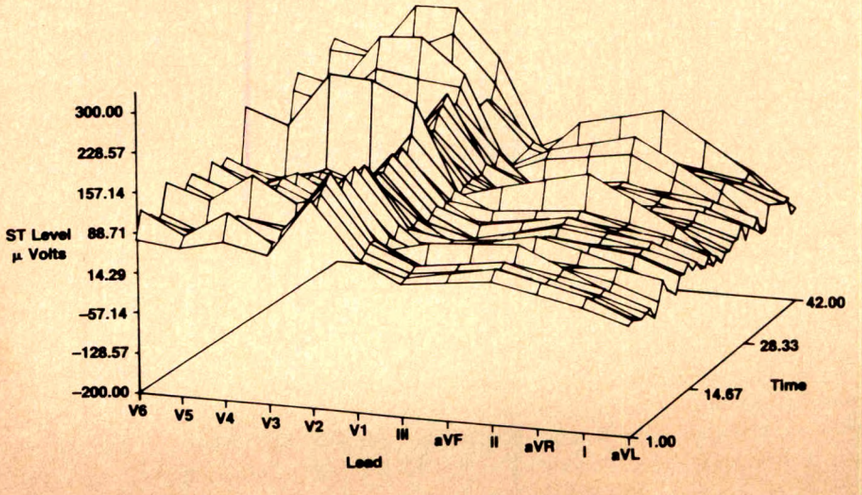

Electrocardiograms are digitally stored and may be down-loaded to an IBM-PC for further analysis (Fig. 2). Low-frequency response of this system meets American Heart Association standards for an electrocardiographic chart.

Computerized Ischemia Monitoring: Results

At the Georgetown Ischemia Monitoring Laboratory data base, over 11,000 hours of monitoring have been completed in 560 patients during and after PTCA. That includes almost 2,600 transient coronary occlusions during angioplasty, as well as 23 spontaneous myocardial infarctions after angioplasty.

Each patient averaged 4 to 5 occlusions lasting more than 60 seconds in duration. The population distribution was fairly typical, with 49% left anterior descending (LAD), 32% right coronary artery, and 19% left circumflex occlusions. About one-third of the patients had visible collateral flow and about two-thirds had multivessel disease.

The average recording period after PTCA was 19.6 hours. Some ST deviation was recorded during PTCA in 79% of patients. Most of the other 21% of patients had collaterals visible to the target vessel. Of those who had ST deviation, 86% had injury current recorded in 1 of the standard placement leads; the other 14% had ST depression only. Only ST depression was seen most often with circumflex lesions or with collateralized vessels, or both. About one-fourth (25%) of patients showing ST elevation had involvement in more than 2 leads. About 20% had only ST elevation, and nearly 50% had some combination of ST elevation and reciprocal ST depression.[7]

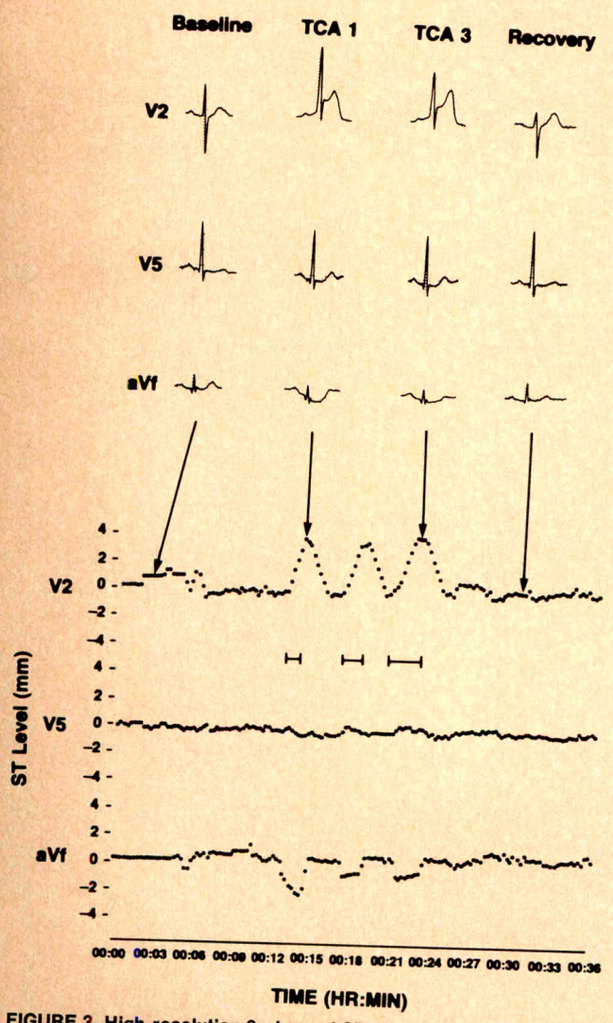

FIGURE 3. High-resolution 3-channel ST trend during percutaneous transluminal coronary angioplasty (TCA) of lesion in the left anterior descending artery showing anterior ST elevation with reciprocal inferior ST depression. Monitoring of lead V_5 in this patient would have completely missed all 3 left anterior descending occlusions. (Reprinted with permission from Springer-Verlag, Darmstadt.)

Detection of ST Changes in Different Leads: How Many Leads Are Enough?

The detection rate of ST-segment changes in our patients varied according to lead analyzed and site of obstruction. With occlusion of the LAD, approximately 95% of patients had ST deviation (elevation or depression) in V_2, 65% had some change in V_5 and 70% had a change manifested in aVF. Occlusion in the right coronary artery was associated with 78% incidence of ST change in V_2, 68% had changes in V_5 and 86% had aVF changes. In the circumflex artery, 90% of patients had some change anteriorly, 70% had ST elevation or depression in V_5 and 72% had changes in aVF.

Conversely, we see the potential for completely missing ST-segment changes during arterial occlusions (Fig. 3). With LAD obstruction, V_5 is the least sensitive lead. With blockage of the right coronary artery, about one-third of patients have no activity at all in the V_2 or V_5 locations. In a circumflex obstruction, V_5 and aVF each fail to detect any ST deviation in about one-third of patients.

Single-lead monitoring could not only miss ischemic episodes entirely but also would fail to show the full scope of ST changes. If only V_2 was monitored over our entire population, ST elevation would be missed in about one-third of the events and ST depression would be missed in approximately 40% of the coronary occlusions. With use of V_5 alone, ST elevation or ST depression, or both, are missed in 81% of occlusions. With aVF alone, the ranges are similar to those with V_5, missing ST elevation in about 50% of the cases and ST depression in about 30%.

Two-channel monitoring improves both the detection and the definition of ischemic episodes. Combining V_2 and V_5 records ST changes completely in 59% of patients, misses some ST elevation in 17% and misses ST depression in 23%. The combination of V_2 and aVF gives the best yield for complete definition (87%); 5% of the time it misses ST elevation and 7% of the time ST depression is missed. Using V_5 and aVF together completely defined ST episodes in 45% of patients. In 32% ST elevation was missed and in 21% ST depression was missed.

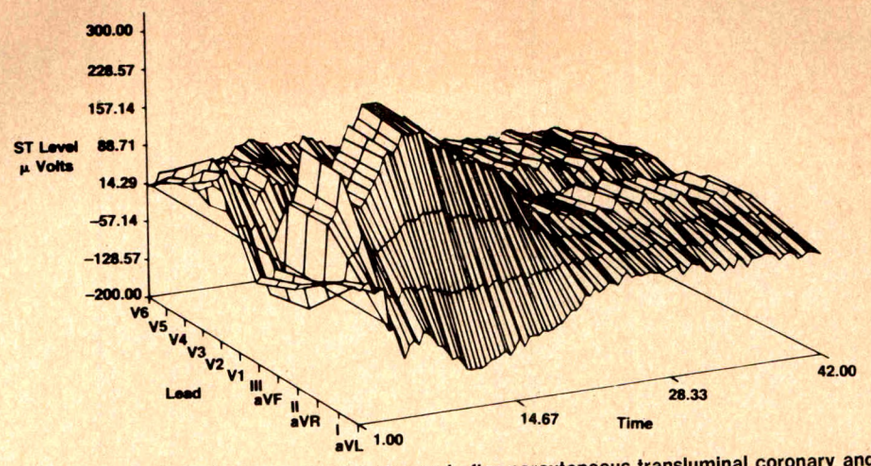

FIGURE 4. High-resolution 12-lead acquisition in a patient during and after percutaneous transluminal coronary angioplasty in the right coronary artery. Initial electrocardiograms show ST elevation in anterior leads from early repolarization at baseline. Inferior ST elevation with reciprocal anterior ST depression is then seen during percutaneous transluminal coronary angioplasty. Despite excellent angiographic results, ST fingerprint recurs during 6-hour-long inferior myocardial infarction. The patient had no symptoms at all. (Reprinted with permission from Springer-Verlag, Darmstadt.)

Our data thus illustrate how incompletely single- and dual-channel monitoring would characterize transient ischemic episodes. Even if nonquantitative episode detection was the goal, our data show that the lead pair V_2 and aVF perform best for detection of transient coronary occlusion, whereas previous work has indicated that V_5 performs best for episodes of subendocardial ischemia. Thus, comprehensive quantitation of total ischemic burden requires monitoring of a minimum of 3 lead locations.

Quantitative ST Monitoring: Prognosis After Percutaneous Transluminal Coronary Angioplasty

Although accurate multilead quantification of total ischemic burden is technically feasible, the prognostic significance requires definition. We have examined ST-segment episodes in patients after successful PTCA to see if ST-segment deviation can identify patients who are at high risk for coronary events while still in the coronary care unit. Of our first 282 patients after successful PTCA, 65 (23%) had some ST deviation during the 19 hours of ST monitoring after the procedure. In this group, 18 patients had myocardial infarction, 5 patients had bypass and 2 died. Patients who had no ST deviation had no coronary events after angioplasty.[8]

Of the 65 patients with ST episodes after PTCA, 40% had no symptoms at all during ischemic episodes (Fig. 4), 22% had a mixture of silent and symptomatic episodes, and 25% had an "early warning period" of >15 minutes in which ST segments were markedly abnormal before symptoms appeared. In a hospital setting, this time window is adequate for intervention. Thus, transient ischemia after PTCA was silent in 84% of the patients who had any ischemia early after angioplasty.

Importance of Multilead Recording: The ST Fingerprint

Whereas patients with detectable ST episodes had a worse prognosis than patients with no ST episodes after PTCA, multilead recording allowed further definition of such episodes, establishing a hierarchy of higher and lower risk patterns. By recording during PTCA, individualized ST patterns during balloon inflation were established as templates or ST fingerprints of coronary occlusion at that site.[7]

Among patients with ST episodes after PTCA, 8% of patients with only ST depression had myocardial infarction, compared with 60% of patients with any ST elevation. Of patients with ST elevation, all of those with late episodes in the same pattern as that seen during PTCA, i.e., those whose ST fingerprint matched that taken during PTCA, had myocardial infarction or urgent coronary artery bypass graft.[8]

Thus, patients with ST episodes were at higher risk than those with no episodes, patients with ST elevation were at higher risk than those with ST depression, and patients with ST elevation matching the multilead ST fingerprint seen during PTCA were at higher risk of myocardial infarction, urgent bypass or death.

Conclusion

New technologies with improved electronics and data-processing capability have made real-time multilead continuous ST-segment monitoring feasible for quantitating total ischemic burden in patients in critical-care settings. When added to the widely used symptomatic and rhythm monitoring performed in the coronary care unit in patients after successful PTCA and using multilead ST fingerprint patterns recorded during PTCA in each patient, ST-segment monitoring provided a hierarchy of patterns for subgrouping pa

tients at risk of myocardial infarction in the hospital. Patients with any ST episodes were at greater risk than those with no ST episodes; patients with any ST elevation were at greater risk than those with only ST depression; and patients with ST elevation in a pattern matching the ST fingerprint obtained during PTCA were at the highest risk of all.

Discussion IV

Dr. Cohn (*Stony Brook, New York*): I would like to entertain questions and comments pertaining to Dr. Krucoff's presentation.

Dr. Cabin (*New Haven, Connecticut*): Dr. Krucoff, did you evaluate prognostic data in relation to other prognostic variables, such as residual gradient stenoses or dissections?

Dr. Krucoff (*Washington, D.C.*): We didn't have gradient data because we don't record them with the equipment we use. Our patients were those whose dissection and other high-risk variables did not clearly identify. All had apparently successful angioplasty, had left the catheterization laboratory, and were in the coronary care unit. In that subgroup, the presence of intimal dissection, especially, did not identify a lot of these patients. All complications were in-hospital.

Dr. Cabin: Have you examined long-term outcome?

Dr. Krucoff: Not yet.

Dr. Friesinger (*Nashville, Tennessee*): Dr. Krucoff, how available is this technology, especially the data processing?

Dr. Krucoff: The Holter system that we use—a 3-channel recorder—is available from Scole Engineering in Los Angeles. The data processing on the Holter is a standard, commercially available Marquette 8000 playback. Their commercial software will now handle 3 simultaneous leads. It is no more or less difficult than playing back any other Holter tape. Obviously, the same considerations apply as in analyzing 2-channel readout—artifact has to be edited, aberrantly conducted beats have to be deleted, all of that. The 12-lead Mortara EL-I is a commercially available device. The software playback to generate the 3-dimensional graphic displays will probably be a part of that package in the coming year. Currently, the device gives a real time, full-disclosure output; it has its own little minireport that it will print out.

Dr. Sharma (*Little Rock, Arkansas*): My colleagues and I have been monitoring epicardial leads with simultaneous multiple surface leads in patients during percutaneous transluminal coronary angioplasty. This epicardial electrode is the bare 0.5 mm tip of the otherwise Teflon®-coated steerable guidewire. Thus, we have a unipolar epicardial electrode with which to monitor iatrogenic myocardial ischemia during angioplasty. We have used this technique to analyze 188 patients undergoing percutaneous transluminal coronary angioplasty and found it to be highly sensitive. We find virtually all patients have epicardial evidence of myocardial ischemia associated with balloon inflation. However, only 20% of patients reflect the epicardial evidence of ischemia on the surface precordial leads. What we and other investigators (Friedman et al) are suggesting is that many episodes of regional myocardial ischemia may remain undetected when standard surface electrocardiography techniques are used. Can you comment on that?

Dr. Krucoff: Yes. I think that epicardial recording, as has been reported, is a very elegant technique. However, we can go one step beyond the electrocardiogram in the catheterization laboratory. Echocardiography data have been reported, with an even superior detection of ischemic ventricular wall motion abnormalities. The problem is with the practicality of this in the clinical world and in the patient who goes to the coronary care unit. You can't leave a guidewire in an epicardial artery, and the patient can't drag an echo machine as he or she goes around.

Dr. Sharma: What we have found in about 16% of patients is an ST-T alternation, with one being elevated and one being depressed. How would your mapping handle this?

Dr. Krucoff: We've seen this, but not in actual up-down. We've seen it go from 5 to 4, to 5 to 4.

Dr. Sharma: We have seen just the reverse.

Dr. Krucoff: That's a new one on me, at least in this population. Our devices would handle this by taking a mathematical average of all normally conducted beats recorded at the highest resolution, which is 10 seconds. So, if there is an up-down, up-down, it will just take the mean of that 10-second period. In terms of our detection rate, if you subtract our patients with collaterals, we see ST deviation in 91% of patients. Around 10% or 11% is ST depression only, and the other 80% is ST elevation. Some of that clearly has to do, I think, with circumflex locations; we're still following old recording techniques. The high lateral area is still elusive for standard lead placements, as are the true apex and distal left anterior descending distributions.

Dr. Silber (*Birmingham, Alabama*): The results are convincing that 2 leads are better than 1, but are 3 leads much better than 2? How many percent were missed by using 2 leads compared with 3?

Dr. Krucoff: In the setting of coronary artery occlusion, using aVF and V_2, you would see nothing in 1% of the patients; in 99%, you would detect a "yes-no." The trouble is, if you used an aVF and V_2 for people on treadmill, you would miss significantly more than that because V_5 is actually the most active area. And, in V_5, you entirely miss almost 30% of coronary occlusions.

Dr. Silber: But, in your model you only miss 1% by using 2 leads.

Dr. Krucoff: With aVF and V_2. So, again, those are not the same 2 channels that you'd probably want to use in ambulatory patients.

Clinical Implications of Coronary Arteriographic Findings Soon After Non-Q-Wave Acute Myocardial Infarction

MARCUS A. DeWOOD, MD

A significant incidence of death and myocardial infarction after non-Q-wave infarction belies the earlier impression that it is less serious than Q-wave infarction. Coronary angiography in the early stages after non-Q-wave infarction shows a progressive increase in the number of totally occluded vessels. This is paralleled by an increase in number of collateral vessels. Thrombus also becomes increasingly prevalent over the week after non-Q-wave infarction, and plays a role in 30 to 40% of infarctions.

(Am J Cardiol 1988;61:36F–38F)

Although non-Q-wave myocardial infarction (MI) was orignially considered to be less serious than Q-wave infarction, subsequent investigations have indicted that the incidence of death and recurrent MI is as great as that associated with Q-wave infarcts.[1,2] My co-workers and I were interested in defining coronary arteriographic findings early after non-Q-wave MI. The goals of this study were to determine the presence of complete coronary occlusion in the infarct-related vessel, as well as to determine frequency of coronary collaterals.

Study Design

We tried to define the frequency of coronary occlusion within a week of the peak symptoms in patients who had sustained non-Q-wave MI. We also attempted to determine the frequency of coronary collaterals in the same population.

The criteria for non-Q-wave MI were standard: (1) chest pain, (2) ST- and T-wave abnormalities without evolution of new Q waves, and (3) abnormal MB-creatine kinase activity.

The investigation was conducted as a combined retrospective and prospective study over a 10-year period. A total of 341 patients were studied: 161 during the retrospective period from 1974 to 1979, and 180 during the prospective period from 1980 to 1984.

From the Deaconess Medical Center, Sacred Heart Medical Center, Spokane, Washington.

Address for reprints: Marcus A. DeWood, MD, Deaconess Medical Center, 800 West Fifth Avenue, Spokane, Washington 99204.

Of those 341 patients, 192 were studied within 24 hours of peak symptoms, while 94 underwent investigation in the 24- to 72-hour time period, and 55 were studied after 3 days but within 1 week of non-Q-wave MI. The clinical and laboratory characteristics of the various groups were similar. We were surprised that many patients (approximately 50% in each group) had anterior ST-T changes, and yet lesions were thought to be active elsewhere in the coronary tree—not indicating involvement of the left anterior descending artery. This may have been due to distant ischemia. All patients underwent coronary arteriography and left ventriculography within 1 week of peak symptoms.

Results

None of the patients had normal results on coronary arteriography. Serious left main disease (over 50% obstruction) was present in 30 of the 341 (9%) patients. Although a few patients had filling defects, most patients simply had tight coronary stenosis (Fig. 1). Most of the patients also had coronary collaterals, probably protecting them (at least partially) from major ST-segment elevation associated with a current of injury (Fig. 2).

Essentially, 26% of the patient population studied within the first 24 hours had complete coronary occlusion; 37% in the 24- to 72-hour group had complete coronary occlusion, and slightly over 40% had complete occlusion in the 3 to 7-day group (Fig. 3). The percentage of patients who had 70% to 90% obstruction did not differ significantly between the 3 groups. There was a trend in progression from subtotal to total occlusion. Almost every patient who had complete

coronary occlusion also had collaterals supplying the distal bed of the occluded vessel.

From these data, we conclude that complete coronary occlusion is infrequent during early non-Q-wave MI, and that coronary collaterals increase in parallel in patients demonstrating complete coronary occlusion.[3]

Coronary Thrombus in Non-Q-Wave Myocardial Infarction

Recently, we reviewed all coronary arteriograms.[4] We compared arteriographic findings with surgical

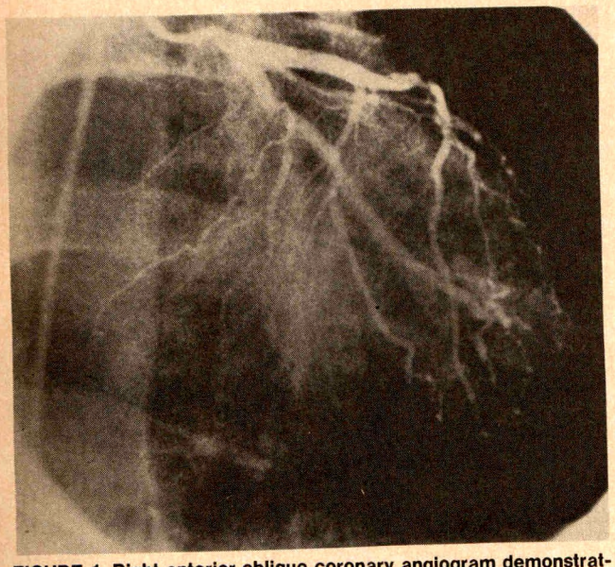

FIGURE 1. Right anterior oblique coronary angiogram demonstrating subtotal stenosis of the left anterior descending coronary artery. (Reprinted with permission from the New England Journal of Medicine 1986;315:417–423).

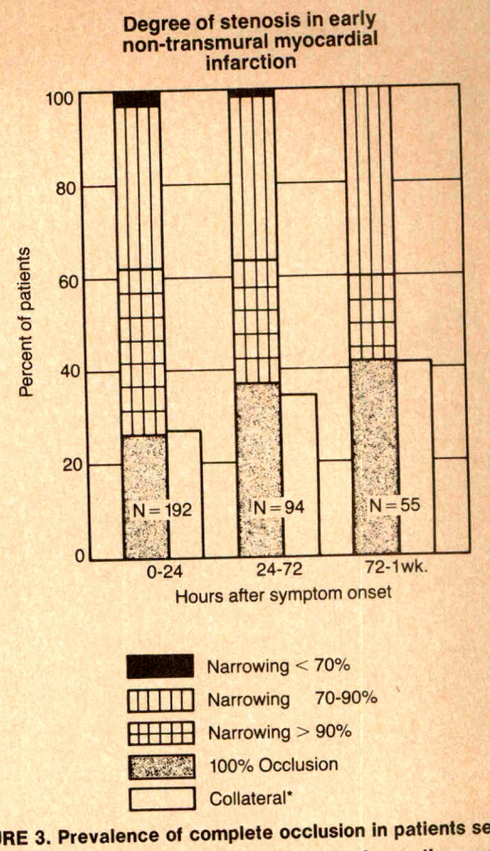

FIGURE 3. Prevalence of complete occlusion in patients seen during non-Q-wave myocardial infarction. As is shown, the percentage of patients with complete coronary occlusion increased over time and was dependent on the interval from symptom onset to the time arteriography was performed. Also demonstrated is the extent of coronary collaterals, which almost uniformly matched the increase in complete coronary occlusion. (Reprinted with permission from the New England Journal of Medicine 1986;315:417–423).

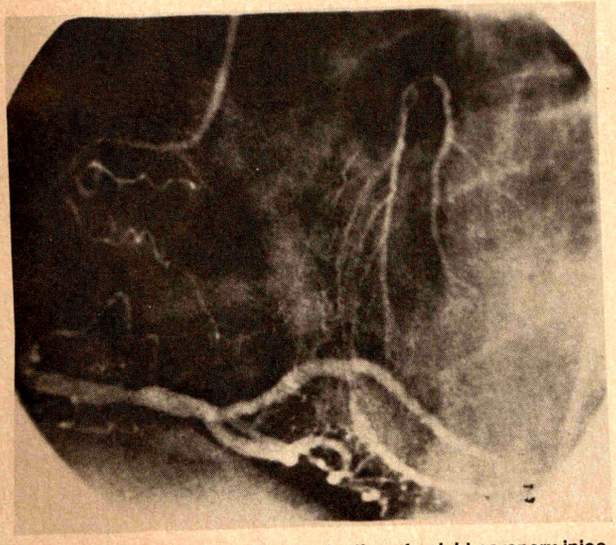

FIGURE 2. Left anterior oblique projection of a right coronary injection. The left anterior descending coronary artery is completely occluded. Collaterals are seen going from the right coronary artery to the distal left anterior descending coronary artery and the equal perforating branches.

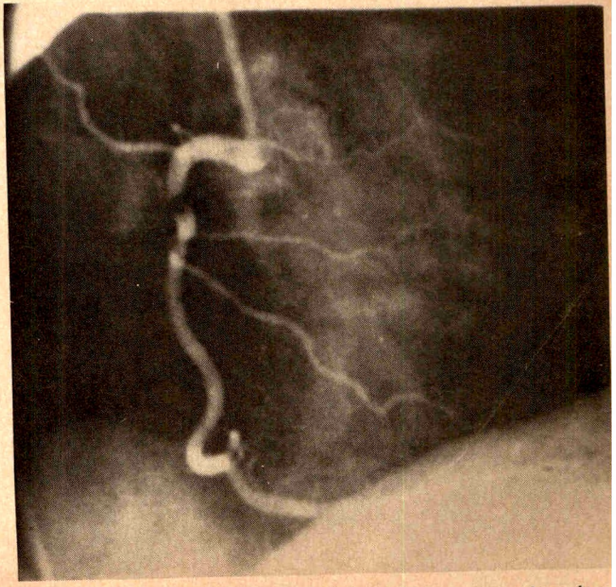

FIGURE 4. Coronary arteriogram of the right coronary artery demonstrating intraluminal filling defect. Thrombus was retrieved at surgery.

findings to determine how often coronary thrombus was present on arteriography. These data are currently undergoing further refinement. Most of the time, coronary thrombus was identified by a filling defect (Fig. 4). When patients did have complete coronary occlusion and obvious coronary thrombosis (identified by persistent staining of the infarct-related vessel), coronary collaterals usually filled the distal bed.

Conclusions

Although Q-wave MI is associated with a high frequency of complete coronary occlusion and infrequent coronary collaterals, we found that the reverse was true in early non-Q-wave MI. Likewise, preliminary data suggest that coronary thrombosis is much less evident on arteriograms in patients with non-Q-wave MI.

Because non-Q-wave MI is frequently associated with continued anterograde perfusion or perfusion via collateral vessels in the setting of complete coronary occlusion, the distal vessel can be visualized. Furthermore, because non-Q-wave MI is frequently associated with multivessel disease,[3] and preliminary data suggest there is a lower angiographic evidence of coronary thrombosis,[4] it is likely that strategies aimed at the treatment of multivessel disease in the absence of coronary thrombosis should be implemented. This is especially so since the mortality associated with non-Q-wave MI approaches that of Q-wave MI in the absence of interventions.

Discussion V

Dr. Cohn (*Stony Brook, New York*): Dr. DeWood, when your study began, resolving questions about unrecognized non-Q-wave infarction probably was not a primary objective. Considering the emerging interest in silent infarction and ischemia, do you have any comments on the incidence of unrecognized non-Q-wave infarctions? It currently appears that unrecognized transmural infarctions account for about 25% of all myocardial infarctions.[1]

Dr. DeWood (*Spokane, Washington*): We believe the incidence of unrecognized non-Q-wave infarction is probably much less than Q-wave infarction, because the amount of myocardial involvement in non-Q-wave is much less. We reviewed more than 25,000 electrocardiograms with subendocardial ischemia earlier this year. These electrocardiograms were cross-referenced against those hospitalized patients with documented infarctions. The patients who had a diagnosis of transmural infarction (Q-wave infarcts) felt their infarct much more frequently than did those patients wiht non-Q-wave infarcts. The non-Q-wave infarcts were more likely to have indiscreet or intermittent symptoms, whereas the patients with Q-wave infarcts had a discreet onset of chest pain frequently.

Dr. Epstein (*Bethesda, Maryland*): Dr. DeWood, what do you think is the underlying mechanism responsible for the infarction?

Dr. DeWood: I'm not sure that I can answer that. It's convenient to have total coronary occlusion and a blood clot sitting in the coronary artery with staining. When these are retrieved, clearly platelet aggregates are seen mixed with fibrin. In contrast, the non-Q-wave infarction patients may still have small microaggregates and platelets going downstream that are causative of non-Q-wave infarction, but cannot be visualized by arteriography because they are beneath the resolution of the coronary arteriogram. There seems to be continued perfusion in the face of the MB-creatine kinase leakage from the myocardium. I think we need to focus on an interaction between microaggregates and other mechanisms of reduced flow, which is abnormal vasomotion.

Dr. Kupersmith (*Louisville, Kentucky*): Concerning the same study, if you were to use the TIMI [Thrombolysis in Myocardial Infarction Study] classification of arteriography, would the patients be toward grade 1 (minimal perfusion) or toward grade 3 (complete perfusion)? Secondly, were there many exercise-induced infarcts?

Dr. DeWood: There were no exercise-induced infarcts. With regard to the TIMI classification, most would be between 2 and 3. We saw the distal vessel quite a bit of the time through the primary vessels, not necessarily with collaterals.

Dr. Kennedy (*St. Louis, Missouri*): In the course of this meeting, we have all agreed with the idea of educating the public about the phenomenon of silent myocardial ischemia, and have tried to understand early prognostic data. Dr. Krucoff's paper is very important, because we need to also focus on the technical and quality control in aspects of diagnosis. As members of the Council on Silent Myocardial Ischemia & Infarction, we need to start thinking about the practicality of teaching this information. In clinical practice, our patients get a 12-lead electrocardiogram, with the lead placed where there is maximal ST depression. But the minute we start going back on old data bases, we resort to a V_5 lead. There is no question about how much ischemia might be missed through lack of a V_3 or an aVF. Where are people going to go out and put these leads? I had hoped that our earlier discussions would focus more on the emerging technical and quality control problems that surround the diagnosis of silent myocardial ischemia. Even with a controlled environment and controlled angioplasty inflation, we can see changes in sensitivity by having an additional lead. Three-channel electrocardiography is in the marketplace now. However, the state of commercial manufacturing is such that, although ST depression goes down in 1 channel, the J point doesn't. The ST segment goes out 80 ms from the J point, and when it gets depressed, we see it. What we need to do is to examine ST changes in real time, print them out, and make sure they are valid. Technically, we are at the brink of this capability. The commercial manufacturers are working on algorithms that detect J-point depression. So, although 3-channel systems are available, remember that a controlled environment, as was present during Dr. Krucoff's study, won't exist in your hospital. There will be patients with minor ST-segment changes, and if you consider these recordings a valid representation of significant ST depression associated with ischemia, you will be fooled a great deal. So, I just wanted to provide a little focus, because I'm being asked in Dubuque, Iowa, "Dr. Kennedy, what leads do you use?" And I say, "There are some data on aVF and V_5, and we are exploring that." These types of practical questions are going to start emerging this year.

Dr. Cohn: While not disputing the benefits of multiple leads, exercise testing and Holter monitoring have both shown that V_5 yields a lot of information. However, it may not be the complete story and, in fact, can underestimate the amount of silent ischemia present. The addition of newer technology, rather than casting doubt on anything that we have learned thus far, can only further show what a widespread phenomenon silent ischemia is, and how much it affects the daily lives of our patients.

Dr. Epstein: There is a potential limitation of that. Whenever sensitivity is increased, specificity decreases. I'm not questioning what happens in the cath lab, but in everyday practice, a single lead, while it picks up fewer episodes of ischemia, may detect those that are more dangerous from a prognostic view. And, if you miss it with V_5, it may not be important. So, one has to consider that part of the sensitivity/specificity issue as well.

Dr. Hollenberg (*San Francisco, California*): Just to amplify upon Dr. Kennedy's remarks, analysis of Holter recordings is still a very labor-intensive technology. Some additional cautions: If you monitor at a fixed spot, that is, at J plus 80 ms or J plus 60, and ignore what happens at the J plus 0 point, then with just transient T-wave changes, as may occur with positional changes, you'll be classifying changes as ST-segment depression that, in fact, are not ST-segment depression, but are only T-wave changes. We never monitor the ST at longer than J plus 60 ms. Once heart rates start approaching 115 to 120, even J plus 60 falls within the rising or falling slope of the T wave. So if we are moving toward more automated analysis, there has to be a variable J-point sampling spot, which is heart-rate sensitive, and you cannot sample at only 1 point in a 24- or 48-hour period. Not only is there a need for better automated algorithms that can sense heart rate and RR intervals, but we need to have algorithms that accurately sense the J points. Currently, proper analysis of Holter tapes is a very labor-intensive period of time, where the technician has to sit in front of that monitor and keep adjusting the sampling point, not only at the J plus 60 or 40, but at the J, because QRS complexes continuously vary in width. It is misleading to think that these systems are really totally automated.

Dr. Amsterdam (*Davis, California*): Concerning technical aspects of monitoring, something has plagued me about interpretations of the exercise electrocardiogram: how to analyze the electrocardiogram if the ST segment is abnormal to begin with. That becomes very difficult to understand, because the abnormal, chronically depressed ST segment is a more labile ST segment and can lead to a lot of false-positive responses in the absence of coronary disease. What do we do in Holter monitors? A lot of people with coronary disease, for example post-MI patients, have diffuse ST abnormalities. How do we interpret that? In the exercise lab, we arbitrarily call for an additional 2 mm beyond an already depressed ST segment. That gives the best trade-off between sensitivity and specificity. It may or may not be the right thing to do. Dr. Cohn, what do you do with the Holter?

Dr. Cohn: We've had a lot of experience with exercise testing. However, with the Holter, I think it is prudent to avoid leads in which there are anything more than very minor ST-segment abnormalities.

Dr. Kennedy: Perhaps this is an appropriate time to establish a criterion of 2 mm below persistent ST-segment *depression* and examine that for predictive value. Dr. Amsterdam's point is absolutely correct. The very people who need this are those who have recurrent coronary artery disease. They may have had a bypass or angioplasty, they often have a scar, and we've got to deal with them.

Dr. Cohn: I am not disputing that. But as of right now, if someone comes to you with lead V_5 showing 3-mm ST depression and criteria for left ventricular hypertrophy, you know as well as I do that you are not going to be able to interpret any further ST depression in a meaningful way.

Dr. Pepine (*Gainesville, Florida*): Listening to us talk, one would think the sensitivity/specificity issue is a trade-off and is going to get worse the more we start sampling. But in fact, it hasn't worked that way. The Multiple Risk Factor Intervention Trial is probably the best example of that.[2] A computer-read electrocardiogram was used to examine the area between the baseline and the ST segment. When physicians read the electrocardiograms, as we do now—with the Holter recording in a true positive/negative fashion using the criterion of 1-mm depression—they identified very few ischemic responses. Only when using the computer-processed electrocardiogram to assess the area of ST-segment depression did the high-risk group emerge. It seems the more technology we use to refine our assessment of the ST segment and perhaps the entire electrocardiographic signal, the more specific for ischemia, and hence high risk, we will become.

Diagnostic and Therapeutic Considerations in Silent Myocardial Ischemia

JOHN S. SCHROEDER, MD

Attempts at diagnosis and treatment of silent myocardial ischemia appear to be justified in patients with known or suspected coronary artery disease. A positive exercise test result or ambulatory electrocardiographic monitoring showing ST-segment deviation is an appropriate indication for adjustment of anti-ischemic therapy. With the documentation of more severe ischemia, angiography should be considered to determine the extent of coronary artery disease. Medical therapy, antianginal agents and risk reduction may improve survival. When ischemic involvement is severe, as in 3-vessel disease, interventional surgery may be required, whether or not ischemia is accompanied by angina. Selected clinical practice cases are presented to illustrate these diagnostic and therapeutic considerations, and are followed by group discussion.

(Am J Cardiol 1988;61:41F–47F)

The physician concerned about silent myocardial ischemia faces a number of unresolved questions. Among the most clinically pressing are: What is the best way to detect silent myocardial ischemia? How often should screening tests be performed for silent myocardial ischemia? How should patients with silent myocardial ischemia be managed, once diagnosed?

Approach to the Patient with Silent Myocardial Ischemia: Current Considerations

Despite advances in current knowledge about silent myocardial ischemia, many questions remain unanswered in the quest to formulate a clinically rational approach to this problem within the realm of existing diagnostic and therapeutic capabilities.

For instance, how sensitive and specific is a positive treadmill test for identifying patients with silent myocardial ischemia? Is it really necessary to look any further for silent myocardial ischemia if a patient has a negative treadmill test result, i.e., one that shows no ST-segment changes?

If the treadmill test response is positive, can the number of episodes of ST depression be used as a therapeutic marker rather than reliance on a report of symptoms? It is well known that objective evidence of ST depression or ischemia has important prognostic implications. However, should physicians be as aggressive in treating the asymptomatic patient as they are in treating the symptomatic patient who has ST depression on the exercise stress test? If so, what criteria provide a reliable indication of therapeutic efficacy? Is the patient going to be treated until there is <1 or 2 mm of ST depression, or is it enough to require less ST depression at maximal exercise?

How do Holter monitoring studies fit into the diagnostic scheme, and are they really necessary to follow the progress of treatment? It would be simpler to just repeat the treadmill test in the patient who is able to exercise. Should therapy for patients with silent myocardial ischemia be adjusted according to review of follow-up ambulatory electrocardiographic studies? Perhaps Holters are only necessary in patients unable to exercise.

Group Discussion

Dr. Schroeder: Dr. Parmley, how do you use the exercise treadmill test to make management decisions in patients with suspected silent myocardial ischemia?

Dr. Parmley: If the treadmill identifies ischemic-type ST-segment depression in the asymptomatic patient, my next step is to have the patient wear a Holter monitor to see what happens in the work and home environment. If it shows no ischemia, I feel a little bit more comfortable. If the Holter shows ischemia, I try to associate it with a precipitating stimulus.

Dr. Schroeder: So if you have a positive treadmill test, you almost always do a Holter, even in the asymp-

tomatic patient. But with a negative treadmill, you might not.

Dr. Pepine: Clinical experience has shown that if a patient has a high-level negative treadmill, he is unlikely to have ischemia identified on an ambulatory monitor. A few additional cases can be detected by adding an ambulatory monitor—probably those related to spasm.

Dr. Schroeder: But is that really worth the expense of doing Holters on many patients?

Dr. Parmley: One of the more important things to keep in mind is what we are trying to do. The goals of management are to prolong life, i.e., reduce mortality, and to reduce the incidence of such cardiac events as myocardial infarction. Very few interventions in coronary artery disease have been shown clearly to do that. So, getting to your first question, an asymptomatic patient with a high-exercise negative treadmill has less than a 1% chance per year of dying, and less than a 3% chance of developing some coronary event. Frankly, the likelihood of intervening beneficially in that patient is so low, based on current data, that I would not do anything else. The negative treadmill alone puts the patient in such a good risk category that, unless there was some other factor that would affect this patient's outcome, I would go no further.

Dr. Schroeder: What about a 48-year-old patient with a positive treadmill showing 1.5 mm of ST depression without pain at a heart rate of 116 beats/min. Would you do a Holter?

Dr. Parmley: We are dealing with about a 75% sensitivity and specificity. Depending on the population, statistically there are more false-positives in patients who have a low risk of having the disease. If silent myocardial ischemia was suspected, an independent test for ischemia, such as a thallium scan, would be appropriate. Some could argue that a radionuclide ventriculogram with exercise or other test might be as effective but, currently, the next step would be to obtain an independent marker of ischemia.

Dr. Schroeder: Is there any group, for instance those with known angina, in whom you would use the treadmill test to adjust medications?

Dr. Pepine: No, because adjusting medications to change the treadmill response has not been proven to alter prognosis.

Dr. Schroeder: Then why bother performing repeat treadmill tests to look for silent ischemia?

Dr. Pepine: Once you identify a high-risk treadmill, i.e., 2 mm of ST depression, prolonged recovery, ST shifts at a low work load—nothing can erase it. In my view, even if 5 more treadmills were negative, they would not override the importance of 1 positive test.

Dr. Parmley: The issue is whether there is data to prove that treating ST depression has a beneficial effect on either myocardial infarction or mortality. Currently, there is none. We know that ST depression, like arrhythmia and depressed left ventricular function, is an independent marker of poor prognosis and should be measured in the high-risk patient by some technique. Therefore, it would certainly seem that if ischemia could be reduced in the same way that we reduce arrhythmias, these patients would live longer. In patients with chronic heart failure, the association between improved ejection fraction and prolonged life is well known. But in the hope of benefiting the patient, I think we could consider treating silent ischemia either medically or, more aggressively, by interventional therapy...including surgery. Again, we are left with the dilemma of recognizing factors that identify high-risk patients, and ischemia is certainly one of them, but we are not sure that treating it has a beneficial effect.

Case 1: The Patient with a Positive Thallium Scan

A 73-year-old man who had a positive result on thallium study in 1984 had not been given any antianginal medicine. He had been followed at Stanford Hospital for about 11 years for mixed lymphoma, had an excellent response to therapy, a normal electrocardiographic result and was asymptomatic. During a treadmill test, the patient exercised for 4.7 minutes with no angina, but experienced a decrease in blood pressure.

Group Discussion

Dr. Schroeder: Dr. Pepine, what would be your approach to this patient?

Dr. Pepine: I would consider this a high-risk treadmill response, with at least 2 markers for ischemia. The patient is also high risk because of such independent variables as age, sex, etc. Therefore, I would proceed immediately to coronary angiography.

Dr. Cohn: What about the ST response during exercise?

Dr. Schroeder: The patient really had minimal ST displacement; the primary abnormality was a drop in blood pressure.

Dr. Cohn: Why did he stop exercising?

Dr. Schroeder: Fatigue.

Dr. Amsterdam: Could you tell us a little bit more about that blood pressure response? Was there an initial elevation? Were there any symptoms when blood pressure dropped, and was this a true exercise-induced blood pressure drop?

Dr. Schroeder: The patient really only got into stage 2 of the Bruce protocol, so there was only 1 additional blood pressure and it was slightly elevated before falling.

Dr. Amsterdam: The patient has not had a previous infarct or aortic stenosis?

Dr. Schroeder: No, but he did have a positive thallium.

Dr. Amsterdam: Right, but that is not what usually gives you a blood pressure drop.

Dr. Parmley: How positive was the thallium scan?

Dr. Schroeder: We don't know, since it is only referred to in his history as being "positive" 3 years earlier.

Dr. Parmley: But the details of that must be very important. What we all know from experience is that

there can be an apical defect in thallium scans. In this age group, that might be a relatively nonspecific high incidence of false positives.

Dr. Epstein: I think we ought to ask: On the basis of the data we know in this 73-year-old man, what is the chance of him having a MI or dying of ischemic heart disease over the next 5 years?

Dr. Amsterdam: Taking it 1 step further, what is the chance for preventing such a coronary event, say with coronary artery bypass graft (CABG) or percutaneous transluminal coronary angioplasty? Based on the information you presented, I don't think I would do coronary angiography in a 73-year-old man with a mixed lymphoma who is asymptomatic.

Dr. Schroeder: So, despite exercise-induced hypotension and a short exercise time, you feel his expected survival is not sufficiently jeopardized to intervene?

Dr. Epstein: Well, I think your information is not specific. Besides the thallium study in 1984, of which we have no details, there is no objective evidence of ischemia; the patient doesn't have pain or ST-segment depression. I certainly would not go ahead with coronary angiography because of what Dr. Parmley has pointed out.

Dr. Schroeder: But aren't there many people who feel the post-MI treadmill showing poor exercise time is actually a better predictor than ischemia?

Dr. Amsterdam: That is a different setting; you know the person has myocardial damage. This could be a deconditioned older man who can't do very well. He has a VO_2 that is over 15, he is 73, he may not be that different from other sedentary 73-year-old men. There is nothing specific on that treadmill, and based on the information shown, I am not convinced about the blood pressure response. If the blood pressure really rose and then fell and the blood pressure was dropping, that would be convincing. What's up there is suggestive, but it's not convincing.

Dr. Schroeder: The patient's exercise electrocardiogram showed significant ST depression during stage 2 of the treadmill test, so we proceeded to coronary angiography. The patient had about a 60% left main lesion, and some disease elsewhere. He went on to uneventful coronary bypass surgery in the hope of prolonging life.

Case 2: The Patient Hospitalized to Rule Out Myocardial Infarction

A 59-year-old man was hospitalized to rule out MI. He had a small increase in myocardial enzyme levels, suggesting subendocardial MI or unstable angina. The patient's condition stabilized in the hospital and he performed a treadmill test about 3 or 4 weeks later, which showed inferior ischemia. Coronary angiography showed very diffuse disease in the left anterior descending artery, an occluded circumflex artery, an occluded mid-right, and mild anterior hypokinesia. The patient was considered to have nonoperative coronary disease. Because of his inoperable state and the diagnosis that ruled out MI, the risk for subsequent cardiovascular event was considered to be extremely high. The patient was prescribed maximal doses of diltiazem, 90 mg 3 or 4 times daily, along with small doses of β blockers. Annual follow-up treadmill testing continued to show silent ischemia. The patient, who has been followed for 5 years, averages 1 episode of angina a month, but otherwise is asymptomatic.

Group Discussion

Dr. Schroeder: This man has a normal electrocardiogram and an excellent ventricle at rest, but has absolutely terrible coronary disease. His treadmill shows marked ischemia, not only inferiorly, but in some of the other leads. Repeat treadmill showed a normal resting electrocardiogram, but even more dramatic ST depression with no pain at a heart rate of about 90 or 100 beats/min. Should this patient have Holter monitoring, or should he have a thallium scan to evaluate risk and help determine which vessel should be bypassed? Or, should the same regimen, which has worked well for 5 years, be continued?

Dr. Pepine: Rejection for surgery in 1982 doesn't mean that the patient would necessarily be turned away again in 1987.

Dr. Schroeder: Should the coronary ateriogram be repeated?

Dr. Pepine: Remember, the quality of these films in 1982 was not as good as it is now, nor were surgical capabilities the same. Contemporary surgeons are more ambitious with endarterectomies and other procedures. Several times, people have been referred to me with that kind of a film in their records, and they turn out to be surgical candidates after all. That would be one thing that I would do; otherwise, there isn't much more that could be done diagnostically. The patient has been documented to have a lot of ischemia, and has been maximally treated with anti-ischemic medications. So, the major question here is whether or not to perform surgery.

Dr. Cohn: Suppose the patient controlled his activities to prevent ischemia out of hospital? Would you feel better about him then?

Dr. Schroeder: Not necessarily. The patient is a very active fellow who plays golf. He gets angry easily. He has a couple of children in their late teens. I think that even if the Holter didn't show much, there are certainly going to be times in his life that he's going to have ischemia whenever he gets a heart rate of 90 or 100.

Dr. Cohn: So, actually, that would make you feel worse than if you did the Holter and found out that he had many episodes.

Dr. Parmley: This patient throws clubs on the golf course, he's a high-stress, major-risk individual. Dr. Pepine's point to reconsider any possibility of revascularization was an important one. I, too, would treat with anti-ischemic agents at doses that provide protection from angina but can be well tolerated. I'm not sure Holter monitoring would be beneficial. The patient is already at maximal medical therapy, and you know he has ischemia when he exercises. I think I would tend to stay with that regimen.

Dr. Epstein: I don't think CABG is applicable to this patient. We don't know what his left ventricular ejection fraction is, but he has a normal rest electrocardiogram. So there is a good chance that he has normal left ventricular function.

Dr. Amsterdam: If the man limited activity to avoid exercise-induced ischemia, would that make you feel better and would it change his prognosis? It's a very interesting issue. We like to keep people away from the threshold level of ischemia because intuitively, it sounds prudent. But we don't have good data that it will change the outlook. The important thing is, the treadmill identifies a risk factor for poor prognosis, not a risk factor if the person exercises at that level. We don't know that it's at that work load or at that heart rate that he will get in trouble. So, to be prudent, we might keep the patient below that level of activity. But, the treadmill is just 1 risk factor.

Dr. Schroeder: And we know that most people don't have a myocardial infarction during exercise or even golf. He's retired and golf is important to him and I've not restricted that.

Dr. Cohn: To me, simply reviewing the films again is not the answer. There is a good chance that the patient is still not going to be considered operable. What can we do for him then? We need to empirically maximize medical therapy. The patient has to be put on medication titrated to the point of side effects, or we are not doing our job. We cannot assume surgery is going to answer our problems.

Dr. Schroeder: And there, I think the Holter might be more helpful.

Dr. Pepine: This patient has a real need for Holter monitoring, because we certainly don't want to make him worse. Blindly adding another calcium blocker to the diltiazem regimen can potentially increase ischemia. So, in this totally asymptomatic man, I would use the Holter to guide therapy.

Dr. Kupersmith: There is absolutely no validation for using either Holter monitoring or the stress test for assessing therapeutic endpoint. In a man with this much coronary disease, there is no way to prevent ischemia, even if you happen to see some reversibility on a 24- or 48-hour Holter. The goal would be to achieve maximum tolerable medical therapy.

Case 3: The Patient with a Strong Family History of Coronary Artery Disease

A 48-year-old bread salesman, who appeared in excellent condition and had no known coronary disease, was referred for evaluation because his brother had coronary disease on a routine treadmill test. The patient had a strong family history of coronary artery disease, smoked, and had markedly abnormal lipids, so was an excellent candidate for treadmill evaluation. Resting heart rate was 60 beats/min, which increased to 135 with a mild fall in blood pressure. The patient rapidly recuperated and exercised about 6 minutes without pain, but had about 3 mm of ST depression in the inferolateral lead.

Group Discussion

Dr. Schroeder: Should this patient have coronary arteriography, or should he have a Holter or thallium scan first? What should be done for this patient to ensure the best chance for a normal life?

Dr. Becker: I don't think a thallium scan is necessary when the exercise test is as strongly positive as this one.

Dr. Schroeder: Results of coronary angiography showed 3-vessel disease and multiple lesions in the right coronary artery. The patient has multiple proximal and mid-left anterior descending lesions, as well as some distal left anterior descending and obtuse marginal disease. Based on these findings, we considered the patient a candidate for CABG, even though he had absolutely no symptoms and a normal left ventricle. I was quite convinced in 1980 that CABG was going to save the patient's life. So I had to face this person who had never had any symptoms and recommend CABG, which would disable him from his job for several months. He looked me in the eye and said, "You mean despite the fact that I don't have any pain, this is serious?" Maybe today he would have been considered for angioplasty. The patient had a routine CABG, which went well. He was discharged on Anturane® therapy, which was the medicine of the year. Because the patient never had symptoms, the only way I could really follow him was with a yearly treadmill. The first treadmill looked good. The patient had taken my advice about exercising seriously. Consequently, he achieved a high heart rate, with a markedly improved exercise capacity. He continued to be asymptomatic. For the following year, he still had a normal electrocardiogram, with excellent exercise tolerance (he was able to exercise for 13 minutes). The third year, however, the patient began to show the first signs of ischemia in the lateral leads. Since ischemia had appeared at a high heart rate, the patient was not given anti-ischemic medication. Over the next year or so, the patient continued to have excellent exercise tolerance without the development of hypotension, but the ST depression was becoming more dramatic and more severe. His last treadmill showed marked ST depression in leads II and V_5 during exercise stages 4 and 5.

Dr. Schroeder: Does this patient need another coronary arteriogram and possible repeat surgery? He has never had a symptom. Do you think he is going to believe me if I tell him that? Should I have put him on medication?

Dr. Pepine: I don't agree that these treadmill responses are as serious a prognostic problem as you identified previously. The patient's blood pressure doesn't drop. He goes to stage 5, whereas he only exercised for 4.3 minutes the first time. So, from a prognostic standpoint and in terms of markers, the patient looks better. Secondly, from what we know about the conduits that were used in 1980, I wouldn't be surprised if at least 1, and possibly 2, are functional or occluded. Whether or not disease has progressed

not is debatable, but most likely it has. I wouldn't do anything immediately. I would, however, start mentioning to the patient that he is approaching the limits of therapy for a generally progressive disease, and I'd start preparing him over the next year or 2 for additional intervention. When the stress test again shows him at a high risk, then I would proceed with coronary angiography.

Dr. Schroeder: How about a thallium study to detect the degree or extent of myocardium at risk?

Dr. Pepine: I probably wouldn't do that right now. I would be happy with the treadmill.

Dr. Parmley: Let me just ask a couple of questions. I assume that you vigorously intervened to reduce risk factors?

Dr. Schroeder: I did. The patient does not smoke anymore, and is taking fish oils, with some response in triglycerides, but they remain quite high—around 200 to 300 mg/dl. His cholesterol averages 300 mg/dl.

Dr. Parmley: Is he currently being treated with anti-ischemic medication?

Dr. Schroeder: No. That's really one of the questions here.

Dr. Parmley: I concur with Dr. Pepine in terms of prognosis. Looking at your data, the patient is at a different point now. It would be reasonable to consider some anti-ischemic medication, if he can tolerate it. I would not do a thallium scan, because I'm not sure how it would further help at this point. Since there is good exercise tolerance, with a reasonably high heart rate and no drop in blood pressure, the patient tends to fall out of the high-risk group. So I would not do a thallium, but I might consider some anti-ischemic therapy.

Dr. Schroeder: Should I test the patient again after a course of diltiazem, or is it safe to assume it's going to protect him?

Dr. Parmley: I don't see any reason to titrate the diltiazem, if that's what you are asking.

Dr. Epstein: Just a point about the post-CABG patient. There are no data on the prognostic value of ST segment deviations in the post-CABG patient; it may or may not be analogous to that in the virginal patient. There are so many differences that I don't think we can use the treadmill with the same degree of prognostic certainty as we do with a patient who has not had a CABG. A second bypass carries with it an appreciably higher risk than a first bypass procedure. If you decided to do percutaneous transluminal coronary angioplasty, the risk would also be higher. So, I think that the risk/benefit ratio is going to be altered by the greater risk of interventional therapy. I would not, at this point, perform repeat coronary angiography, because would not reveal anything that would lead me to recommend percutaneous transluminal angioplasty or bypass surgery in this post-CABG patient.

Dr. Krucoff: Dr. Epstein, would you agree that the lower heart rate response and the lack of hypotension on the treadmill is a much better prognostic sign that ST-segment changes?

Dr. Epstein: Yes, I would agree with that. I'm wondering, however, about the choice of diltiazem as opposed to a β blocker.

Dr. Schroeder: Because the patient is basically healthy, and if he became impotent because of β blockade, I would also have created another disease. Diltiazem is very well tolerated.

Dr. Kennedy: I absolutely agree with the perspectives of Drs. Pepine and Parmley, but I want to come back to this because as with the arrhythmia issue, we are discovering a phenomenon and instituting therapy with no idea of what the therapy is doing. To institute a calcium channel blocker in the belief that it will decrease ischemia is absolutely correct. But, just as we discovered about proarrhythmic effect, we have no idea now of what the treadmill is going to be. If we start anti-ischemic therapy, let's look at the results of it. I agree that we must try to modify mortality and morbidity. We hope to do that and to stop infarction. All of us know that this is a progressive disease. We are all thinking that we have to do coronary angiography at the appropriate time and try to prevent infarction. But we don't know if therapy creates a proischemic effect. So, we have to examine whether or not therapy had any benefit.

Dr. Parmley: I think the proarrhythmic effect of the antiarrhythmic drugs is pretty standard at 10%, or maybe more. A proangina effect of antianginal agents—for instance, reflex tachycardia—is occasionally seen with drugs like nifedipine, but it's extraordinarily uncommon. So I don't think a repeat treadmill is necessary to rule out a proangina or proischemia effect, but I do agree with the notion of trying to assess therapeutic efficacy. A repeat treadmill showing that the ST depression was 0.5 mm more or less would not necessarily influence clinical management.

Dr. Kennedy: Let's quantitate this. If the initial dosage of diltiazem has no anti-ischemic effect, I would increase the dose to 90 mg every 8 hours, and then higher. If there was less ST-segment depression in fewer leads, I would try to determine what constitutes anti-ischemic effectiveness. There is tremendous analogy to what we know about arrhythmias: the same variability factors, and the same applications. This is all new knowledge and we can't skip over it.

Dr. Pepine: I agree with your concept. There is no question that we ought to be looking at the potential for risk, but I don't like the idea of equating ischemia with arrhythmias. First of all, we have good drugs for ischemia, which are very unlikely to increase ischemia. Our drugs for arrhythmias are very poor and can cause a 10% or more incidence of proarrhythmia in patients who need therapy the most. No one feels that a little ischemia is good, but all of us have inconsequential premature ventricular contractions while we are sitting here. So the 2 are not alike. This patient reminds me not so much of a coronary bypass case, but of what we see every day with angioplasty. This patient with multivessel disease had angioplasty last year, and that's what his treadmill looks like now. So, Dr. Epstein, without all of the compounding influences and

the reduction in the risk/benefit ratio provided by previous bypass surgery, would you feel differently about how far you would go with this patient, compressing time to months instead of years, and given this exercise test?

Dr. Epstein: I would completely agree with the implications. I would treat this patient totally differently from the way I would treat a post-CABG patient. Given the recurrence of profound ST-segment depression, I would repeat the angiogram and I would consider repeating percutaneous transluminal coronary angioplasty.

Dr. Amsterdam: I think the treadmill is reliable in this post-CABG patient because, after surgery, he apparently returned to a normal baseline on the treadmill. So the compound variables may not be there. If a negative treadmill later becomes positive, it is highly unlikely to be a false positive. So, a negative treadmill followed by a positive one means ischemia has been reestablished. The patient's heart rate was tremendous-it looked like it was in the 160s or higher. At what heart rate did it become positive? To me, the heart rate at which the patient initially became ischemic is more important than the number of millimeters of ST depression at maximum.

Dr. Schroeder: It looks like 1 mm of ST depression at a heart rate of 111 beats/min and about 2 mm at 128 beats/min.

Dr. Amsterdam: That's low heart rate, so I would take a different viewpoint. I definitely would do a thallium scan to determine the extent of myocardial involvement and provide a much greater perspective than the treadmill. This doesn't mean I'll necessarily do an angiogram. Once the thallium is done, I can make my next move. If the person is positive at a low rate and has a drop in blood pressure, this is a bad response. A drop in blood pressure is a very unusual finding. Most high-risk patients are high risk based on ischemia at a low heart rate, without a drop in blood pressure. It's an extremely unusual finding and is not necessarily a key tip-off. Its predictive accuracy is very good, but its sensitivity is minuscule.

Dr. Krucoff: I, too, would take this gentleman back to the catheterization lab for several reasons. First, since the ST changes are in similar leads, we know he is post-CABG, and his anatomy is clearly not the same as was visualized initially. Second, in a post-CABG patient, which is an increasingly common subgroup, there is at least the potential to intervene with angioplasty revascularization in a partially protected scenario. There may be a compromised rather than an occluded graft, and you may be able to work on a native vessel with some distal circulation, despite what's being done through that graft. Given that there has been such a clear change in this patient's ischemic activity, waiting until he again becomes high-risk may force a second operation or render the patient intractable to medical therapy. Now may be exactly when you could intervene in a semiprotected environment and help him with angioplasty.

Dr. Cohn: Suppose this man presented again with the same exact story, good ejection fraction and so forth, same exercise response, same catheterization data, except that it is 1987, and the medical vs surgical longevity for 3-vessel disease with left ventricular function is pretty similar. What would your inclination be now?

Dr. Schroeder: I think it would be the same, just because it is my bias that these patients, even though there may not be a difference in mortality, are still at high risk for infarction or other type of cardiac event that may not result in death, but can cause disability.

Dr. Epstein: I admit that we don't have very good longevity data, aside from Erikssen's study in totally asymptomatic people, so are forced to make clinical decisions with incomplete information. If a person has significant ST-segment depression—and I would do a gated blood pool study to confirm that there is inducible ischemia—in the presence of 3-vessel disease, I would consider that patient to be at high risk of death and would recommend revascularization . . . even in the absence of symptoms.

Dr. Cohn: If the patient fell into a high-risk group, with profound ST-segment depression and profound ejection fraction on exercise, you would consider this man bypassable in 1987?

Dr. Epstein: Absolutely, but I disagree slightly with Dr. Krucoff. If angioplasty is done, 3% to 5% of these patients—even those with 1- or 2-vessel disease—run into trouble that necessitates an urgent bypass operation.

Dr. Krucoff: Except that he may be in a more protected group. If he has a graft to distal circulation, you work on a native vessel.

Dr. Epstein: I'm just saying that it's a different risk situation. Perhaps I'm intrinsically a little more conservative but have a higher threshold in doing invasive therapeutics in a patient who has already had bypass surgery, because of the higher risk if problems develop.

Dr. Hollenberg: What about the recovery phase?

Dr. Horwitz: I agree that looking for a drop in blood pressure frequently is unrewarding. I think that you shouldn't lose sight of the point that Dr. Pepine made. This man has superb exercise capacity. At whatever level he's beginning to develop ischemia, the most disturbing thing is that there is a change. We should get the maximum amount of information about that change. It would also seem that this patient is an ideal candidate for a Holter monitor. For example, ambulatory electrocardiography showing multiple persistent episodes of silent ischemia signifies the need for aggressive intervention. If there was nothing—no arrhythmia and no ischemia—I think you'd feel a little better about it. I don't think that this man on a gated is going to suddenly deteriorate at a moderate load...n with the kind of exercise performance he is showin on this test. He's not a high-risk exercise test. But think what we are all trying to do is to pick the point which we may intervene. The patient is beginning show signs that his initial therapy hasn't been ve good. He is still probably not at an enormous risk. B the maximum information you can get would be hel ful so, since symptoms can't help you, perhaps a Holte could.

Dr. Hollenberg: I can't let this discussion go without commenting on exercise testing. We need a quantifiable, reproducible test. We have ignored many variables in this exercise test, that is, his ST changes occur late so he has late evolutionary changes, and they resolve fairly quickly. These are all hallmarks of mild involvement. We also know that his exercise duration is quite excellent. Sure, the patient gets ST depression at 13 minutes of exercise, but by 2 minutes of recovery, he is almost back to normal. So I think you have to quantify the changes that occur in evolution and resolution, and, in fact, we have a treadmill exercise score that quantifies all of these variables. I have found that a very reproducible, quantifiable exercise test can identify either significant graft occlusion or new lesions in the native vasculature in many patients. So, a quantifiable reproducible exercise test is a very helpful technique to follow post-CABG patients. It also is a very subjective test; the patient stops at variable endpoints according to how he feels that day, and it is very hard to quantify him, unless one uses all these complex features. To still look at this the way we read exercise tests 20 years ago is really a little simplistic, and I think we are shortchanging the information that we do gain with the exercise test.

Case 4: The Postmyocardial Infarction Patient

A 69-year-old man had an inferior MI and was treated with intravenous streptokinase. Recovery was uneventful. Because stenosis was not severe, angioplasty or CABG was considered unnecessary. The patient, who had very few risk factors, remained asymptomatic during treatment with diltiazem and aspirin. Several months after MI, repeat treadmill testing showed evidence of lateral wall ischemia, despite good functional capacity and no chest pain. The resting electrocardiogram showed a small inferior MI, and there were small Q waves between leads III and aVF. But during exercise, it appeared that this inferolateral area was still in jeopardy. Recovery at 3 minutes showed significant ST depression. Because the patient was asymptomatic, the dosage of calcium blocker was reduced despite the marked ST depression. The patient returned 6 months later feeling better than ever, still asymptomatic. A repeat treadmill looked about the same, and functional capacity was normal. There was residual evidence of an old inferior MI, with ST depression at stage 3. Exercise was stopped at stage 6 of the Bruce protocol and a heart rate of 150 beats/min. Marked ST depression subsided rapidly.

Group Discussion

Dr. Schroeder: Again, the question is what to do for this patient.

Dr. Pepine: What was angiographic anatomy after the infarct?

Dr. Schroeder: The patient had about a 50% mid-right lesion and a normal left system. So, he was felt not to require angioplasty.

Dr. Pepine: This is becoming more common in our postrevascularization patients, where we see much less than 50% narrowing in the revascularized vessel or in the reperfused vessel, with a very abnormal exercise response. I attribute some of this to the abnormal resting electrocardiogram, with those T-wave inversions. However, I don't think this is the whole picture. I can't attribute it all to a gross underestimate of the significance of the stenosis from the coronary arteriogram. I don't know what it means prognostically. I probably would have treated this patient with a Q-wave infarction with a β blocker, and I don't know that I would have done anything differently, Dr. Schroeder, than you have.

Dr. Parmley: This is more than a year postinfarction at this point?

Dr. Schroeder: It is now about a year postinfarction.

Dr. Parmley: So, the patient has gone through the "high-risk period," i.e., he hasn't died in the first 6 weeks, 3 months or 6 months. He has documented coronary artery disease, which was only right coronary artery disease 1 year ago. This is really a difficult case to become overly aggressive with at the moment, with superb exercise tolerance despite the ischemia shown there. In the absence of any other data, I am not sure that I would recatheterize the man at this point. I would probably err on the side of conservatism.

Dr. Schroeder: Should I increase his diltiazem, or decrease it? The dosage was decreased because the patient had no pain on the treadmill. However, I am not sure it made much difference. He is on 60 mg 3 times a day.

Dr. Parmley: That is a reasonable dose, although not a maximum dose, so I am not sure I would be persuaded necessarily to push at this point.

Dr. Krucoff: I would pursue this patient at least with a thallium scan or similar to look at the actual anatomic perfusion defect. If there is none, I think I would use his symptom-free, high functional capacity status to keep withdrawing diltiazem. If, on the other hand, there was a clear-cut defect, I would more strongly consider angiography. Clearly, in 3 or 6 months people can evolve very malignant stenoses in what initially looked insignificant. If the thallium scan revealed a focal defect, I would probably arrange for catheterization.

Group Discussion: Relevancy of Silent Myocardial Ischemia to the Practicing Physician

Dr. Kennedy (*St. Louis, Missouri*): Most practicing clinicians realize that exercise testing has been used for 15 to 20 years and are comfortable using it in various situations. There can't be much discussion about ambulatory monitoring in the setting of silent myocardial ischemia because it has only been applied to prove that asymptomatic ischemia exists, and this predominantly in physiologic studies. Only in the next 5 to 10 years will ambulatory monitoring for asymptomatic ischemia evolve in clinical use. Is each of you going to feel comfortable that ambulatory monitoring will actually do this, or that we will really be able to interpret the results accurately? Full knowledge of this technique, including interpretation of the data it provides in the setting of silent ischemia, is still evolving.

Dr. Cohn (*Stony Brook, New York*): Perhaps that's a good starting point for some discussion on the relevancy of silent ischemia to the practicing physician. It's obvious that in the years ahead, when we talk about silent ischemia, it will be about Holter findings in addition to the treadmill test. We are going to have to start feeling more comfortable with the Holter, in terms of telling practicing physicians about it. How can we best use the Holter, and in what kind of situation is it most appropriate and useful? I think that for the totally asymptomatic patient, the Holter has no value as a screening procedure at the present time. The exercise test does. In research centers, the Holter might be used for further risk stratification, but that's a limited area. Certainly in the post-infarction patient, the exercise test is still very important. Though, again, in those patients who can't exercise, there seems to be a role for the Holter. Certainly in the patient with angina, the Holter seems to be the most useful. Since we'll be talking in terms of practicing physicians, perhaps we should be addressing this issue now. Dr. Kennedy gave us his viewpoint. What do others think?

Dr. Lauler (*New London, Connecticut*): Perhaps I could generalize the discussion here a bit. Dr. Cohn, you and Dr. Kennedy both talked about the challenge of transmitting information about silent ischemia from the realm of investigation to the "real world" of the clinician. The practicing physician is very conservative. He's going to weigh benefit vs risk, and is going to be very reluctant to treat an asymptomatic group. All we need to do is look at the history of hypertension. I can recall an assistant dean at a well-known northeastern medical school who, 25 years ago, elected not to take antihypertensive therapy because he was asymptomatic and because of the side effects of the drugs. He later had a stroke with massive central nervous system damage, but at the time he thought that declining treatment was a valid option. It's a difficult challenge in the totally asymptomatic group. As we look at the practicing physician, the cost factor is an important consideration; perhaps not so much in terms of drug therapy as because of the high cost of technology. As I listen to discussions about Holters, repeat Holters, and scanning images, I am concerned that, as we go to capitation costs, the high-tech evaluation of these patients may be more restrictive than those of you on the leading edge of technological research would like. The other side of the coin is that, if it could minimize hospitalization, it would be worthwhile. So, it's a bit of a 2-edged type of endeavor, with the trend toward keeping patients out of the hospital. But the practicing physician is looking for a working definition of silent myocardial ischemia. The currently accepted criterion is more than 1 episode of 1 mm ST-segment depression lasting more than 1 minute.

Dr. Cohn: That was established in an attempt to define what an ischemic episode on a Holter was.

Dr. Lauler: True, but that was a working definition, something that the practicing physician could look at. One of the difficulties I have, on behalf of practicing physicians, is to know what silent myocardial ischemia is objectively. But the data coming out, particularly those on quantitating ischemia, are disturbing.

For the practicing physician, logic and rationale are important, even if later they are not shown to be perfectly correct. This concept of total ischemic burden is a useful one, because in practice, the physician can say that the total ischemic burden is equal to the symptomatic plus the asymptomatic episodes, and that more aggressive treatment is necessary. It may be that, lacking a clear consensus in terms of Holter and other ways of quantitating ischemia, we conceptualize what we mean by silent myocardial ischemia—for instance, that the majority of episodes are silent; that we are missing them in many of the monitoring episodes in the hospital. We are buying time until the concept of total ischemic burden can be more precisely quantitated.

Dr. Kupersmith (*Louisville, Kentucky*): In most of th country, the practicing physician is no longer conservativ when it comes to high-tech medicine. I think there is a ver large potential for abuse of this test, particularly when man physicians have equipment that is not adequate to the task One ought to enter this into the equation. The second point i that ambulatory Holter monitoring has not been validate for use as a diagnostic or screening test. It has some valid tion as a physiologic monitor of the asymptomatic ischem phenomenon, and it appears to have validation as a progno tic index at certain times, though perhaps not always. It ha

very little or no validation in determining therapeutic endpoint. Perhaps one could say that there is some therapeutic value to this test at this time, but one has to be very conservative about recommendations to practicing physicians.

Dr. Krucoff (*Washington, D.C.*): One of the best things about a council like this, though, is that some education from a responsible source has to occur. Because if it doesn't, there are members of the industry who will propel devices that are not validated, that are lucrative in private-practice use, and which have more potential than any other factor to destroy the credibility of all the work done thus far. One of the most important functions that we have before us is to find a way to communicate to the real-world practitioners about the limitations, strengths and risks of these devices, as well as the applications of these technologies, despite the potential financial benefits of using such devices.

Dr. Silber (*Birmingham, Alabama*): Most of the devices that have been used to detect silent myocardial ischemia are not validated. The first step is to validate these systems, especially a real-time system, real-time ST-segment Holter monitoring system in widespread use. To go a step further, only 2 out of all these real-time Holter monitoring systems have 100% retrieval rate, so, with most of the so-called silent ischemic episodes, it's not possible to look at them beat by beat. Several speakers have pointed out how important it is to look not only at the trend, but also at each individual beat. Most of the real-time systems don't give us a chance to look at this. So, I think the first step would be to validate a system, look at the reliability, and not to jump into all these problems.

Dr. Cohn: What you have said is certainly important. I don't think that any of the real-time systems can be recommended unless they (1) have been validated against an FM system, which is still the standard and, (2) allow inspection of the electrocardiographic data, to check what is being called an ischemic event. I think we'd all agree that this type of session is very useful, primarily because it does allow discussions, give and take, with people free to say whatever they want—and in fact, they do. It's obvious that we've come a long way in terms of our knowledge of silent ischemia. The fact that the number of studies in this particular field has expanded is wonderful, because the more we learn, the more we can translate our knowledge into benefits for patients. Studies on silent ischemia are appearing every month in our most prestigious cardiology journals—which would not have happened 5 years ago. It's this dissemination of knowledge that I think will one day soon make silent ischemia accepted as an integral part of ischemic heart disease.

The concept of total ischemic burden is perhaps how the practicing physician, in the future, will think of ischemia: symptomatic episodes, painless episodes, unrecognized infarction, painful infarction—all part of a spectrum. There is no question that the major source of controversy is how important silent ischemia is prognostically and, if we treat ischemia, whether painful or painless, are we going to influence outcome? This is going to be determined by ongoing therapeutic trials which will hopefully give us answers in the course of the next several years. At meetings like today's, we will be discussing the results of such trials and perhaps coming up with positive conclusions. I would be disappointed to learn that alleviating a patient's ischemia, painful or otherwise, has no effect whatsoever on his life-style, morbidity or mortality. This is indeed how it may come out, we don't know yet, but I think that, being physicians, we hope that by doing something positive, we will be doing some good for the patient.
